Normal Stars. The CXO has optical instrumentation aboard that provides an "aspect solution," which shows where the observatory was pointing during an observation to an accuracy of about 1 second of arc. However, it is usual for Chandra observations to detect the X-ray emission from several stars that have much more accurate cataloged positions based on their optical emission. Using the stellar positions as a local reference, the remaining X-ray sources in the field can be positioned far more precisely to about 0.2 to 0.4 seconds of arc. One example of using such positions is the determination of the positions of the more than 1000 X-ray sources in the Orion Nebula star cluster (Fig. 10). It is interesting that this single Chandra image contains more X-ray sources than had been detected in the first 15 years of X-ray astronomy. The Orion Trapezium, a region only 3 light years across at the core of the Orion Nebula star cluster, contains very young stars and therefore offers astronomers a view into a region where stars are born. The cluster is composed of stars whose a median age is only around 300,000 years, and, at a distance of 1400 light years, is one of the nearest star-forming regions. The CXO was used to identify X-ray emission from individual stars and found that almost all of these young stars were much hotter than expected.

The Center of Our Galaxy. Precise positioning was critical for the unique identification of the X-ray emission from the object known as Sagittarius A*, the source at the extremely crowded center of our own Milky Way galaxy (Fig. 11). This source is a moderately small black hole of about 3 million solar masses, and is very faint compared to other galactic nuclei. X rays are emitted just beyond the horizon within which no light can escape, and thus the black hole may be "seen." A bright flare was detected by the CXO on 27 October 2000, whose X-ray intensity increased by more than a factor of 10 for about 3 hours and then rapidly dipped on a timescale of 10 minutes. The rapid variation in X-ray intensity indicates that the flare was due to material as close to the black hole as Earth is to the Sun. This is compelling evidence that matter falling toward the central black hole is fueling energetic activity at the center of our galaxy.

Supernova Remnants. Another example of Chandra's ability to provide high-contrast images is exemplified by the now classic image of the remains of the remnant formed by the implosion of a star, a supernova, called the Crab Nebula and its compact core, a rotating neutron star that pulses. The image (Fig. 12.) shows the intricate structure produced by the pulsar interacting with the local environment. This image is not static; observations by the CXO spaced out over time have shown the dynamic motions that take place as a result of the interaction of the pulsar at the center of the remnant and the local environment.

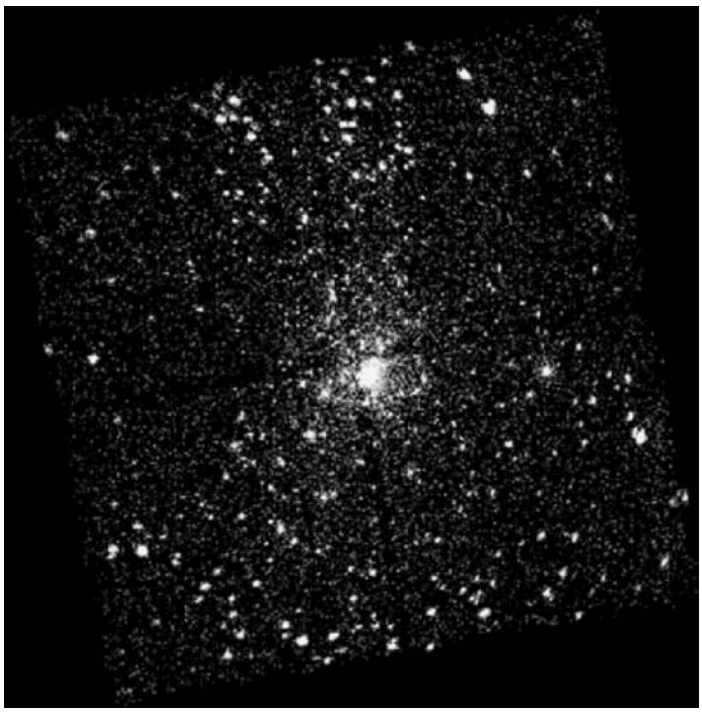

Fig. 10. The CXO image of the Orion star cluster. The region shown in this image is about 10 light years across. The bright stars in the center are part of the Trapezium, an association of very young stars whose ages are less than a million years (*courtesy of NASA/Pennsylvania State University*).

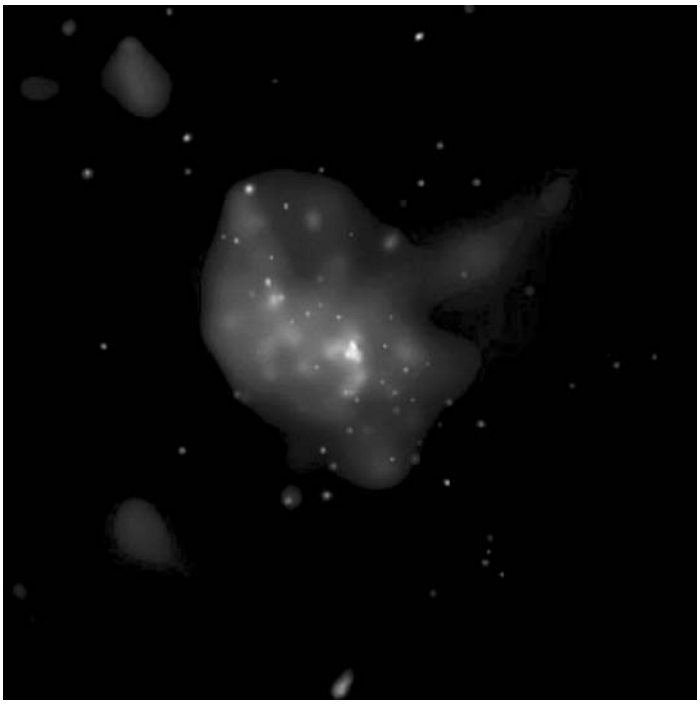

Fig. 11. The ACIS-I image of the galactic center. This image shows the central region of our Milky Way Galaxy as seen by the CXO. The bright, point-like source at the center of the image was produced by a huge X-ray flare that occurred in the vicinity of the black hole at the center of our galaxy (*courtesy of NASA/Massachusetts Institute of Technology/Baganoff et al.,* 2001).

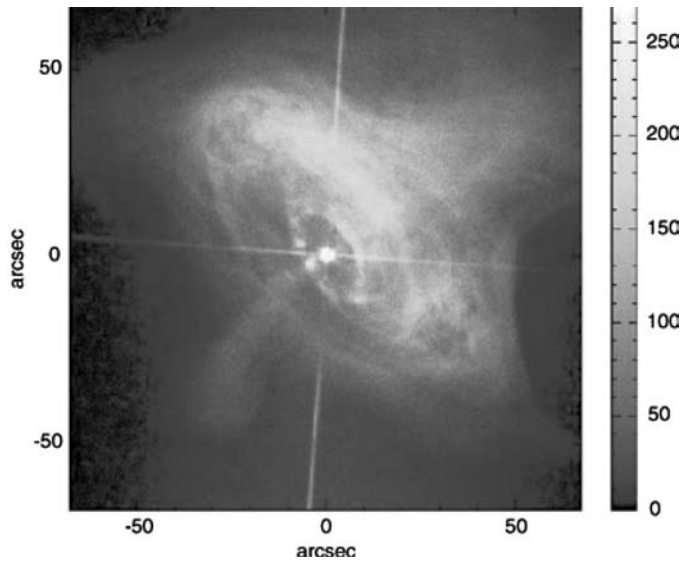

Fig. 12. Chandra image of the Crab pulsar and nebula made using the LETGS and the HRC-S. The nearly horizontal line in the figure is a cross-dispersed spectrum of the pulsar produced by the LETG fine support bars. The nearly vertical line is the LETG-dispersed spectrum from the pulsar (*courtesy of NASA/Marshall Space Flight Center/Weisskopf et al.,* 2000).

Globular Clusters. One of the most striking examples of the power of Chandra X-ray imaging is in the spectacular Chandra images of globular clusters. Figure 13 is an ACIS-I image of the globular cluster 47 Tucanae. The left panel is composed of red/green/blue images derived from X rays recorded in different energy bands and shows the central portion of the

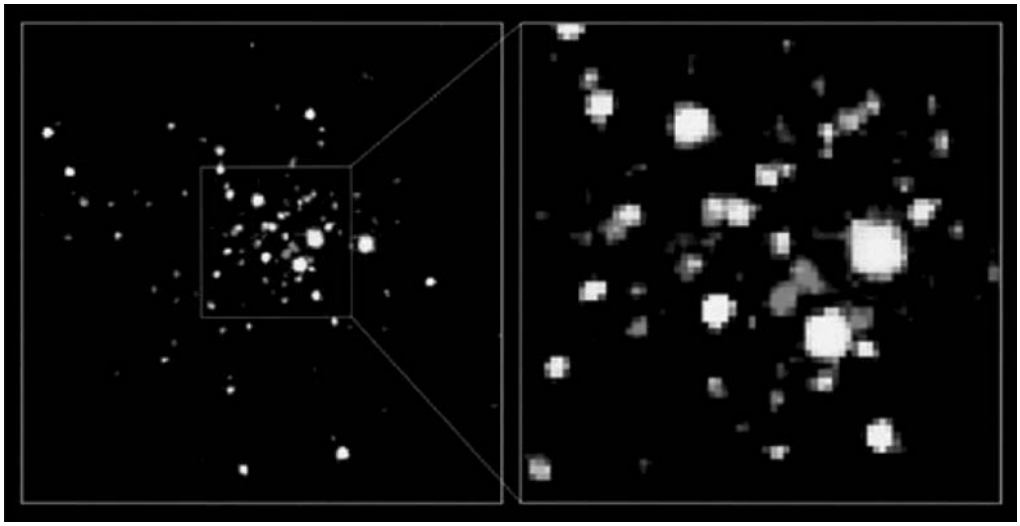

Fig. 13. Chandra image of 47 Tucanae. The left image covers the central $2' \times 2.5'$. The further enlargement of the central region to the right is $35' \times 35'$. The different colors represent the dominant X-ray energy range: low-energy X-ray emission (red), intermediate-energy X-ray emission (green), and high-energy X-ray emission (blue). The white sources are bright in each of these ranges. The faint red sources are mostly millisecond pulsars, whereas the bright white sources are mostly binaries containing white dwarfs that produce X-rays by pulling matter from normal stars (*courtesy of NASA/CfA (Center for Astrophysics)/Grindlay et al.*, 2001).

cluster. The enlargement at the right is the central core. Some 108 sources, excluding the central core, are detected. This number is more than ten times that found by previous X-ray satellites.

These Chandra images of 47 Tucanae provided the first complete census of the brighter X-ray producing stars in the core of the globular cluster. As the oldest stellar systems in galaxies, globular clusters are laboratories for stellar evolution. Nearly all objects in the Chandra images are "binary systems," in which a normal, Sun-like star orbits a collapsed star, either a white dwarf or neutron star from which X-rays are emitted. The data also reveal the presence of many "millisecond pulsars," neutron stars that rotate extremely rapidly between 100 to nearly 1000 times a second.

The image, associated spectra, and measured time variability reveal more about the binary content and stellar, as well as dynamic, evolution of a globular cluster than achieved by all previous X-ray observations of globular clusters combined.

Normal Galaxies. In addition to mapping the structure of extended sources and the diffuse (extended) emission due to the presence of hot gas in galaxies, the high angular resolution of the CXO permits studies of ensembles of discrete sources, which would otherwise be impossible owing to the large number of sources crowded together in a small region of the sky (source confusion). A beautiful example comes from observations of the center of the Andromeda galaxy (M31) shown in Fig. 14. The image shows what used to be considered the emission associated with the black hole at the center that is now resolved into five distinct sources. A most interesting consequence is that the emission from the region surrounding the central black hole is unexpectedly faint relative to the mass, as in the Milky Way.

M81 (NGC 3031) is a spiral galaxy at a distance of approximately 3.6 Mpc. The galaxy was observed by using the ACIS-S instrument on Chandra (Fig. 15). Previously, the galaxy had been observed using both the Einstein and Rosat X-ray observatories, and about 30 sources had been detected. This Chandra observation detected 97 X-ray sources, 41 in the bulge of the galaxy and 56 sources in the disk. Twenty-one of these latter sources were close to, or in, the spiral arms. The sheer number of X-ray sources detected by Chandra in a typical nearby galaxy makes studies of the global properties of X-ray source populations possible.

In many galaxies, observations using Chandra have detected one or more sources which are so bright that if truly associated with the galaxy and if the emission is not highly beamed, then the object must have a mass substantially greater than that of a neutron star and is thus likely to be a black hole whose mass is more than 25 times the mass of the Sun. Such "ultraluminous" sources appear to be quite common in nearby galaxies, and there are too many of examples of such objects to give much credence to the idea that they are all more local than one might think. If they are local (closer), then they are not nearly so powerful as they appear and would not be considered "ultraluminous." Because of the ubiquity, the concept of an intermediate-mass black hole is gaining some acceptance. Lower mass black holes are born in explosions of massive stars (supernova); very high mass (hundreds of thousands of solar masses or larger) black-holes are born in (form in) the nuclei of galaxies. Precisely how an "intermediate-mass" black hole is created is not completely understood. See also **Galaxy**.

Quasars. Quasars look like normal stars through an optical telescope. Not until the 1950s, when radio astronomy was first developed, did astronomers discover that these objects were well outside our own galaxy and were therefore emitting massive amounts of radio energy. These objects are called "quasars," short for "quasi-stellar radio sources." Quasars are among the most distant, energetic objects ever observed. Individual quasars are brighter than hundreds of galaxies put together, yet many are smaller than the size of our own solar system. Radio astronomers use a system of numbers to name objects in the sky. 3C273 was named in the 3rd Cambridge catalog as the 273 rd radio source identified. 3C273, along with 3C48, were the first quasars to be identified as such. These objects had bizarre optical spectra unlike any ever studied before. In 1963, astronomers Maarten Schmidt (3C273) and Jesse Greenstein and Thomas Matthews (3C48) noticed that these spectra made sense only if the objects were simply moving away from us, thus causing the apparent wavelengths to shift to the longer (redder) wavelengths (hence redshift) — in the case of 3C273 at about one-tenth the speed of light. Quasars are now considered a subset of active galaxies (called active galactic nuclei or AGN) powered by the presence of a massive black holes at their centers. See also **Quasars**.

More detailed and modern studies of quasars show that there are high-powered jets associated with these objects and often the material in the jets moves at velocities very close to the speed of light. Exactly how this happens is a topic of major astrophysical interest. Furthermore, instead of seeing a smooth stream of material driven from the core of the quasar, most optical, radio, and X-ray observations have revealed inconsistent, "lumpy" clouds of gas. The Chandra image (Fig. 6) of 3C273, however, shows, for the first time, a continuous X-ray flow emanating from the core. One would like to learn how and why matter is so violently ejected from near the quasar's core. The energy emitted probably comes from gas that falls toward the supermassive black hole at the center of the quasar but is channeled by strong electromagnetic fields. The black hole itself cannot be observed directly, but scientists hope to discern properties of the black hole by studying the jet.

Clusters of Galaxies. Chandra observations of clusters of galaxies frequently show us structures that have characteristic angular scales of a few arcseconds. Before Chandra, it was thought that the X-ray emission from galaxy clusters arose from a fairly simple system. The Hydra A radio

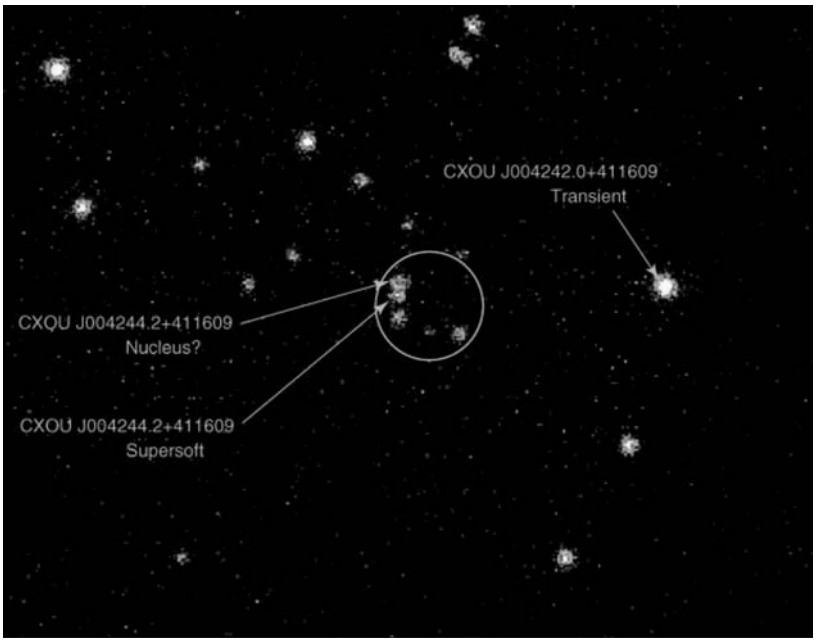

Fig. 14. Central region of M31 observed with the ACIS-I. The circle is 5 arcseconds in radius and illustrates the previous location of the X-ray nucleus. The old X-ray nucleus is resolved into five individual sources, and the source labeled CXO J004244.2+411609 is within 0.15 arcseconds of the black hole at the center of the galaxy (*courtesy NASA/Smithsonian Astrophysical Observatory/Chandra X-ray Center/Garcia et al., 2002*).

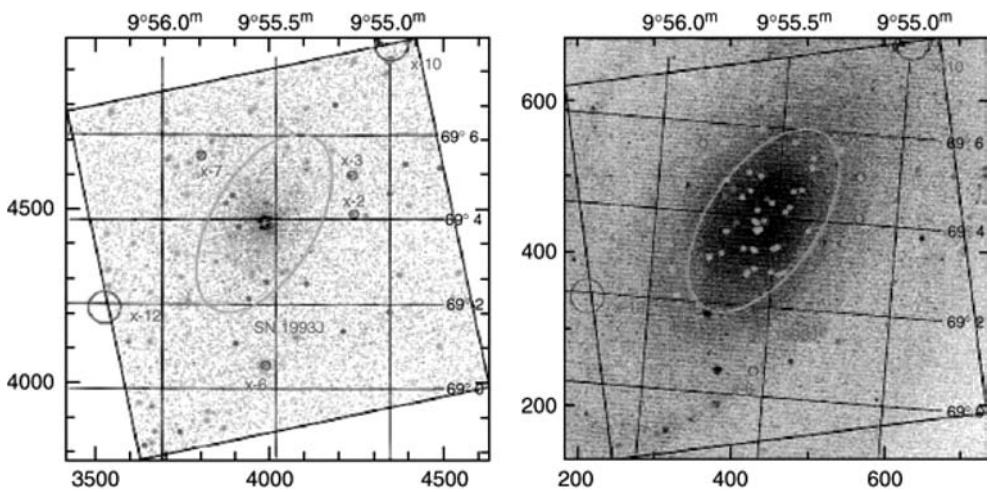

Fig. 15. Chandra observations of M81. Left: X-ray image with contours. Right: X-ray contours on optical image (*courtesy of NASA/Marshall Space Flight Center/Tennant et al.,* 2001).

galaxy (3C 218), shown in Fig. 2, was observed early in the Chandra mission. This very early image shows large areas of low X-ray brightness, indicating the presence of regions of low density or cavities in the hot gas. Similar, but even more dramatic cavities were found in the Perseus cluster shown in Fig. 16.

The X-ray Background — the Chandra Deep Surveys

The first sounding rocket flight in 1962 that detected the brightest X-ray source in the sky, other than the Sun, also detected a general background of X radiation (Giacconi et al., 1962). Since this first experiment, the detailed nature of the background radiation had been a puzzle. The lack of any distortion of the energy spectrum of the much cooler cosmic microwave background could be used to eliminate the possibility that the X-ray background glow was truly diffuse (Mather et al., 1990). Thus, the glow must have consisted of sources so faint as to be unresolved by the telescopes of the time. The question remained — what faint sources were contributing to this backgound glow? Observations by previous X-ray satellites such as ROSAT were a major step in resolving a significant fraction (about 75%) of the glow at low energies into discrete objects (Hasinger et al., 1998) and found that the sources reside mainly in active galaxies at redshifts from 0.1 to 3.5. The Japanese ASCA satellite observations extended the search for sources in the 2–10 keV band and resolved about 30% of the background glow (Ueda et al., 1998).

Chandra is ideally suited to search for faint sources. Two very deep exposures, one of one million, the other of two million seconds have been accomplished to date. These exposures are referred to as the Chandra Deep Fields. A portion of the image of one, the Chandra Deep Field North, is shown in Fig. 17. About 350 sources were detected in each of the one-million-second surveys. The most distant source detected (so far) is a quasar at a redshift of 5.2. The majority of the X-ray sources beyond a redshift of 0.5 are active galaxies that have massive black holes at their centers. The Chandra deep surveys extend the study of the background to signals levels more than an order of magnitude below that which could be previously achieved and have confirmed that most of this background is due to a variety of different types of discrete sources. At very low energies, there is somewhat diffuse component that results from warm-hot intervening matter (referred to as WHIM), concentrated regions of matter

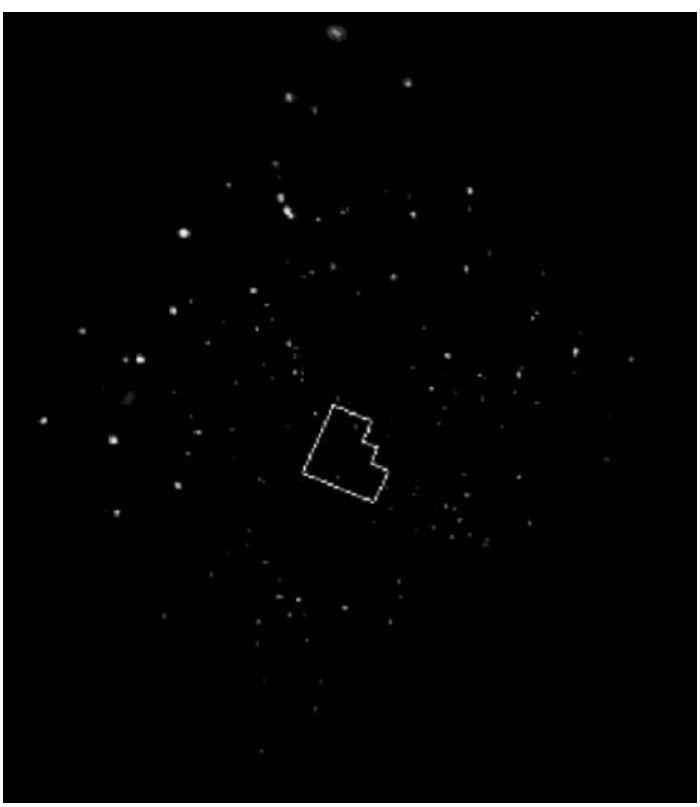

Fig. 17. Chandra "true -color" ACIS image of the Chandra Deep Field North. This image has been constructed from the 0.5–2.0 keV band (red) and 2.0–8.0 (blue) images. Part of the Chandra Deep Field North has also been surveyed in visible light using the Hubble Space Telescope, and this region is shown in outline (*courtesy of NASA/Pennsylvania State University/Hornschemeier et al.*, 2001).

that formed in the early stages of the Universe when the first galaxies and galactic clusters formed.

The spectrum of the X-ray background had also been considered puzzling because it was found that the majority of the bright AGN have an energy spectrum different from that of the background itself. One of the purposes of the Chandra Deep Surveys has been to explore the spectra of the sources, because the faint sources must modify the spectrum from the average of the bright AGN sample. The faint source spectrum was estimated by adding the spectra of individual sources detected in the surveys. This has now been accomplished and the paradox resolved (see, e.g., Rosati et al., 2002).

Sources of Gamma-Ray Bursts

Cosmic gamma-ray bursts (GRBs) were discovered in the late 1960s by satellites designed to detect gamma rays produced by atomic bomb tests on Earth. The bursts appear as a brilliant flash of gamma rays that lasts seconds to minutes. The bursts are often, but not always, followed by afterglows observable at X-ray (always), optical, and radio wavelengths (sometimes). Using one of the experiments on the Compton Gamma-Ray Observatory, astronomers took an important step in understanding the sources of these bursts by determining that the objects that produce them are not in our own galaxy. This discovery implied that the sources of these bursts are extremely energetic. The source of this tremendous energy is unknown. Models currently in vogue involve a fireball of energy where matter moves at nearly the speed of light. The source of this rapidly moving matter is unknown; theories include the merging of neutron stars, or black holes, or the collapse of an extremely massive star. See also **Cosmic Rays**; and **Gamma-Ray Bursts**.

The CXO is being used to help to solve the mystery of gamma-ray bursts by studying X-ray afterglow (Fig. 18). An example of this is the Chandra observation of the gamma-ray burst that took place on 22 February 2001. The Chandra data supported the model in which a very massive star has exploded, a "hypernova."

High-Resolution Spectroscopy

Owing to their unprecedented clarity, Chandra images are visually striking and provide new insights into the nature of X-ray sources. Equally important are Chandra's unique contributions to high-resolution dispersive spectroscopy. High-resolution X-ray spectroscopy is the essential tool for diagnosing conditions in hot plasmas. It provides information for determining the temperature, density, elemental abundance, and ionization stage of X-ray emitting plasma. The excellent spectral resolution of the Chandra gratings isolates individual spectral lines (i.e., features at specific energies), which would overlap at lower resolution. The spectral resolution also enables the determination of flow and turbulent velocities, by measuring Doppler shifts, shifts in the apparent energy, and the widths of the lines produced by these motions. Spectroscopy using the CXO gratings achieves its best energy resolution for nonextended (point) sources. Thus, observations that use the Chandra grating have concentrated on, but are not

limited to, X-ray emission from the hot regions surrounding stars (stellar coronae), X-ray sources in binary systems, and active galactic nuclei.

CHANGE OF PHASE. See **Meteorology**.

CHANNEL FREQUENCY. This term denotes the band of frequencies that is associated with a single unit of intelligence in a communications system. Thus it applies to the band of frequencies radiated by a broadcast station, or to the band of frequencies which must be handled by a carrier system to handle a single conversion. In the various systems the application of intelligence to a given frequency will generate certain other frequencies which are then associated with the original in some manner to convey the intelligence to the receiver. This band of frequencies then determines the response characteristics that the receiver (or other units of the system) must have for satisfactory results. Thus in conventional broadcasting the various stations use channels about 10 kHz wide; in frequency modulation, about 200 kHz; in television, 5 to 6 MHz; in carrier telephony, about 3 kHz.

CHANNELING. The transport of energetic ions and atoms in a lattice along directions parallel to close-packed rows of atoms. The ions or atoms move between atomic rows or planes, down what are effectively tunnels or channels through the crystal. The phenomenon is important in radiation damage studies in solids.

CHANNELING (Meteorological). See **Winds and Air Movement**.

CHAPARRAL. The name applied to a plant association occurring over wide areas in western North America and composed of a mixed population of low-growing shrubs. Some stands of chaparral are dense; others are open. Chaparral is usually found between a lower zone of sagebrush or grassland and an upper zone of woodland or forest. This association is found principally in the foothills of the Coast Ranges and Sierra Nevada in California, of the southern Rocky Mountains, and other ranges in Utah and Arizona. Some types of chaparral, such as that occurring on the Coast Ranges of southern California, are composed largely of evergreen shrubs; others, such as that occurring in the southern Rocky Mountains, largely of deciduous shrubs. See also **Biome**.

CHAPMAN MECHANISM. A series of reactions, first proposed by Sidney Chapman in the 1930s, to explain the presence of the ozone layer in the earth's stratosphere. The reaction sequence is as follows:

$$\mathrm{O_2} + h\upsilon \rightarrow \mathrm{O} + \mathrm{O}$$

$$\mathrm{O} + \mathrm{O_2} + M \rightarrow \mathrm{O_3} + M$$

$$\mathrm{O_3} + h\upsilon \rightarrow \mathrm{O} + \mathrm{O_2}$$

$$\mathrm{O} + \mathrm{O_3} \rightarrow \mathrm{O_2} + \mathrm{O_2}$$

$$\mathrm{O} + \mathrm{O} + \mathrm{M} \rightarrow \mathrm{O_2} + \mathrm{M},$$

where M is any other molecule in the termolecular reaction. Models based only on the Chapman cycle overpredict stratospheric O_3 levels, and it is now recognized that additional destruction of O_3 occurs through catalytic cycles involving oxides of nitrogen, chlorine, and hydrogen.

Chapman, S.: "A Theory of Upper Atmospheric Ozone," *Mem. Roy. Meteor. Soc.*, **3**, 103–125 (1930).

CHAPMAN REGION. A hypothetical region in the upper atmosphere in which the distribution of electron density with height can be described by a theoretical equation derived by Sydney Chapman. Some of the basic assumptions used to develop the equation were that the ionizing radiation from the sun is essentially monochromatic, that the ionized constituent is distributed exponentially (with a constant scale height), and that there is an equilibrium condition between the creation of free electrons and their loss by recombination.

CHAPMAN, SIDNEY (1888–1970). Chapman was an English mathematician and physicist. Early in his career he worked at Greenwich Observatory and helped design a new magnetic observatory. This work sparked his interest in geomagnetism and its connection with solar phenomena. Chapman is acknowledged as discovering gaseous thermal diffusion and confirming it experimentally. He also studied the daily variations of the geomagnetic field and magnetic storms, which led to the improved determinations of the electrical conductivity within the Earth. He investigated currents in the magnetosphere and developed the theory of magnetic storms and the aurora.

Chapman also studied the atmospheres of the sun and the Earth and gave a photochemical theory of atmospheric ozone, which was later confirmed by mass spectrometers that were rocket-borne.

Chapman is acknowledged for his important work with the lunar tide in the Earth's atmosphere, for formulating the "Chapman" ionized layer which is used by radio physicists, and for his work in thermal diffusion.

For his contributions to terrestrial and interplanetary magnetism, the ionosphere, and the aurora, in 1964, Chapman received the Royal Society's Copley Medal.

J. M. I.

CHARACIDS *(Osteichthyes).* Of the order *Ostariophysi*, family *Characidae*, there are 6 families and up to 30 subfamilies. They are found only in South America and central Africa. In appearance, they resemble to some degree carps and minnows. However, jaw teeth are among the distinguishing features. There are numerous sizes and shapes among the characids, ranging from 1 inch (2.5 centimeters) or even less to a length of some 5 feet (1.5 meters). They also have a wide range of eating habits, varying from vegetarians to the omnivorous to the dangerous carnivorous. Unquestionably, the best known of the characids is the piranha. The piranha is probably feared even more than the shark as a killer.

Normally, piranhas have a diet of small fishes, usually other members of their family (characids), but will also attack large animals, including people. Piranhas are famous for their teeth and the manner in which they work in concert in consuming a victim. It has been recorded that a 100-pound (45.4-kilogram) capybara was ravaged and completely reduced to a skeleton by a group of piranhas within less than one minute. Because they are considered good food items, natives fish for them with hook and line. Obviously, strong leader line must be used because otherwise the sharp teeth of the piranha will easily cut it. The piranha must be regarded with respect when taken from the water even if it appears dead-the jaws can snap when touched to remove a finger or toe. The aggressive character of the piranha appears to be related to the strength it derives as a member of a large school because, when in captivity, singly or with just a few others, its aggressiveness is greatly moderated. In any event, however, the piranha should be regarded as a nervous and dangerous fish. See Fig. 1.

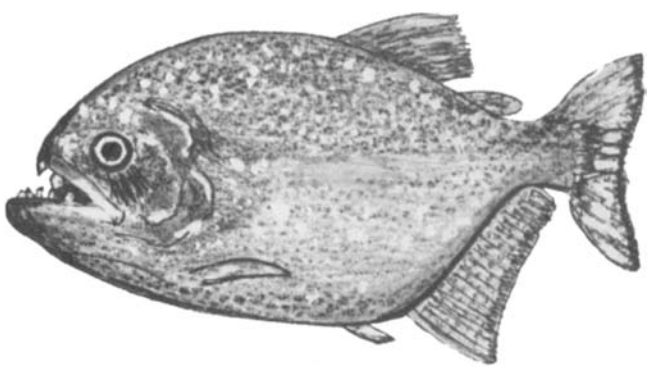

Fig. 1. Piranha (*Serrasalmus piraya*).

The *Serrasalmus natterei* is widely distributed and is the type sometimes seen in tropical fish stores. The *S. piraya* is the largest of the dangerous piranhas and attains a length up to 2 feet (0.6 meter). It is found in eastern Brazil in the River Sao Francisco. Other carnivorous characids include the *Boulengerella lucius*, which has the long jaw and appearance of a pike. It is noted for lurking among plants waiting for its prey. It grows to about 2 feet (0.6 meter) in length, but is not considered a danger to people. The *Hydrocyon goliath* (African Congo tiger fish) appears much as a trout and sometimes attains a weight of 125 pounds (57 kilograms). It is reputed to have attacked natives and is dangerous both in and out of the water until fully expired.

Among the very small characids are several interesting and beautiful fishes that are favorites among tropical-fish fanciers. In this group is the jewel tetra from South America (*Hyphessobrycon callistus*). Some of the common names for fishes of this type include "neon tetra," "glo-lite tetra," "head-and-tail light," and "cardinal tetra."

One of the most interesting of the South American characids is the flying hatchet fish. "Flying" is attributed to quite a few fishes, but all but the flying hatchet fish simply jump and glide, with no propulsion applied during flight. In the case of the hatchet fish, the pectoral fins are used to extend a jump into a somewhat longer flight — hence they are sometimes referred to as true flying fishes. There are nine species of hatchet fishes. They are not to be confused with the hatchet fishes of the family *Sternoptychidae*, which are described in entry on **Hatchet Fishes**.

Pencil fishes (*Poecilobrycon eques*) are also small, very slender characids and favorites of tropical-fish fanciers.

CHARACTER (Computer System). One symbol of a set of elementary symbols, such as those corresponding to the keys of a typewriter, that is used for organization, representation, or control of data. Symbols may include the decimal digits 0 through 9, the letters A through Z, and any other symbol which a computer may read, store, or write. Thus, such symbols as @, #, $, /, are commonly used to expand character availability.

A *blank character* signifies an empty space on an output medium; or a lack of data on an input medium, such as an unpunched column on a punched card.

A *check character* signifies a checking operation. Such a character contains only the data needed to verify that a group of preceding characters is correct.

A *control character* controls an action rather than conveys information. A control character may initiate, modify, or stop a control operation. Actions may include the line spacing of a printer, the output hopper selection in a card punch, etc.

An *escape character* indicates that the succeeding character(s) is in a code that differs from the prior code in use.

A *special character* is not alphabetic, numeric, or blank. Thus, @, #, etc., are special characters.

CHARACTERISTIC EQUATION. 1. A class of equations connecting those variables, such as temperature, pressure, and volume, which define the physical condition of a given substance and are called variables of state.

The ideal gas law and the Boyle-Charles law represent approximately the behavior of all gases, but if one wishes to be accurate, some modification of these must be sought which will take into account the differences between individual gases. The best known characteristic equation for gases is that of van der Waals. Using the same notation as for the ideal gas law, this may be written

$$\left(p + \frac{n^2 a}{v_2}\right)(v - nb) = nRT$$

where n is the number of moles of gas, and a and b are constants characteristic of the gas in question. They are very small; if they were zero we should have the ideal gas law. Following are their approximate values for certain gases, where a is expressed in atmosphere (liter/gram-mole)^2 and b in liter/gram-mole:

Gas	a	B
Ammonia	4.170	0.03707
Helium	0.034	0.03412
Hydrogen	0.244	0.02661
Nitrogen	1.390	0.03913
Oxygen	1.360	0.03183

Characteristic equations of this sort are also known as equations of state. See also **Berthelot Equation**; and **Equation of State**.

2. Equations that have solutions, subject to particular boundary conditions, only for certain specific parameters occurring in them. (See **Eigenfunction**; and **Eigenvalue (Proper Value)**.) In differential equations, the complete solution includes the characteristic solution and the particular solution. The characteristic solution is obtained from the roots of the characteristic equation, and defines the transient or time response of the system. The particular solution is obtained from the forcing function or input signal and defines the steady-state response.

3. An equation in the linearized theory of hydromagnetics whose solutions show the frequencies and modes of the initial perturbations that will decay or grow exponentially in time for any given system. The solutions to this equation indicate the regions of stability for various hydromagnetic systems. See also **Hydromagnetic Equations**.

CHARACTERISTIC FUNCTION. In statistics and mathematics, if $F(x)$ is a probability distribution function, its characteristic function is

given by

$$\phi(t) = \int_{-\infty}^{\infty} e^{itx} dF(x)$$

The characteristic function is a moment generating function,

$$\phi(t) = \sum \mu_r'(it)^r / r!$$

where μ_r' is the rth moment of $F(x)$ about the origin. The characteristic function uniquely determines the distribution function by the formula

$$F(x) - F(0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi(t) \frac{1 - e^{-ixt}}{it} dt$$

Analogous functions can be defined for several variables. A most important property in the theory of sampling is that the characteristic function of a sum (convolution) of independent random variables is the product of their individual characteristic functions.

CHARACTERISTIC IMPEDANCE. This is the impedance that a transmission line would present at its input terminals if the line were infinitely long. If, instead of the line being actually infinite in length, it is finite and is terminated by an impedance equal to its characteristic impedance it will behave, as far as the input is concerned, as if it were infinite. This means that there will be no reflected electrical wave, with the attendant losses, etc., at the terminal point. In electrical circuits this is an extremely important consideration as reflection means some energy which would otherwise go to the load is reflected back down the line to cause losses on the line, objectionably high voltages, echo effects and other undesired conditions. When a line is terminated in the characteristic impedance it is said to be matched, or the load matches the line. While not always attainable, it is a condition highly desirable.

This term is also applied with corresponding meaning to two-port networks and to waveguides.

CHARACTERISTIC MATRIX. Consider the linear transformation $\mathbf{y} = A\mathbf{x} = \lambda\mathbf{x}$, where λ is a constant; thus A merely multiplies the vector $\mathbf{x}$ by a scalar quantity. Rewriting this equation as $[\lambda E - A]\mathbf{x} = K\mathbf{x} = 0$, we see that either $|K|$, the determinant, must vanish or all x_i are zero, the latter a trivial case. The characteristic matrix of A is K, the determinant of K is the secular determinant or characteristic function of A; roots of the latter are eigenvalues, latent or characteristic roots and the corresponding values of x_i are eigenvectors.

The diagonalization of a matrix is a matter of some importance and we now show how this may be done using properties of the characteristic matrix. Let us suppose the eigenvalues of A are known and that we wish to determine a matrix X so that

$$X^{-1}AX = \Lambda = [\lambda_i \delta_{ij}]$$

Choose one eigenvalue, say λ_k, and write $A\mathbf{x} = \lambda_k\mathbf{x}$, which is a set of linear homogeneous equations in the n variables $x_1, x_2, \ldots, x_n$. Since the equations are homogeneous, one can only determine the ratio of the unknowns but, except for an arbitrary constant, they can be written as a column vector, the eigenvector $\mathbf{x}_k = \{x_{1k}, x_{2k}, \ldots, x_{nk}\}$. Continue in the same way to find the eigenvectors for the other eigenvalues. It follows that $AX = X[\lambda_i \delta_{ij}]$; hence, the collineatory transformation $X^{-1}AX = \Lambda$ does indeed diagonalize A.

The arbitrary constant in each eigenvector can be eliminated by the requirement that X be orthogonal. Such a transforming matrix is not only collineatory but also congruent. This means that $X = \tilde{X}^{-1}$ or $X\tilde{X} = \tilde{X}X = E$, where E is a unit matrix. A simple means of obtaining this property is the Schmidt process.

The preceding arguments are based on the assumption that no two or more of the eigenvalues are identical. If this is untrue, degeneracy is said to occur. Some modification of the procedure described is then necessary and the resulting matrix is not truly diagonal.

See also **Schmidt Process**.

CHARADRIIFORMES *(Aves).* This order comprises a great variety of birds of distinctive sizes. It includes: the extremely long-legged stilts; the short-legged seed snipes; the curlews and slender-beaked snipes; the puffins, with their very high and laterally compressed beaks; the skuas, with their hook-shaped beaks; and the skimmers, in which the lower mandible extends far beyond the upper, a unique feature among birds. Despite this external polymorphy, the taxonomic relationship of the families and genera of grallatores, gulls, and auks can be demonstrated by exact comparisons of internal details.

The waders (grallatores), shore birds, and gulls, range in length from 12 to 80 centimeters (5 to 31 inches) and weight from 25 grams to at least 2 kilograms (0.8 ounce to $4\frac{1}{2}$ pounds). The vomer is complete and the breastbone has no inner extensions. There are 11 primaries and 12 (up to 26) rectrices. The rump feathers have aftershafts; the uropygial gland has a long feather tuft. The palates and the vocal organs are constructed alike in most species. They usually produce only one brood a year; the clutch size does not exceed four eggs, which are incubated for a period of 2 to 4 weeks or even longer. The downy chicks either leave the nest immediately or they remain there or nearby until full fledged (with the exception of some auk species). Gulls, terns, and auks breed chiefly in colonies. They feed entirely or nearly so on animals they pick from the ground with their poker beaks or from the water by sudden plunges or wing dives. Their activity range is chiefly aquatic, in marshes, near inland waters, at the seashore, and on oceanic islands. A few species of some families inhabit dry areas, even the desert. The nasal glands, which are usually large, enable those birds that live near salt water to eliminate the salt.

There are 3 well-differentiated suborders with a total of 17 families and 334 species. The ploverlike forms (*Charadrii*), include 12 families; 1. Jacanas (*Jacanidae*); 2. Phalaropes (*Phalaropodidae*); 3. Snipes, etc. (*Scolopacidae*); 4. Avocets (*Recurvirostridae*); 5. Plovers (*Charadriidae*); 6. Painted Snipes (*Rostratulidae*); 7. Oystercatchers (*Haematopodidae*); 8. Sheathbills (*Chionididae*); 9. Seed Snipes (*Thinocoridae*); 10. Coursers and European Pratincoles (*Glareolidae*); 11. Crab Plovers (*Dromadidae*); 12. Stone Curlews (*Burhinidae*). The Gull-like forms (*Lari*), include four families: 1. Skuas (*Stercorariidae*); 2. Gulls (*Laridae*); 3. Terns (*Sternidae*); 4. Skimmers (*Rynchopidae*). The Auks (*Alcae*) include one family (*Alcidae*).

Pluvialines and gulls are worldwide. Many species are pronouncedly migratory. The Arctic tern and the sandpipers share the record as long-distance travelers, for they cover 33,000–35,000 kilometers (20,506–21,749 miles) a year. The Pacific golden plover holds the record for nonstop flights (at least 3300 kilometers; 2051 miles). The auks, on the other hand, are restricted to the Northern Hemisphere. Their principal habitat is the shores and islands of northern waters that have abundant food. See also **Waders, Shorebirds, and Gulls**.

CHARDONNET, H. (1839–1924). A native of France, he has been called the father of rayon because of his successful research in producing what was then called artificial silk from nitrocellulose. He was able to extrude fine threads of this semisynthetic material through a spinnerette-like nozzle, and the textile product was made on a commercial scale in several European countries. He was awarded the Perkin medal for his work.

CHARGE CONJUGATION. The theoretical operation of changing the signs of all electric charges and the direction of all electromagnetic fields in a system. See also **Conservation Laws and Symmetry**.

CHARGE-COUPLED DEVICE (CCD). A three-layered semiconductor device — one layer of metallic electrodes and another of silicon crystal, separated by an insulating layer of silicon dioxide. The CCD stores and transfers information in the form of packets of electrical charge analogous to the tiny magnetic domains in bubble devices.

When charge packets are introduced into a CCD, they can be stored in "potential wells" at the surface. These wells are actually tiny regions in which the presence or absence of charge can represent information. The packets of charge can be sequentially moved (or "coupled") from one well to the next when proper voltages are applied. In this way, the CCD can recirculate or store the charge packets of information until they are needed. Since the amount of charge in a well can be varied continuously from zero to a maximum amount, the CCD is basically an analog device and thus can be used as an efficient device for handling analog communications signals. When the packets of charge are digitized, i.e., the wells are either empty or full, the CCD can act as a digital electronic memory. If the charge packets are introduced optically instead of electronically, such as by an image focused on the light-sensitive silicon surface, the CCD can be used as an imaging device.

The CCD has been used successfully in solid-state television cameras. When light from an image or scene is focused on the CCD, a pattern of electrical charges is created. The charges vary in proportion to the amount of light and thus serve as an accurate electrical representation of picture elements. These charges can be stored, transmitted out of the CCD chip sequentially, and later reassembled on a conventional television screen or facsimile readout. Use of the CCD has eliminated need for vacuum tubes and scanning electron beams previously required by TV cameras.

CCD devices also have been used as memories and analog signal processors.

CHARGE (Electron). See **Electron Theory**.

CHARGE-MASS RATIO. This term refers to the relationship between the electric charge of a particle and its mass, so important in the physics of electrons, ions, and other electrified bodies of molecular orders.

The earliest information on the subject followed from the researches of Faraday on electrochemical equivalents. From his results it appears that, in the electrolysis of chlorine, for example, 1 coulomb of negative electricity is carried by 0.00037 gram of this element, and hence that the carriers or ions have a charge-mass ratio of about 2,700 coulombs, or 8.1×10^{12} electrostatic units of electricity to the gram. Similarly, 1 coulomb of positive electricity is carried by 0.0000104 gram of hydrogen, which gives about 95,700 coulombs or 2.87×10^{14} electrostatic units to the gram for hydrogen ions. This is 35 times the ratio for chlorine ions. But the atomic masses of hydrogen and chlorine are in the ratio 1:35, which means that if the carriers are atoms, the charge per carrier is the same for both elements. Bivalent elements, on the other hand, carry twice this charge per ion.

When J.J. Thomson applied a magnetic field to a stream of hydrogen canal rays, and then neutralized the resulting deflection by means of an electric field, he was able to calculate the charge-mass ratio of these particles from the curvature of the magnetically deflected stream and the values of the two field intensities. This he found to be either 95,700 coulombs per gram as in the electrolysis of hydrogen, or $\frac{1}{2}$ that value, which indicated that some of the ions were atoms and some were molecules carrying the some charge as the atoms. But when a similar test was applied to the cathode rays in a Crookes tube, the ratio was found to be about 5.303×10^{17} electrostatic units per gram, or about 1,850 times that for hydrogen atoms, whatever the nature of the cathode. We know now that this enormous difference is one of mass, not of charge, and, that these experiments were the first direct revelation of the identity of the electron, the mass of which is now known to be approximately 1/1,836 of the mass of the proton (nucleus of hydrogen atom).

CHARGE NEUTRALITY. The approximate equality of positive and negative particles in high-density plasmas. This phenomenon, which is sometimes called electrical neutrality, is a result of the extremely large electric space charge fields that would arise if the densities were not equal. Although the positive and negative charge densities are seldom exactly equal, their percentage difference is so small as to be negligible. It is not difficult to maintain this condition in an active plasma since ionization or recombination always produces or destroys an ion pair together.

CHARLES, JACQUES ALEXANDRE (1746–1823). Charles was a French physicist whose discovery is known as Charles' law, which states that when pressure remains constant, gases expand as temperature rises. He is also known for the first gas-filled balloon.

See also **Balloon**; and **Boyle-Charles Law**.

J. M. I.

CHARLES LAW. Although the coefficients of expansion of different solids or of different liquids are notably different, the coefficients of expansion of all gases are nearly the same, namely, about $\frac{1}{273}$ of the volume at 0 °C per centigrade degree. The law, stated by Charles in 1787 and independently by Gay-Lussac in 1802 (hence sometimes called Gay-Lussac's law) is not strictly true. Regnault obtained the following values of the volume coefficient for various gases:

Air	0.0036706
Hydrogen	0.0036613
Carbon dioxide	0.0037099
Sulfur dioxide	0.0039028
Carbon monoxide	0.0036688
Nitrous oxide	0.0037195
Cyanogen	0.0038767

None of these is far from $\frac{1}{273} = 0.003663$, which is therefore commonly taken as the expansion coefficient for gases; especially as the value for hydrogen, commonly used in the standard gas thermometer, is very near it. If the pressure as well as the volume is allowed to vary, the behavior of the ideal gas must be expressed by the Boyle-Charles law or the ideal gas law; and the behavior of a real gas by one of the other equations of state. See also **Ideal Gas Law**.

CHARNOCKITE. Charnockite is a granular variety of hypersthene granite, first described from the gravestone of Job Charnock, who founded the city of Calcutta, India, whence the derivation of the name charnockite.

CHATTERER *(Aves, Passeriformes).* South and Central American birds making up the family *Cotingidae*. They are quite varied, some with strangely formed plumage and some beautifully colored. The family includes the umbrella bird, bell-birds, cotingas, manakins, and cocks-of-the-rock. A single species, the xantus becard, *Platypsaris aglalae*, enters the United States near the Mexican border.

These birds are related to the flycatchers.

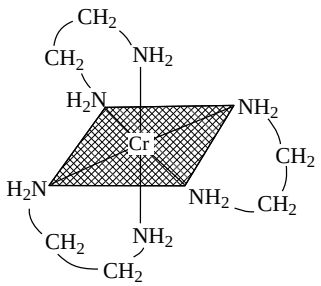
CHATTERMARK. A moon-shaped scratch or gouge on the bedrock assumed to be caused by the "chattering" action of angular boulders carried in the bottom of a glacier. Also, a chattermark may be defined as any mark, pit, or scratch made on a rock surface by the surface of a mass that moves over it.

CHEBYSHEV, PAFNUTY LVOVICH (1821–1894). Chebyshev, a Russian mathematician and a foreign associate of the Institut of France, and also of the Royal Society. He is mostly known for his work on prime numbers. He also wrote on the theory of congruence. Chebyshev studied mechanics and the problems involved in converting rotary motion. He wrote on probability theory, quadratic forms, orthogonal functions, and the theory of integrals.

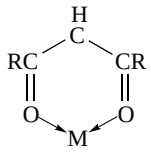
J. M. I.

CHEILITIS. Inflammation of the lips, regardless of cause. Usually due to an allergy to substances which may come in contact with the lips, including cosmetics, dentifrices, chewing gum, mouthwashes, various fruits and fruit dyes. Sometimes the inflammation may be induced by prolonged exposure to wind and sun.

CHELATES AND CHELATION. Chelation compounds are coordination compounds in which a single ligand occupies more than one coordination position. Such ligands are called chelating agents (the word being derived from the Greek meaning *crab's claw*). Thus ethylenediamine, $H_2N-CH_2-CH_2-NH_2$, abbreviated as *en*, forms a $Cr(en)_3^{3+}$ ion having three molecules of ethylenediamine, each occupying two coordination positions.

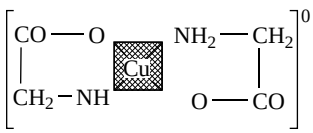


Ethylenediamine is therefore called a bidentate group, as are many other ligands, such as the β-diketones, which form chelation compounds of the type where M is a metal ion.

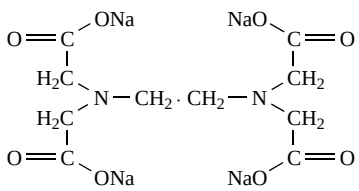


Although bidentate ligands are more common, there are polydentate ligands, which occupy more than two coordination positions; ethylenediaminetetraacetic acid is such a polydentate ligand.

While ethylenediamine, and many other chelating agents, form only covalent bonds, there are others which attach by both covalent and ionic bonds. Thus glycine forms with cupric ions (Cu^{2+}) the compound copper bisaminoacetate.



A number of synthetic chelating agents have been developed. They are substances like ethylenediaminetetraacetic acid (EDTA) (Structure 1) and N-hydroxyethylethylenediaminetriacetic acid (HEDTA) and their salts, usually sodium salts. Many of these compounds and mixtures of these compounds are sold under trademarks.



(**1**)

Chelating agents are being used in increasing amounts for a number of important purposes. These uses may be put into two important categories: first, artificial trace metal carriers and, second, sequestering agents.

As artificial carriers for trace metals, chelating agents can be used as aids in agriculture by supplying the metals for soils which are deficient in their trace metal content. Both EDTA and HEDTA are adequate iron carriers and EDTA can be used as the carrier for bivalent copper, zinc, manganese, and cobalt. By use of such carriers certain plant deficiency diseases can be controlled. Another example of artificial carrier use is the employment of chelating agents such as the EDTA derivatives or mixtures of such derivatives with pyrophosphates or a mixture of EDTA and the sodium salt of N,N-di(2-hydroxyethyl) glycine in controlling polymerization reactions in synthetic rubber manufacture by the controlled release of trace metal catalysts.

As sequestering agents, chelating compounds have a wide variety of uses, for instance: for water softening in both soaps and synthetic detergents; in textile processing, as in kier boiling operations, where iron, copper, zinc, etc., ions are inactivated, so that discoloration of cloth is prevented; in the stabilization of hydrogen peroxide; and in boiler and heat exchanger cleaning.

Chelation in Biological Systems. Chemical reactions in biological systems are usually mediated by selective catalysts called enzymes. The high efficiencies and stereospecificities achieved require that enzymes have definite and characteristic geometries, whereby specific functional groups coordinated to the metal ion are held in definite spatial positions relative to each other and relative to the substances on which they exert their catalytic effects. The incorporation of metal ions into enzyme structures can assist in the maintaining of a definite geometrical relationship between ionic and polar groups, through the geometric requirements of the coordinate bonds of the metal ion. Certain metal ions may also participate in the catalytic properties of enzymes through ionic and coordinate bonding between the metal ion and electron donating groups of the enzyme and substrate, and through the ability of the metal ion to initiate oxidation-reduction reactions. Because of these chemical and steric effects, coordinated metal ions in the complex compounds that catalyze biological reactions frequently are found. See also **Metalloproteins**.

Most of the metal ions that have biological functions have a coordination number of six, with the donor groups arranged in an octahedral fashion. There are a few metals, such as Mg^{2+} and Zn^{2+}, that frequently coordinate only four donor groups tetrahedrally, and Cu^{2+}, which has four coordinations directed to the corners of a square plane with the metal ion at the center of the plane.

Many simple acid-base reactions are catalyzed by both metal ions and hydrogen ions. Because of small size, the electronic interaction of the hydrogen ion with a substrate is much greater than that of a metal ion. The latter, however, has properties not possessed by hydrogen ions, which are useful in catalysis, i.e., the ability to coordinate a large number of electron donor groups simultaneously, the specific geometric orientation of the coordinate bonds of certain metal ions, and the ability of metal ions to undergo oxidation-reduction reactions. Many of these reactions are models of the more complex catalytic effects that occur in biological systems. Since these reactions of simple coordination compounds aid in the understanding of biological reactions, a few of the more common examples are given in Table 1.

The function of the metal ions in the reactions listed is to attract electrons from the substrate. When this effect takes the form of simple polarization of the functional groups of the substrate, charge variations and electron shifts in these groups facilitate the chemical reactions listed under solvolysis and acid catalysts. When the metal ion removes completely one or more electrons from the substrate, the first step in an oxidation reaction occurs. This type of catalysis can be accomplished only by metals capable of existing in more than one valence state.

There is a saturation effect in the coordination of a metal ion by donor groups of both the enzyme and the substrate. Therefore, one would expect that the interaction of a free metal ion with the substrate would be greater than that of the metalloenzyme (in which the metal is already partially coordinated). If this were true, the metal ion would have a greater catalytic effect than the metalloenzyme. The reverse is always the case; thus far, no metal ions, or metal complex enzyme models, have been found to approach the catalytic activities of the corresponding enzyme. This high activity of the enzyme is ascribed to the special environment of the substrate around the active site of the enzyme, through which additional binding of the substrate by adjacent organic groups of the enzyme takes place.

The enzyme aconitase, which contains the Fe^{2+} ion at the reactive center, catalyzes the interconversion of citric, isocitric, and aconitic acids. The reaction has been shown to occur through the formation of a single intermediate carbonium ion structure in which the Fe^{2+} ion is always bound to the same donor atoms, while the interconversion of the substrate occurs through the migration of only protons and electrons.

Some of the more important biological reactions that are catalyzed by metal ions are summarized in Table 2.

Chelates in Food Processing. The most commonly used sequestrants in the food field include:

Calcium acetate	Potassium phosphate (di- and monobasic)
Calcium chloride	Sodium acid pyrophosphate
Calcium citrate	Sodium citrate
Calcium gluconate	Sodium diacetate
Calcium phosphate, monobasic	Sodium gluconate
Citric acid	Sodium metaphosphate
Disodium EDTA	Sodium tartrate
Glucono delta-lactone	Sodium thiosulfate
Oxystearin	Sorbitol
Phosphoric acid	Tartaric acid
Potassium citrate	Triethyl citrate

Phosphates have the ability to combine with metal ions, such as calcium, magnesium, iron, and copper, and so render the metals nonactive. Calcium and magnesium are primarily responsible for the hardness of water. The addition of tripolyphosphate or hexametaphosphate will bind these elements and produce soft water. In a similar manner, sequestration is used to soften the skins of fruits and vegetables for faster cooking, and to increase the extraction and recovery of pectin in fruit. Calcium pectinates, which are insoluble, are converted into sodium pectinates, which are soluble and readily extracted.

Pyrophosphates are especially effective sequestrants for iron, which catalyzes oxidative darkening of fruits and vegetables. Potatoes, in particular, turn dark after cooking unless the iron in the potato is sequestered. Iron or

TABLE 1. METAL ION AND METAL CHELATE CATALYSIS OF CHEMICAL REACTIONS

Solvolysis and Other Reactions Involving Acid Catalysis by the Metal Ion Reaction Type		
Reaction Type	Substrate	Catalyst
Solvolysis	Amino acid esters, peptides, and amides	Cu^{2+}, Co^{2+}, Mn^{2+}
	Phosphate esters	La^{3+}, Cu^{2+}, VO^{2+}
	Fluorophosphates	Cu^{2+}, $UO_2{}^{2+}$ diamine-Cu(II) complexes
	Polyphosphates	Ca^{2+}, Mg^{2+}
	Schiff bases	Cu^{2+}, Ni^{2+}
Transamination	Schiff bases of pyridoxal and α-amino acids	Fe^{3+}, Cu^{2+}, Al^{3+}, Zn^{2+}, Ni^{2+}, Co^{2+}
Decarboxylation	α-Keto polycarboxylic acids (e.g., oxalacetic and oxalsuccinic acids)	Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Fe^{2+}
Acylation	Acetylacetone	Co(III), Rh(III) or Cr(III) chelates of acetylacetone
Catalysis of Oxidation Reactions by Electron Exchange with Metal Ions or Metal Complexes		
Reaction	Substrate	Metal Ion or Complex
Oxidation by molecular O_2	Ascorbic acid, catechols, quinoline, salicylic acid	Fe(III), Fe(III)-EDTA, Cu(II), Cu(II)-EDTA, V(IV)
Oxidation by H_2O_2	Phenol, anisole	Fe(II) (Fenton's reagent), Fe(II)-hydroquinone Fe(II)-EDTA-ascorbic acid
Formation of oxygen	Hydrogen peroxide	Fe^{3+}, Fe(III)-phthalocyanine chelate
Formation of disulfides from mercaptides	Thioglycolic acid	Fe^{3+}, Cu^{2+}

TABLE 2. BIOLOGICALLY ACTIVE METAL CHELATES

Metal	Metalloenzyme	Other Biological Functions
Mg	Polynucleotide phosphorylase, ATPase, choline acylase, deoxyribonuclease, acetate kinase, adenosine phosphokinase, fructokinase, glyceric kinase, hexokinase	Chlorophyll
Ca	α-Amylase, aldehyde dehydrogenase, lipase	
V		Green algae, blood of marine worm (ascidian)
Cr		Glucose tolerance factor
Mn	Arginase, carnosinase, prolinase, enolase, isocitricdehydrogenase, 3-phospho-glycerate kinase, glucose-1-P kinase	
Fe	Aconitase, formic hydrogenylase, phenylalanine hydroxylase, peroxidase, catalase, cytochromes	Hemoglobin, ferritin, hemosiderin, siderophilin
Co	Aspartase, acetylornithinase	Vitamin B_{12}
Cu	Lactase, phenolase, tyrosinase, uricase	Ceruloplasmin, cytochrome
Zn	Carbonic anhydrase, carboxypeptidase, alcohol dehydrogenase, glutamic dehydrogenase, acylase	
Mo	Nitrate reductase, xanthine oxidase	

copper is also responsible for catalyzing oxidative rancidity in meat, poultry, and fish. The effectiveness of combinations of an antioxidant, chelating agents, and polyphosphates in retarding the chemical and organoleptic deterioration of mechanically deboned flounder meat during frozen storage has been investigated. Treatment with polyphosphates, usually applied for moisture binding, will also inhibit rancidity and prolong storage life of various meats. Canned fish frequently develops crystals of a compound known as *struvite*, which appears to the user to be pieces of glass. Although not harmful, these substances are the cause for rejection. Struvite formation is effectively prevented by the addition of a small amount of pyrophosphate to the canned fish.

CHEMICAL ABSTRACT SERVICE REGISTRY NUMBER (CAS). This universally used number permits use and comparison of data on a given material no matter the synonym with which it might be published. It will, in fact, permit absolute identification of a compound with all of its synonyms. CAS numbers also facilitate extraction of information from computerized databases.

CHEMICAL AFFINITY. The entropy production due to a chemical reaction has the form

$$\frac{d_i S}{dt} = \frac{1}{T}\mathbf{A}v \geq 0 \tag{1}$$

where $\mathbf{A}$ is the chemical affinity and v, the reaction rate. $\mathbf{A}$ is related to the characteristic functions U, H, A, G, and to the chemical potentials μ

by the relations:

$$\begin{aligned}\mathbf{A} &= -\left(\frac{\partial U}{\partial \xi}\right)_{S,V} = -\left(\frac{\partial H}{\partial \xi}\right)_{S,p} \\ &= -\left(\frac{\partial A}{\partial \xi}\right)_{T,V} = -\left(\frac{\partial G}{\partial \xi}\right)_{T,p} \\ &= -\sum_i v_i \mu_i\end{aligned} \tag{2}$$

when ξ is the extent of reaction and v_i the stoichiometric coefficient.

The basic properties of the affinity **A** are that it is always of the same sign as the reaction rate, and that if the affinity is zero the reaction rate is also zero, i.e., the system is in equilibrium.

This definition of affinity is essentially due to De Donder and is called De Donder's fundamental inequality. In the notation used by G.N. Lewis and his school, it is supposed that ξ increases by unity; therefore the relations of (2) are written in the form:

$$\mathbf{A} = -(\Delta U)_{S,V}, = -(\Delta H)_{S,p} = -(\Delta A)_{T,V} = -(\Delta G)_{T,p,} \tag{3}$$

Note that in this entry, **A** is the affinity and *A*, the Helmholtz function (work function).

See also **Chemical Reaction Rate**.

CHEMICAL COMPOSITION. Matter is composed of the chemical elements, which may be in the free or elementary state, or in combination. In the former case, as exemplified by iron, tin, lead, sulfur, iodine, and the rare gases, matter commonly exhibits the properties of the atoms of the particular element, including the chemical properties whereby they combine to form molecules. Molecules may (1) be monoatomic; (2) they may consist of atoms of one element only, such as nitrogen or hydrogen molecules (N_2 or H_2), (3) they may be composed of atoms of more than one element, called compounds, which usually have distinctive properties.

The molecular formulas of gaseous compounds are obtained from a study of the composition by elements and the density, by a method introduced by the Italian chemist, Cannizzaro, in 1858. Later, in 1872, in the course of his Faraday Lecture before the Chemical Society (London) on the subject, "Some Points in the Teaching of Chemistry", Cannizzaro stated that "Symbols and formulas, in my opinion, constitute the introduction, preparation, and base of the study of the transformations of matter, which is the true object of our science." The simplest way to understand the *Cannizzaro method* is to arrange in tabular form: (1) the individual gases; (2) the weight in grams of 1 liter (at 0 °C, 760 millimeters of mercury pressure) of each gas; and (3) the weight in grams of *each element* present in the above volume (1 standard liter) found by exact analysis (percentage composition by chemical elements using the methods of analytical chemistry). See Table 1.

Careful examination of the figures in the last six columns reveals the experimental fact that (1) in each separate vertical column the figures represent a minimum weight or a small multiple (approximately) of this weight, and (2) the smallest of the six minimum weights is that for hydrogen, namely, 0.045 gram in 1 standard liter of hydrogen chloride gas.

The next step involves changing 0.045 gram of hydrogen to exactly 1.000 gram and finding arithmetically the volume of hydrogen chloride containing this weight (1.000 gram hydrogen). The volume is found to be 22.2 standard liters.

Therefore, 1.000 gram minimum weight of hydrogen is contained in 22.2 standard liters of hydrogen chloride.

Using this standard volume of 22.2 liters, the next step is to ascertain the minimum weight of the other elements in this volume.

Chemical Element	Approximate Minimum Weight in Grams of Each of the Six Chemical Elements in the Standard Volume, 22.2 Liters
Hydrogen	1
Oxygen	16
Carbon	12
Nitrogen	14
Sulfur	32
Chlorine	35.5

TABLE 1. CANNIZZARO METHOD OF COMPOUND COMPUTATION

Gas	Grams per Standard Liter	Percentage Composition by Chemical Elements		Grams per Standard Liter by Chemical Elements					
				Hydrogen	Oxygen	Carbon	Nitrogen	Sulfur	Chlorine
1. Hydrogen chloride	1.639	{Hydrogen	2.76%}	0.045					1.594
		{Chlorine	97.24}						
2. Ammonia	0.771	{Hydrogen	17.75}	0.137			0.634		
		{Nitrogen	82.25}						
3. Carbon dioxide	1.977	{Oxygen	72.73}		1.438	0.539			
		{Carbon	27.27}						
4. Carbon monoxide	1.250	{Oxygen	57.14}		0.714	9.536			
		{Carbon	42.86}						
5. Methane	0.717	{Hydrogen	25.14}	0.180		0.537			
		{Carbon	74.86}						
6. Ethylene	1.260	{Hydrogen	14.38}	0.181		1.079			
		{Carbon	85.62}						
7. Acetylene	1.173	{Hydrogen	7.75}	0.091		1.082			
		{Carbon	92.25}						
8. Oxygen	1.429	Oxygen	100.00		1.429				
9. Hydrogen	0.090	Hydrogen	100.00	0.090					
10. Nitrogen	1.251	Nitrogen	100.00				1.251		
11. Chlorine	3.214	Chlorine	100.00						3.214
12. Sulfur dioxide	2.927	{Oxygen	49.95}		1.462			1.465	
		{Sulfur	50.05}						
13. Hydrogen sulfide	1.539	{Hydrogen	5.91}	0.091				1.448	
		{Sulfur	94.09}						
14. Nitrous oxide	1.978	{Oxygen	36.35}		0.719		1.259		
		{Nitrogen	63.65}						
15. Nitric oxide	1.340	{Oxygen	53.32}		0.715		0.625		
		{Nitrogen	46.68}						
Minimum weight (approximate)				0.045	0.715	0.538	0.626	1.45	1.60

Note: Data are displayed in this table to illustrate the Cannizzaro method of arriving at the symbol and symbol weight of chemical elements; and the formula and formula weight of chemical compounds.

Then, the abbreviation is introduced by the representation:

COMMONLY USED SYMBOL WEIGHTS OF EACH ELEMENT BY THE SYMBOLS

1 gram of hydrogen by the symbol H
16 grams of oxygen by the symbol O
12 grams of carbon by the symbol C
14 grams of nitrogen by the symbol N
32 grams of sulfur by the symbol S
35.5 grams of chlorine by the symbol Cl

By setting up again the second half of the table for the 15 gases, this time for 22.2 standard liters instead of 1 standard liter, the results obtained may be observed in Table 2.

Thus, it is seen, the chemical formulas and formula weights (last column) of 15 gaseous chemical compounds have been arrived at, using the Cannizzaro method, by purely experimental and rational means, involving no theoretical considerations. Extension of the method serves to ascertain the chemical formula of all gases and vaporizable substances. For compounds which are neither gases nor vaporizable, other methods are available. Of these the most used are those of Raoult depending upon the depression of the freezing point or the elevation of the boiling point of a compound dissolved in a given solvent.

It remains to be noted that, when there is no method available for ascertaining the formula weight of a compound, the *simplest* formula, based on chemical analysis and the use of symbol weights of the contained elements, is used, e.g., ferric oxide, Fe_2O_3, ferroferric oxide, Fe_3O_4, ferrous oxide, FeO, cupric oxide (black copper oxide), CuO, cuprous oxide (red copper oxide), Cu_2O. The customary formula of water is H_2O, which is correct at temperatures above 100 °C — actually, liquid water is mainly dihydrol $(H_2O)_2$.

It should be understood from the above discussion that a chemical formula is no chance throwing together of chemical symbols, but represents the results of careful analysis, and the scrutiny and deduction of the most skillful workers in the field. On this score alone, chemical formulas demand the greatest respect in understanding and use.

Symbol weights and atomic weights are used synonymously, as are formula weights and molecular weights. Unless otherwise stated, symbol weights and formula weights are expressed in grams, and the numbers used are those taken from the accepted list of atomic weights. See **Chemical Elements**.

One formula volume of a gas is 22.242 liters. It is necessary to state that actual gases under ordinary conditions show some variation from this value, so that for accurate work the records should be consulted in each case.

Summarizing, the formula "HCl" states that "36.5 grams of hydrogen chloride gas occupies a standard volume of 22.2 liters and is composed of 1 gram of hydrogen element chemically united with 35.5 grams of chlorine element." The reason for the formulas of the simple gases, oxygen, O_2, hydrogen, H_2, nitrogen, N_2, chlorine, Cl_2, is apparent from the general method of deduction. The formula O_2 represents 22.2 liters or 32 grams of oxygen *gas*, whereas O represents 16 grams of oxygen *element* in any substance, or more precisely, 15.9994 grams.

Non-Stoichiometric Compounds. It has become customary in chemical literature to use the formula of a substance as an accepted abbreviation for the name of the substance, especially in cases of frequent repetition.

Up to this point, the discussion in this entry has related to substances that are either elements, or single compounds of elements combined in proportions that can be represented by the ratio of small whole numbers. Such compounds are called *stoichiometric compounds* or *Daltonide compounds* (after the British chemist Dalton). There exist, however, some compounds in which the ratios of the amounts of elements present are not integral. Such compounds are called *non-stoichiometric compounds* or *Berthollide compounds* (after the French chemist Berthollet), and are exemplified by some oxides of the transition elements, by many intermetallic compounds, by the copper sulfide $Cu_{1.7}S$, the copper selenide $Cu_{1.6}Se$ and the cerium hydride $CeH_{2.7}$. Some such compounds vary over a range of composition, depending upon their method of preparation.

In spite of these departures of some compounds from whole number formulas, the fact remains that the great majority of compounds with which the chemist is concerned do contain their constituent elements in integral multiples of their atomic weights. In fact, there is even a further uniformity in the behavior of many of the elements. Thus the great majority of the compounds of the alkali elements (Group 1 in the periodic table) contain equal atomic weight proportions of hydrogen or its equivalent in other elements. Thus the hydrides of this group have compositions corresponding to the formulas LiH, NaH, KH, etc.; the halogen compounds of the group have the compositions, LiF, NaF, KF, LiCl, NaCl, KCl, etc.; while their simple sulfur compounds (since in many of its compounds sulfur combines with two hydrogen equivalents as represented by the formula H_2S) have the compositions Li_2S, Na_2S, K_2S, etc. However, there also exist more complex binary sulfur compounds of these elements, which contain higher proportions of sulfur, so that they combine with sulfur in more than one atomic proportion. Thus this relative combining power, which is called valence, has more than one value for many elements, but is still useful in organizing the data of chemistry. It is discussed at length in the entry on valence, and is explained in structural terms in the entry on molecule.

Radicals. In many chemical compounds there are groups of two or more elements that frequently have the properties of or enter into chemical reaction as a unit. Of those which are of outstanding importance the following are cited:

1. Ammonium NH_4- behaves as a unit in ammonium compounds and in some of these compounds is very similar to potassium K− in potassium compounds.
2. Hydroxyl −OH which behaves as a unit in bases (e.g., sodium hydroxide, NaOH), alcohols (e.g., methyl alcohol, CH_3OH), and phenols (e.g., phenol, C_6H_5OH).

TABLE 2. DERIVATION OF FORMULAS AND FORMULA WEIGHTS OF GASES

Gas (Symbol Weight) (Symbol)	Ix 22.2 Liters						Formula of Gas	Grams of Same Gas in 22.2 Liters
	1 g. H	16 g. O	12 g. C	14 g. N	32 g. S	35.5 g. Cl		
1. Hydrogen chloride	1					1	HCl	36.5
2. Ammonia	3			1			NH_3	17
3. Carbon dioxide		2	1				CO_2	44
4. Carbon monoxide		1	1				CO	28
5. Methane	4		1				CH_4	16
6. Ethylene	4		2				C_2H_4	28
7. Acetylene	2		2				C_2H_2	26
8. Oxygen		2					O_2	32
9. Hydrogen	2						H_2	2
10. Nitrogen				2			N_2	28
11. Chlorine						2	Cl_2	71
12. Sulfur dioxide		2			1		SO_2	64
13. Hydrogen sulfide	2				1		H_2S	34
14. Nitrous oxide		1		2			N_2O	44
15. Nitric oxide		1		1			NO	30

Note: Derivation assumes data available on the percentage composition by chemical elements of each gas and the symbols and symbol weights of the elements contained.

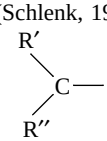
3. Anion-groups of acids, their salts and their esters: Sulfate $> SO_4$, sulfite $> SO_3$, nitrate $-NO_3$, nitrite $-NO_2$, phosphate $\rightarrow PO_4$, perchlorate $-ClO_4$, chlorate $-ClO_3$, chlorite $-ClO_2$, hypochlorite $-OCl$, carbonate $> CO_3$, formate $-CHO_2$, acetate $-C_2H_3O_2$, palmitate $-C_{16}H_{31}O_2$, stearate $-C_{18}H_{35}O_2$, oleate $-C_{18}H_{33}O_2$, oxalate $> C_2O_4$, lactate $-C_3H_5O_3$, malate $> C_4H_4O_5$, tartrate $> C_4H_4O_6$, citrate $\rightarrow C_6H_5O_7$, benzoate $-C_7H_5O_2$, cinnamate $-C_9H_7O_2$, phthalate $> C_8H_4O_4$, salicylate $-C_7H_5O_3$.
4. Alkyl- and aryl-groups of alcohols, phenols, their esters and their alcoholates and phenolates: (a) Alkyl (non-benzenoid)-methyl CH_3-, ethyl C_2H_5-, propyl C_3H_7-, butyl C_4H_8- and similar radicals of alcohols; (b) Aryl (benzenoid)-phenyl C_6H_5-, tolyl C_7H_7-, xylyl C_8H_9-, naphthyl $C_{10}H_7-$ and similar radicals of phenols.
5. Acyl-groups of organic acids: acetyl CH_3CO-, benzoyl C_6H_5CO-.
6. Miscellaneous radicals, for example, cacodyl $(CH_3)_2As-$, celebrated on account of the investigations by Bunsen (1838).

All of the above radicals are associated with a corresponding radical or element in a compound. While a radical frequently and rather generally enters into chemical reaction as a unit, it is not implied that this is always so, the stability in each case is characteristic of each radical and each reaction in which it is involved. Thus, ammonium hydroxide NH_4OH yields ammonia gas NH_3 and water H_2O at room temperature; ammonium nitrate NH_4NO_3 is decomposed, upon heating, with the accompanying disruption of both the ammonium and nitrate radicals to yield nitrous oxide N_2O gas and water H_2O.

Radicals enter widely into reactions involving electrolytic dissociation of salts, acids, bases in water solution.

Radicals exist most commonly in combination with atoms or other radicals. However, they can be produced "free," and can so exist for a finite period. Even when it is very short, the radical itself is often of great interest in elucidating reaction mechanisms. The first free radical discovered was triphenylmethyl.

Gomberg, by treating triphenylmethyl chloride in carbon dioxide, with zinc, silver, or mercury, obtained the free radical, triphenylmethyl. On dissolving the colorless solid in organic solvents a yellow solution is obtained, and the reactivity (due to unsaturation) of the yellow solution is marked towards oxygen, dissolved iodine, ether. Triphenylmethyl is present in solution in two forms, (1) monomolecular $(C_6H_5)_3C$ yellow, in equilibrium with (2) dimolecular $((C_6H_5)_3C)_2$ colorless. But tribiphenylmethyl $(C_6H_5-C_6H_4)_3C$ occurs only in the monomolecular form, purple. The action of alkali metals on ketones in some cases produces metallic ketyl (Schlenk, 1913) thus:



which is a free radical, or contains trivalent carbon as does monomolecular triphenylmethyl. Many other free radicals are known. See also **Free Radical**.

This entry has dealt with two types of chemical composition — elements and compounds. Many materials, including the great majority of those found in nature, are mixtures of compounds and often elements. Practically all biochemical materials and rocks are complex mixtures. Obviously the first step in the determination of the composition of such substances is their separation into the individual compounds, and elements if any, which they contain.

CHEMICAL ELEMENTS. A chemical element may be defined as a collection of atoms of one type which cannot be decomposed into any simpler units by any chemical transformation, but which may spontaneously change into other units by radioactive processes. A chemical element is a substance that is made up of but one kind of atom. Of the over 100 chemical elements known, only 90 are found in nature. The remaining elements have been produced in nuclear reactors and particle accelerators. Theoretical physicists do not all agree, but some believe that fission-stable nuclei should exist at atomic numbers 109, 114, and 126. Claims thus far have been made for the discovery, isolation, or creation of elements up to 110. The element with the highest atomic number officially named and entered into the formal table of atomic weight is darmstadtium (Ds) with an atomic number of 110.

The chemical element group numbering system was officially changed in the mid-1980s. The new notations are used throughout this encyclopedia. For clarification of differences between former IUPAC numbers and prior CAS versions, consult table in the entry on the periodic table.

Some of the principal characteristics of the elements are given in Table 1. All of the 110 elements described on this table also are explained in further detail under individual alphabetical entries throughout this volume. The lanthanide series elements also are described further under **Rare-Earth Elements and Metals**. The platinum group metals are further detailed under **Platinum and Platinum Group**; the refractory metals are detailed under **Niobium**. The great versatility of carbon is described under **Niobium**. In 1817, Johann Dobereiner noticed that strontium had similar chemical properties to calcium and barium, and that its molecular weight fell midway between the two. Additional work led him to discovering a similar trend for another triad of elements: chlorine, bromine, and iodine along with lithium, sodium and potassium. In 1829 he proposed the "Law of Triads" which states that, "nature contains triads of elements where the middle element has properties that are an average of the other two members of the triad when ordered by the atomic weight. It was later noticed that these patterns extended beyond that of a triad and eventually led to the "Law of Octaves" discovered by John Newlands in 1863. This discovery originated from Newlands to classifying the current 56 elements into 11 groups based on similar physical properties. He noticed that many pairs of similar elements existed with atomic weights that differed by a multiple of eight. The Law of Octaves states that any given element will exhibit analogous behavior to the eighth element following it in the 11 groups. Not much later, in 1869, did Dimitri Mendeleev publishing a table from elements with symbols and atomic weights on them, arranged in a periodicity of eight. The resulting matrix arrangement is called the Periodic Table. See also **Periodic Table of the Elements**.

The first listing of the elements is generally attributed to Lavoisier in 1789. Of the twenty elements listed, the discovery of five was the result of research conducted by Scheele of Gothenberg. With the development of nuclear physics and the application of these principles to astronomy and cosmology, in recent years the chemical elements have been viewed from new vantage points with much concentration on physical and nuclear characteristics as well as chemical properties.

Origin of the Elements

An excellent summary of progress made in the study of the origin of the elements was given by Penzias in a lecture delivered in Stockholm when he received the Nobel Prize in Physics in 1978. See reference listed.

Another outstanding account was given in the lecture by William A. Fowler (Kellogg Radiation Laboratory, California Institute of Technology) in his acceptance of the 1983 Nobel Prize in Physics (shared with Chandrasekhar). Although life on Earth depends upon the energy of sunlight (originating from nuclear fusion of hydrogen and helium in the solar interior), the sun did not produce the chemical elements found in the earth. Rather, it is theorized by some scientists that these first two elements and their stable isotopes emerged from the first few minutes of the early high-temperature, high-density stage of the expanding Universe (so-called big bang concept). Although it has been theorized that a small quantity of lithium (element 3 in the periodic table) was also produced during the big bang, it has been proposed that the remainder of the Li and all of the beryllium and boron (elements 4 and 5, respectively) were produced by the spallation of still heavier elements in the interstellar medium by the process of cosmic radiation. The fact that these latter elements are relatively rare is consistent with this concept.

Early 1990s studies of very old stars, such as HD140283, brought some surprises. This star, considered so old that it only has about 1% of the oxygen and other heavy elements of the sun, was found by one of the first observations of the Hubbel Space Telescope to contain about 1000 times more beryllium than could be attributed to cosmic radiation. See also **Beryllium**.

As pointed out by Fowler, the question remains pertaining to the origin of the heavier elements, namely, those ranging upward from carbon (6) to

TABLE 1. PRINCIPAL CHARACTERISTICS OF CHEMICAL ELEMENTS

Name	Symbol	Atomic Number	Atomic Weight	Periodic Group[a]	Valency (Oxidation state)	Specific Gravity (20 °C)	Melting Point, °C	Boiling Point, °C	Discovery (year)

[a] New Periodic Group notation.
[b] Mass number of isotope of longest known half-life (or a better known one for Bk, Cf, Po, Pm and Tc).
[c] Specific gravity, arsenic: Yellow orpiment form, 1.97; gray metallic form, 5.73.
[d] Specific gravity, boron: Crystalline, 2.34; amorphous, 2.37.
[e] Density, bromine: Gas, 7.59 g/l; liquid, 3.12 g/ml.
[f] Specific gravity, carbon: Amorphous, 1.8 to 2.1; graphite, 1.9 to 2.3; diamond, 3.15 to 3.53 (gem). Melting point, carbon: Natural, 3550 °C: graphite sublimes, 3342–3392 °C (at 12–13 GPa). Triple point, graphite-liquid-gas, 3577–3677 °C (at 10.1 MPa); graphite-diamond-liquid, 3830–3930 °C (at 12–13 GPa)
[g] Density, chlorine: 3.2 g/l. Specific gravity (−33.6 °C), 1.56.
[h] Density, fluorine: 1.696 g/l (0 °C, 1 atm). Specific gravity, 1.108 (at boiling point).
[i] Density helium: 0.1785 g/l (0 °C, 1 atm).
[j] Density, hydrogen: Gas, 0.08988 g/l; liquid (−253 °C), 70.8 g/l; solid (−262 °C), 70.6 g/l.
[k] Density, krypton: 3.7 g/l (0 °C).
[l] Specific gravity, manganese: 7.2–7.4, depending on allotropic form.
[m] Density, neon: Gas (0 °C. 1 atm), 0.8999 g/l; liquid (at boiling point), 1.207 g/cm^3.
[n] Niobium is sometimes called columbium in the U.S. and a few other countries.
[o] Density, nitrogen: 1.25 g/l. Specific gravity, liquid (−195.8 °C), 0.808; solid (−252 °C), 1.026.
[p] Density, oxygen (0 °C), 1.429 g/l. Specific gravity, liquid (−182.96 °C), 1.4.
[q] Specific gravity, phosphorus: White, 1.82; red, 2.20; black, 2.25 to 2.9. 1.14.
[r] Density, radon: Gas, 9.73 g/l; liquid (−62 °C), 4.4.
[s] Specific gravity, rubidium: Solid (20 °C), 1.532; liquid (39 °C), 1.475.
[t] Specific gravity, selenium: Gray. 4.79; vitreous, 4.28.
[u] Atomic weight of sulfur varies slightly because of naturally occurring isotopes 32, 33, 34, and 36, the total possible variation amounting to ±0.003.
[v] Specific gravity, sulfur: Rhombic, 2.07; monoclinic, 1.957.
[w] Melting point, sulfur: Rhombic, 112.8 °C; monoclinic, 119.0 °C.
[x] Specific gravity, tin: Gray, 5.75; white, 7.31.
[y] Density, xenon: Gas, 5.89 g/l. Specific gravity (liquid at −109 °C), 3.52.

Abbreviations used in table:

est	Estimated
sub	Sublimation temperature
atm	Unit of pressure
fp	Freezing point

Note: Terms such as *alpha*, *gray*, and *white* refer to specific forms of element.
Values for all rare-earth elements furnished by Rare-Earth Information Center, Energy and Mineral Resources Research Institute, Iowa State University, Ames, Iowa.

radioactive uranium (92). The origin of these elements has been attributed to nuclear processes in the interior of stars, particularly in the stars of our own Galaxy and prior to the formation of the solar system (some $4\frac{1}{2}$ billion years ago). The general process is believed to have occurred during a period of some 5 to 15 billion years prior to formation of the solar system and is related to star formation and degradation in our Galaxy during that long period. It is believed that old stars, during their giant stage of stellar evolution, were sources of the heavier elements. Possibly, greater activity occurred during outbursts (*novae*) or stellar explosions (*supernovae*). The current commonly held concept is that the planets of the solar system, including Earth, condensed under the forces of gravitation and rotation from a gaseous solar nebula in the interstellar medium, this medium containing hydrogen and helium (from the big bang) and admixed with the heavier elements synthesized in the earlier generations of galactic stars. It is interesting to note that the abundance of heavy elements in the older galactic stars is less than 1 percent of that found in the solar system. Element building in the manner described is sometimes referred to as the *nucleosynthesis* in stars. It is assumed, of course, that a similar process has occurred and continues to occur in galaxies other than our own, such as the Andromeda Nebula, and that the process is thus universal.

The principal targets of nuclear astrophysics are: (1) an understanding of the energy generation in the sun and other stars at all stages of stellar evolution, and (2) a comprehension of the nuclear processes which caused the relative abundances of the elements and their isotopes in nature. Suess and Urey, in 1956, first systematized the terrestrial, meteoritic, solar, and stellar data that are related to the origins and abundances of the elements. During the interim, these data have been periodically updated by Cameron; major work in the experimental measurement of atomic transition rates required to determine solar and stellar abundances has been contributed by Whaling. Check references at the end of this article. See also Fig. 1(**a**) and (**b**).

The remainder of the Fowler article is of great interest, but in detail that is beyond the scope of this encyclopedia. Topics covered by Fowler include early research on element synthesis; stellar reaction rates from laboratory cross sections; hydrogen burning in main-sequence stars and the solar neutrino problem; synthesis of ^{13}C and ^{16}O and neutron production in helium burning; carbon, neon, oxygen, and silicon burning; astrophysical weak interaction rates; calculated abundances for $A \lesssim 60$ and comments on explosive nucleosynthesis; isotopic anomalies in meteorites and evidence for ongoing nucleosynthesis; observational evidence for nucleosynthesis in supernovae; neutron-capture processes in nucleosynthesis; and nucleocosmochronology.

In his concluding remarks, Fowler observes; "In spite of the past and current research in experimental and theoretical nuclear astrophysics, the ultimate goal of the field has not been attained. Hoyle's grand concept of element synthesis in the stars will not be truly established until we attain a deeper and more precise understanding of many nuclear processes operating in astrophysical environments. Hard work must continue on all aspects of the cycle: experiment, theory, and observation. It is not just a matter of filling in the details. There are puzzles and problems in each part of the cycle which challenge the basic ideas underlying nucleosynthesis in stars."

Fowler further concludes: "My major theme has been that all of the heavy elements from carbon to uranium have been synthesized in stars. Our bodies consist for the most part of these heavy elements. Apart from hydrogen, we are 65 percent oxygen and 18 percent carbon, with smaller percentages of nitrogen, sodium, magnesium, phosphorus, sulfur, chlorine, potassium, and traces of still heavier elements. Thus, it is possible to say that each one of us and all of us are truly and literally a little bit of stardust."

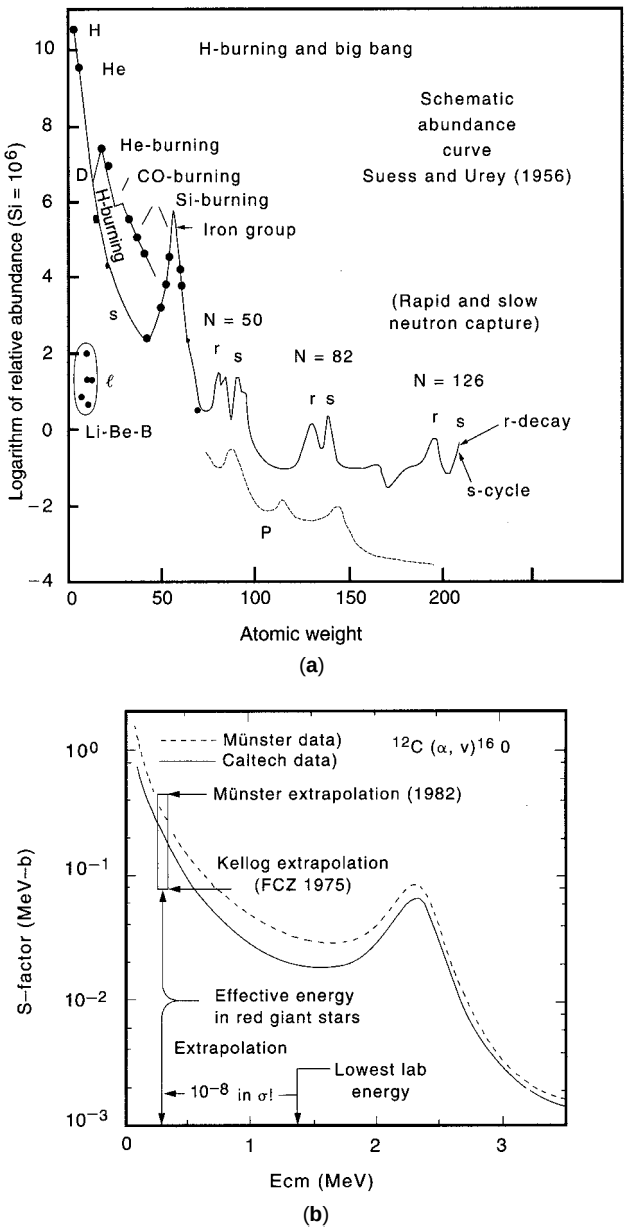

Fig. 1. (**a**) Atomic abundances relative to $Si = 10^6$ versus atomic weight for the sun and similar main-sequence stars. (**b**) Cross-section factor S (in MeV-varns) versus center-of-momentum energy (in MeV) for $^{12}C(\alpha, \gamma)O$ Dashed and solid curves are theoretical extrapolations of Münster and Kellog Caltech data by Langanke and Koonin (see references). [*After paper on "The Quest for the Origin of the Elements" by William A. Fowler, presented in December 1983, when author received the Nobel Prize for Physics. Complete article in Science,* ***226***, 922–935 (November 23, 1984) and in "Les Prix Nobel en 1983," Elsevier, New York, 1984.]

Abundance of the Chemical Elements

Considering the large number of chemical elements, it is interesting to note that insofar as the earth's crust and the oceans are concerned, and given our knowledge of the cosmos to date, there is far from a uniform distribution of the elements. In fact, the distribution is exceedingly unbalanced with, for example, only nine elements making up 99.25% of the earth's crust. In terms of abundance, many of the materials considered quite common are, in fact, scarce in terms of their percentage of the total materials in the earth's crust. In order of descending occurrence in the earth's crust, all but the very scarce elements are listed in Table 2. The occurrence of these elements in seawater also is given where data are available.

The situation alters considerably in terms of cosmic abundance of the elements, although again the abundance is heavily slanted toward a comparatively few of the total number of elements. In 1952, Harold C. Urey made an estimate of the abundance of the chemical elements in the cosmos, wherein earlier values of V.M. Goldschmidt and Harrison S. Brown were used in the calculations. A base figure of 10,000 for silicon was used, the other elements being expressed in relationship to that base figure. The study indicated that hydrogen (3.5×10^8) is the most likely superabundant element in the cosmos, closely followed by helium (3.5×10^7). Other elements high on the list include oxygen (220,000), nitrogen (160,000), carbon (80,000), and neon (with a range estimated between 9,000 and 240,000). Magnesium, silicon, and iron also are relatively high.

Researchers at California Institute of Technology (Pasadena, California) have been studying the occurrence of various isotopes in the earth's

TABLE 2. ABUNDANCE OF THE CHEMICAL ELEMENTS (In Grams/Metric Ton)[a]

[a] Presented in order of diminishing terrestrial abundance.

crust as a lead to understanding the mechanics of continental crust formation. A means for determining the time of formation of new crustal segments is paramount to an understanding of how the continental crust was evolved. In this work, they have studied samarium–neodymium and rubidium–strontium isotopic systematics. In a study by Anderson (Seismological Laboratory, California Institute of Technology), more recent estimates of solar composition pose new questions. Compared with earlier findings, the study shows an enrichment of Fe and Ca relative to Mg, Al, and Si. The Fe/Si and Ca/Al atomic ratios are some 30–40% higher than chondritic values as found in chondrules (meteoric stones assumed to be of cosmic origin). Anderson suggests that the new data may require a revision in the estimates of cosmic abundance and the composition of nebula from which the planets accreted, inasmuch as the latter data previously have been based upon chondritic values. If so applied, the earth's mantle would contain about 15% (weight) more of FeO and more $CaMgSi_2O$ than once calculated.

Critical Importance of Certain Elements

The uneven distribution of the chemical elements in the earth's crust causes severe imbalances in their availability for industrial manufacturing uses. Frequently, the largest consuming nations are long distances from elemental sources, as in the case of the United States. This clearly indicates the need for the various political entities of the world to stockpile and to project their needs many years in advance. Hence, for obvious reasons, these needs are commonly reflected in foreign policies.

Nuclides, Isotopes, and Isobars

A nuclide may be defined as a species of atoms, with specified atomic number and mass number. The term *nuclide* should be used, *not* isotope. Different nuclides having the same atomic number *are* isotopes. Different nuclides having the same mass number are *isobars*.

A comprehensive listing of the nonradioactive nuclides of the chemical elements is given in Table 3. The isotopic abundance and mass number are given. In all but a few instances, the isotopes listed are stable. The elements also have a number of radioisotopes each, the number varying considerably from one element to the next. Extensive tables also listing the radioactive isotopes, giving lifetime, modes of decay, decay energy, particle energies, particle intensities, and thermal neutron capture cross section, among other factors, can be found in the literature.

An important fact pertaining to naturally occurring elements is that many of them consist of several isotopes and that these isotopes are present in nearly all cases in the same proportion by weight. These constant isotopic compositions have enabled scientists over the years to analyze materials by weight, making reference to a table of atomic weights. In fact, for many years the atomic weight of an element was regarded as its most distinguishing characteristic, even though some discrepancies were noticed in the periodic table. It was not until the work of Mosley on characteristic x-ray spectra and the development of positive-ray analysis that the nuclear charge was recognized as the fundamental chemical characteristic of an element. The use of mass spectrography, with other methods of determining

[a] Following elements in increasing mass number are all radioactive: Po, At, Rn, Fr, Ra, Ac, Th, Pa, U, Np, Pu, Am, Cm, Bk, Cf, Es, Fm, Md, No, and Element 104 and heavier.

the masses of the atoms in a given element and the proportions in which they are present, has permitted the determination of the isotopic composition of the elements.

Sulfur is one of the few exceptions to the constancy of isotopic proportions, in that there is sufficient variation, dependent upon the source of the sulfur, to cause a variation in its atomic mass by approximately ±0.01%. For normal stoichiometric calculations, however, this small variation is unimportant.

Naturally occurring elements which do not display any isotopic behavior include aluminum, arsenic, beryllium, bismuth, cobalt, fluorine, gold, helium, holmium, iodine, manganese, niobium (columbium), phosphorus, praseodymium, rhodium, scandium, sodium, terbium, thulium, and yttrium. Elements that have one predominating isotope (in excess of 98%) include argon, carbon, lanthanum, lutetium, nitrogen, oxygen, tantalum, and vanadium. Elements that have several isotopes and in which no one isotope is in excess of 80% of the total include antimony, barium, bromine, chlorine, copper, dysprosium, erbium, gadolinium, gallium, germanium, hafnium, iridium, krypton, lead, magnesium, mercury, molybdenum, nickel, osmium, palladium, platinum, rhenium, rubidium, ruthenium, selenium, silver, tellurium, tin, titanium, tungsten, xenon, ytterbium, zinc, and zirconium. Tin leads with a total of ten isotopes; xenon has nine isotopes; cadmium and tellurium each have eight isotopes.

Radioactive Elements

There are (1) naturally occurring radioactive and (2) artificially produced radioactive elements. There are three series of naturally occurring radioactive elements:

The Actinium Series. This series commences with ^{235}U and ends with the stable isotope ^{207}Pb. The decay scheme is represented by:

$$^{235}U \xrightarrow{\alpha}$$

$$^{231}Th \xrightarrow{\beta} {}^{231}Pa \xrightarrow{\alpha} {}^{227}Ac \xrightarrow{\beta \text{ and } \alpha} {}^{227}Th \xrightarrow{\alpha} {}^{223}Fr \xrightarrow{\beta} {}^{223}Ra$$

$$\xrightarrow{\alpha} {}^{219}Rn \xrightarrow{\alpha} {}^{215}Po \xrightarrow{\alpha \text{ and } \beta} {}^{211}Pb \xrightarrow{\beta} {}^{215}At \xrightarrow{\alpha} {}^{211}Bi$$

$$\xrightarrow{\beta \text{ and } \alpha} {}^{211}Po \xrightarrow{\alpha} {}^{207}Tl \xrightarrow{\beta} {}^{207}Pb \text{ (stable).}$$

The Thorium Series. This series commences with ^{232}Th and ends with the stable isotope ^{208}Pb. The decay scheme is represented by:

$$^{232}Th \xrightarrow{\alpha}$$

$$^{228}Ra \xrightarrow{\beta} {}^{228}Ac \xrightarrow{\beta} {}^{228}Th \xrightarrow{\alpha} {}^{224}Ra \xrightarrow{\alpha} {}^{220}Rn \xrightarrow{\alpha}$$

$$^{216}Po \xrightarrow{\alpha} {}^{212}Pb \xrightarrow{\beta \text{ and } \alpha} {}^{216}At \xrightarrow{\alpha} {}^{212}Bi \xrightarrow{\beta \text{ and } \alpha} {}^{212}Po \xrightarrow{\alpha}$$

$$^{208}Tl \xrightarrow{\beta} {}^{208}Pb \text{ (stable).}$$

The Uranium-Radium Series. This series commences with ^{238}U and ends with the stable isotope ^{206}Pb. The decay scheme is represented by:

$$^{238}U \xrightarrow{\alpha} {}^{234}Th \xrightarrow{\beta} {}^{234}Pa \xrightarrow{\beta} {}^{234}U \xrightarrow{\alpha} {}^{230}Th \xrightarrow{\alpha} {}^{226}Ra$$

$$\xrightarrow{\alpha} {}^{222}Ra \xrightarrow{\alpha} {}^{218}Po \xrightarrow{\alpha \text{ and } \beta} {}^{214}Pb \xrightarrow{\beta} {}^{218}At \xrightarrow{\alpha} {}^{214}Bi$$

$$\xrightarrow{\beta \text{ and } \alpha} {}^{214}Po \xrightarrow{\alpha} {}^{210}Tl \xrightarrow{\beta} {}^{210}Pb \xrightarrow{\beta} {}^{210}Bi \xrightarrow{\beta \text{ and } \alpha}$$

$$^{210}Po \xrightarrow{\alpha} {}^{206}Tl \xrightarrow{\beta} {}^{206}Pb \text{ (stable).}$$

In the foregoing series, the type of radiation given off during the decay process is indicated above the arrows.

The production of artificially produced radioactive elements dates back to the early work of Rutherford in 1919 when it was found that alpha particles reacted with nitrogen atoms to yield protons and oxygen atoms. Curie and Joliot found (1933) that when boron, magnesium, or aluminum were bombarded with alpha particles from polonium, the elements would emit neutrons, protons, and positrons. They also found that upon cessation of bombardment the emission of protons and neutrons stopped, but that the emission of positrons continued. The targets remained radioactive. They also found that the radiation emitted dropped off exponentially as would be expected from a naturally occurring radioactive element. Further investigation indicated that nuclear reactions lead to the formation of radioactive isotopes. This and subsequent work by several investigators led to the formulation of another series of radioactive elements, namely, the Neptunium Series, which commences with ^{245}Cm (curium) and ends with the stable isotope 209Bi. The decay scheme is represented by:

$$^{245}Cm \xrightarrow{\alpha} {}^{241}Pu \xrightarrow{\beta} {}^{241}Am \xrightarrow{\alpha} {}^{237}Np \xrightarrow{\alpha} {}^{233}Pa \xrightarrow{\beta}$$

$$^{233}U \xrightarrow{\alpha} {}^{229}Th \xrightarrow{\alpha} {}^{225}Ra \xrightarrow{\beta} {}^{225}Ac \xrightarrow{\alpha} {}^{221}Fr \xrightarrow{\alpha}$$

$$^{217}At \xrightarrow{\alpha} {}^{213}Bi \xrightarrow{\beta \text{ and } \alpha} {}^{213}Po \xrightarrow{\alpha} {}^{209}Tl \xrightarrow{\beta} {}^{209}Pb \xrightarrow{\beta}$$

$$^{209}Bi \text{ (stable).}$$

A *radioactive element* is an element that disintegrates spontaneously with the emission of various rays and particles. Most commonly, the term denotes radioactive elements such as radium, radon (emanation), thorium, promethium, uranium, which occupy a definite place in the periodic table because of their atomic number. The term *radioactive element* is also applied to the various other nuclear species, (which are produced by the disintegration of radium, uranium, etc.) including the members of the uranium, actinium, thorium, and neptunium families of radioactive elements, which differ markedly in their stability, and are isotopes of elements from thallium (atomic number 81) to uranium (atomic number 92), as well as the partly artificial actinide group, which extends from actinium (atomic number 89) to lawrencium (atomic number 103), and includes the following transuranic elements: neptunium (atomic number 93), plutonium (atomic number 94), americium (atomic number 95), curium (atomic number 96), berkelium (atomic number 97), californium (atomic number 98), einsteinium (atomic number 99), fermium (atomic number 100), mendelevium (atomic number 101), nobelium (atomic number 102). The radioactive nuclides produced from nonradioactive ones are discussed under **Radioactivity**.

A radioactive element may be designated as being in a *collateral series*. In addition to the three main natural and one artificial disintegration series of radioactive elements, each has been found to have at least one parallel or collateral series. The main series and the collateral series have different parents, but become identical in the course of disintegration, when they have a member in common.

Superheavy and Transactinide Elements

Those elements with an atomic number above 103 are sometimes referred to as the *transactinide elements*; and those with atomic (proton) numbers $Z \geq 110$ are sometimes called *superheavy elements* (SHEs). Considerable research has been concentrated on synthesizing elements heavier than 103. The last of the elements to be synthesized with positive proof of identity, timing of research, and place and persons associated with discovery — and thus relatively little controversy pertaining to the naming of the element — was lawrencium (103), discovered by Ghiorso, Sikkeland, Laesh, and Latimer in March 1961 at Berkeley. Research in this direction had been underway in the early 1960s at the Joint Nuclear Research Institute at Dubna (Russia). The half-lives of the Lr isotopes range from 8 to 35 seconds, enabling researchers to use solvent extraction techniques for determining the chemical characteristics and atomic number of the element. However, with the possible exception of a predicted *island of stability*, as one goes up the scale of heavier elements, the half-lives appear to become progressively shorter, making chemical separation, needed for identifying the atomic number of any laboratory-produced superheavy nucleus, increasingly difficult. Much research has been directed toward improving these techniques and, as of the late 1980s, methodology is available to cope with nuclei having a half-life of 1 second or greater. Separation techniques include the ion-exchange behavior of the bromide complexes of the elements; and the ease with which the elements coprecipitate with cupric sulfide (Seaborg-Loveland-Morrissey, 1979).

Applying modern theories of nuclear structure, scientists working in the late 1960s and early 1970s made calculations that showed for superheavy elements in the vicinity of $Z = 114$ (proton number) and $N = 184$ (neutron number), ground states of nuclei were stabilized against fission. As pointed out in the aforementioned reference, "This stabilization was due to the complete filling of major proton and neutron shells in this region and is analogous to the stabilization of chemical elements, such as the noble gases by the filling of their electronic shells." Some of the calculations indicated that the half-lives of some of these superheavy nuclei might be on the order of the age of the universe. This observation, of course, was stimulating to further research. Calculations indicated that there should be an island of relative stability, which would extend above the *Z* and *N* figures previously given. The calculations also showed that between the presently known elements and these stable superheavy elements, there would be an intervening region of instability.

Although beyond the scope of this volume, in the early 1930s a new mechanism for the interaction of heavy ions was discovered. The method, known as *deep inelastic scattering*, involves a massive transfer of energy and nucleons between the projectile and the target.

A team of researchers from the Oak Ridge National Laboratory, the University of California (Davis, California), and Florida State University reported an x-ray spectrum in June 1976 that appeared to confirm the existence of superheavy elements with atomic numbers near 126. For a short period, this finding created much interest in the scientific community — mainly because the atomic numbers reported were much greater than might be expected at that stage of research, and, possibly of even greater interest, because the findings were based upon the elements being part of monazite crystals believed to be about 1 billion years old, thus giving rise to the previous mention of their life on the order of the age of the universe. Further confirmatory proof was lacking, capped by the finding of a researcher at Florida State University who showed that a gamma ray with the same energy as the x-ray peak for "element 126" is emitted when an excited praseodymium nucleus relaxes after being created from cerium during bombardment by protons. It is noteworthy that cerium is a major constituent of monazite.

Element 104. Rutherfordium [CAS: 53850-36-5], Researchers at Dubna (Russia), in 1964, bombarded plutonium with accelerated 113–115 MeV neon ions. During this process, an isotope that decayed by spontaneous fission was observed. It was reported that the isotope had a half-title of 0.3 ± 0.1 second and it was reasoned that the isotope was $^{260}104$, resulting from $^{242}_{94}\mathrm{Pu} + {}^{22}_{10}\mathrm{Ne} \rightarrow {}^{260}104 + 4n$. Although subsequent work toward chemically separating the new element from all others has not been conclusive, considerable evidence for evaluation has been obtained. Estimates of the half-life of the element have been reduced from the prior 0.3 second to 0.15 second. Ghiorso, Nurmia, Harris, K. Eskola, and P. Eskola (University of California, Berkeley) reported in 1969 the positive identification of two and possibly three isotopes of the element. The Berkeley discovery resulted from bombarding a target of ^{249}Cf with ^{12}C nuclei of 71 MeV, and ^{13}C nuclei of 69 MeV. The first combination resulted in the instant emission of four neutrons to produce $^{257}104$. The isotope was reported to have a half-life of 4–5 seconds. Decay was by emission of an alpha particle into ^{253}No with a half-life of 105 seconds. In further research, several thousand atoms of $^{257}104$ and $^{259}104$ were produced. Thus far, the Dubna workers have proposed the name *kurchatovium* (Ku): and the Berkeley group has suggested *rutherfordium* (Rf). The name *rutherfordium* (Rf) has been adopted for element 104 in honor of Ernest R. Rutherford.

Element 105. Dubnium [CAS: 53850-35-4], In 1967, workers at Dubna (Russia) reported producing a few atoms of element $^{260}105$ and $^{261}105$, as the result of bombarding ^{243}Am with ^{22}Ne. Appropriate confirmations of identification, however, were lacking, the evidence being based upon time-coincidence measurements of alpha energies. In 1970, it was reported that the Dubna researchers had investigated all the types of decay of the new element and had determined its chemical properties. As of that time, the Dubna group had not proposed a name for element 105. Ghiorso, Nurmia, Harris, K. Eskola, and P. Eskola (University of California, Berkeley) reported a positive identification of element 105. This resulted from bombarding a target of ^{249}Cf with 84-MeV nitrogen nuclei. Upon absorption of ^{15}N nuclei by a ^{249}Cf nucleus, four neutrons are emitted, forming element $^{260}105$, with a half-life of 1.6 seconds.

In October 1971, Ghiorso and co-workers at Berkeley, using the heavy ion linear accelerator, announced production of element $^{261}105$ by bombarding ^{250}Cf with ^{15}N and by bombarding ^{249}Bk with ^{16}O. The isotope emits 8.93-MeV alpha particles, decaying to ^{257}Lr with a half-life of about 1.8 second. Element $^{262}105$ was produced by bombarding ^{249}Bk with ^{18}O. This isotope emits 8.45-MeV alpha particles and decays to ^{258}Lr, with a half-life of about 40 seconds. Element 105 has been name Dubnium (Db) after the location of the Joint Institute for Nuclear Research where the element was created.

Element 106. Seaborgium [CAS: 54038-81-2], In late 1974, two groups announced the synthesis of the 14th transurium element, namely, element number 106 (ekatungsten). The Russian group at Dubna bombarded a target of lead atoms with ions of various weights. Argon ions were used to form a short-lived isotope of fermium which decayed by spontaneous fission. After this trial, the Soviet group used ions of titanium to produce a similarly short-lived isotope of element 104. Then, the Soviet scientists finally used ions of chromium to produce what they believe to be element 106. This presumed element is described as having 151 or 152 neutrons, and decays by spontaneous fission with a half-life of about 4 to 10 milliseconds. The Russian scientists claim that the chromium and lead will combine to form element 106.

An American group at the University of California's Lawrence Berkeley Laboratory, using the modified super-HILAC accelerator (heavy ion linear accelerator) to bombard a target of californium-249 with ions of oxygen-18, caused the oxygen ions to combine with molecules in the target, releasing four neutrons per collision and producing eka-tungsten-263. It is reported that this isotope of element 106 has a half-life of 0.9 second. Contrary to earlier predictions, it does not decay by spontaneous fission, but emits an alpha particle with an energy of 9.06 MeV to become an isotope of element 104. The previously observed daughter isotope emits an alpha particle with an energy of 8.8 MeV, becoming nobelium-255. The latter, in turn, emits an alpha particle with an energy of 8.11 MeV. The American scientists believe that observation of this complete sequence of transmutations is conclusive proof of the formation of eka-tungsten. The American team first observed element 106 in 1970, but lead impurities in the target presented difficulties in providing conclusive evidence of the existence of the new element. The HILAC accelerator was shut down shortly after the experiment and two years were required for the improvements that resulted in the super-HILAC. Then other experiments were given a higher priority. Thus there was an approximately four-year delay in the American experiments. The isotope of element 106 synthesized at Berkeley contains 157 neutrons.

Element 106 has been named Seaborgium (Sb) in honor of the Glenn T. Seaborg, the father of nuclear chemistry and discoverer of plutonium.

Element 107. Bohrium [CAS: 54037-14-8] is a chemical element in the periodic table that has the symbol Bh and atomic number 107. It is a synthetic element whose most stable isotope, Bh-262, has a half-life of 102 ms. It was synthesized in 1976 by a Soviet team led by Y. Oganessian at the Joint Institute for Nuclear Research at Dubna, who produced isotope 261 Bh with a half-life of 1–2 ms (later data give a half life of around 10 ms). They did this by bombarding bismuth-204 with heavy nuclei of chromium-54. In 1981 a German research team led by P. Armbruster and G. Münzenberg at the Gesellschaft für Schwerionenforschung (Institute for Heavy Ion Research) at Darmstadt were also able to confirm the Soviet team's results and produce bohrium, this time the longer-lived Bh-262. The Germans suggested the name nielsbohrium to honor the Danish physicist Niels Bohr. The Soviets had suggested this name be given to element 105 (dubnium). There was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted unnilseptium (symbol Uns) as a temporary name for this element. In 1994 a committee of IUPAC recommended that element 107 be named bohrium. While this conforms to the names of other elements honoring individuals, where only the surname is taken, it was opposed by many who were concerned that it could be confused with boron. Despite this, the name bohrium for element 107 was recognized internationally in 1997.

Element 108. Hassium [CAS: 54037-57-9] is a chemical element in the periodic table that has the symbol Hs and atomic number 108. It is a synthetic element whose most stable isotope is Hs-265, with a half-life of 2 ms. It was first synthesized in 1984 by a German research team led by Peter Armbruster and Gottfried Münzenberg at the Institute for Heavy Ion Research at Darmstadt. The name hassium was proposed by them, derived from the Latin name for the German state of Hessen where the institute is located. There was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted

unniloctium (symbol Uno) as a temporary name for this element. In 1994 a committee of IUPAC recommended that element 108 be named hahnium. The name hassium was adopted internationally, however, in 1997.

Element 109. Meitnerium [CAS: 54038-01-6] is a chemical element in the periodic table that has the symbol Mt and atomic number 109. It is a synthetic element whose most stable isotope is Mt-266 with a half-life of 3.4 ms. Meitnerium was first synthesized on August 29,1982 by a German research team led by Peter Armbruster and Gottfried Münzenberg at the Institute for Heavy Ion Research at Darmstadt. The team did this by bombing a target of bismuth-209 with accelerated nuclei of iron-58. The creation of this element demonstrated that nuclear fusion techniques could be used to make new, heavy nuclei. The name meitnerium was suggested in honor of the Austrian-Swedish physicist and mathematician Lise Meitner, but there was an element naming controversy as to what the elements from 101 to 109 were to be called; thus IUPAC adopted unnilennium (symbol Une) as a temporary, systematic element name. However in 1997 they resolved the dispute and adopted the current name.

Element 110. Darmstadtium [CAS: 54083-77-1] (formerly Ununnilium) is a chemical element in the periodic table that has the symbol Ds and atomic number 110. It has an atomic weight of 271 making it one of the super-heavy atoms. It is a synthetic element and decays in thousandths of a second. Due to its presence in Group 10 it is believed to be likely to be metallic and solid. It was first created on November 9,1994 at the Gesellschaft für Schwerionenforschung (GSI) in Darmstadt, Germany. It has never been seen and only a few atoms of it have been created by the nuclear fusion of isotopes of lead and nickel in a heavy ion accelerator (nickel atoms are the ones accelerated and bombarded into the lead). Scientists are not always serious, so some suggested the name *policium* for the new element, because 110 is the telephone number of the German police. The element was named after the places of its discovery, Darmstadt (actually, the GSI is located in Wixhausen, a small suburb north of Darmstadt). The new name was given to it by the IUPAC in August 2003.

Allotropes

Some of the elements exist in two or more modifications distinct in physical properties, and usually in some chemical properties. Allotropy in solid elements is attributed to differences in the bonding of the atoms in the solid. Various types of allotropy are known. In *enantiomorphic allotropy*, the transition from one form to another is reversible and takes place at a definite temperature, above or below which only one form is stable, e.g., the alpha and beta forms of sulfur. In *dynamic allotropy*, the transition from one form to another is reversible, but with no definite transition temperature. The proportions of the allotropes depend upon the temperature. In *monotropic allotropy*, the transition is irreversible. One allotrope is metastable at all temperatures, e.g., explosive antimony.

Examples of allotropes include:

Arsenic with four forms, metallic, yellow, gray, and brown.
Boron with two forms, crystalline and amorphous.
Carbon with five forms, amorphous, diamond, graphite, buckmeisterfullerenes, and nanotubes.
Phosphorus with four forms, two white forms, a violet, and a black form. Red phosphorus is a mixture of the white and violet forms.
Selenium with four forms, amorphous, two crystalline monoclinic forms (red), and the stable, crystalline gray metallic form.
Sulfur with two forms, alpha-rhombic sulfur with a density of 2.07 and a mp of 112.8 °C, and beta-monoclinic sulfur with a density of 1.96 and a mp of 119 °C. The beta form changes to the alpha form below 96 °C.

In the case of some of the less common elements, impure forms have been mistaken in the past as allotropic forms. A number of elements that once were considered to exist in both crystalline and amorphous forms have been found to exist in only one form when perfectly pure.

Gaseous Elements

Several gaseous elements (at standard conditions of temperature and pressure) form molecules of two atoms each. These are known as *diatomic gases*. Included in this category are hydrogen, H_2, nitrogen, N_2, oxygen, O_2, and chlorine, Cl_2. The inert gases, helium, neon, argon, krypton, and xenon, are *monatomic gases* and their symbols do not carry a subscript.

Atomic Structure of the Elements

The internal structure of an atom consists of electrons moving within a region having a diameter slightly greater than 10^{-8} cm and of protons and neutrons that are confined to a nucleus at the center of the electron distribution in a region having a diameter of about 10^{-12} cm. The electrons of a neutral atom are sufficient in number so that their total negative charge is equal to the positive charge on the nucleus. For example, atoms of the element hydrogen have in their neutral state a single electron moving about a nucleus, which has a positive charge equal to the negative charge of an electron. Helium, which has two electrons moving about its nucleus, has a positive charge on its nucleus equal to twice one electronic charge and lithium, which has three electrons moving about its nucleus, has a positive charge on its nucleus of three electronic charges. One basis for the classification of atoms is by those numbers which correspond to the number by which the charge on the hydrogen nucleus must be multiplied to equal the nuclear charge of the atom in question. These numbers, ranging from one, for hydrogen, to 110, for darmstadtium, are called atomic numbers.

The atomic number may be defined as the number of protons in an atomic nucleus, or the positive charge of the nucleus, expressed in terms of the electronic charge. Atomic number usually is denoted by the symbol Z. In the symbolic designation of individual nuclides, the atomic number sometimes is written as a subscript to the left of the chemical symbol of the atomic species, such as ${}_{8}^{16}\mathrm{O}$ for the oxygen isotope of mass number 16. This usage is redundant, in that the chemical symbol per se specifies the atomic number of the nuclide.

Besides nuclear charge, atoms also differ in their masses. The mass is determined by the number of protons Z and the number of neutrons N in the atomic nucleus. The total number of nuclear particles, $Z + N$, in an atomic species is known as its mass number A.

The nuclear model for an atom is of relatively recent origin for, at the beginning of the twentieth century, J.J. Thomson's "plum-pudding" model of an atom was the more generally accepted version. In this model Thomson supposed that the positive charge forms a plasma that is distributed throughout the atomic volume and that the electrons are mixed into this plasma with a relatively uniform distribution. E. Rutherford proposed the nuclear model on the basis of experimental work by H. Geiger and E. Marsden in which they observed that a small number of alpha particles from a naturally occurring radioactive source are scattered through angles greater than 90° by thin foils of gold and silver. Although some small-angle scattering is predicted by the Thomson model, such large-angle scattering is not at all expected. Large-angle scattering is, however, completely consistent with the idea that the alpha particles interact with point positively charged objects of large mass at the center of each gold and silver atom.

Subsequently (1913), N. Bohr found that he could use the Rutherford nuclear model to explain in almost complete detail the observed spectrum of hydrogen (see **Atomic Spectra**). Bohr proposed that, in a neutral hydrogen atom, a single electron revolves in a stationary orbit around a point nucleus that has a charge $+e$. This electron is held in its orbit by the electrostatic force between the positive charge on the nucleus and its own negative charge. The stationary-orbit assumption was classically unsatisfactory but necessary to account for the behavior of the electron. If the laws of classical electrodynamics, according to which accelerated charges must be sources of electromagnetic radiation, were strictly obeyed, the electron would gradually lose energy; hence it would revolve in orbits of smaller and smaller radii and eventually fall into the nucleus. Furthermore, Bohr postulated that the magnitude of the orbital angular momentum of each stationary orbit is $L = nh/2\pi = n\hbar$, where n is an integer, h is Planck's constant, and $\hbar$ is simply an abbreviated form for $h/2\pi$.

The angular momentum of an electron moving in an orbit of the type described by Bohr is an axial vector $\mathbf{L} = \mathbf{r} \times \mathbf{p}$, formed from the radial distance $\mathbf{r}$ between electron and nucleus and the linear momentum $\mathbf{p}$ of the electron relative to a fixed nucleus. Figure 2 shows the customary method used to illustrate the axial vector $\mathbf{L}$ in terms of the orbital motion of any object, of which the electron of the Bohr atom is only one example. Although Bohr's planetary model needed only circular orbits to explain the spectral lines observed in the spectrum of a hydrogen atom, subsequent development of similar models for other atoms containing more than a single electron needed elliptically shaped orbits to explain the observed spectra. For such orbits $\mathbf{r}$ and $\mathbf{p}$ are usually not perpendicular to each other, so that the magnitude $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ is $rp \sin\theta$.

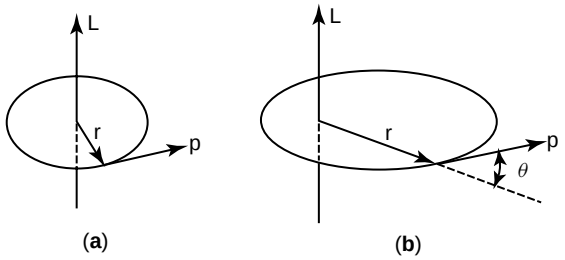

Fig. 2. Direction of angular momentum vector is perpendicular to plane formed by radial vector **r** and momentum vector **p**.

A significant change in the theoretical treatment of atomic structure occurred in 1924 when Louis de Broglie proposed that an electron and other atomic particles simultaneously possess both wave and particle characteristics and that an atomic particle, such as an electron, has a wavelength $\lambda = h/p = h/mv$. Shortly thereafter, C.J. Davisson and L.H. Germer showed experimentally the validity of this postulate. De Broglie's assumption that wave characteristics are inherent in every atomic particle was quickly followed by the development of quantum mechanics. In its most simple form, quantum mechanics introduces the physical laws associated with the wave properties of electromagnetic radiation into the physical description of a system of atomic particles. By means of quantum mechanics a much more satisfactory explanation of atomic structure can be developed.

The quantity n introduced by Bohr in his description of the hydrogen atom is what is called a quantum number. These numbers enter quite naturally from quantum-mechanical descriptions of atomic energy states, including nuclear states. In quantum-mechanical descriptions of atoms, the number n characterizes a limited number of electron states that have very nearly the same energy. A group of electrons in an atom with a common value of n are usually said to be in a single shell of the atom. In the simple two-body problem of the hydrogen atom, all states having the same value of n have the same energy, but in multielectron atoms there are interactions between individual pairs of electrons as well as between electrons and the atomic nucleus. The result is a limited spread in energy between the most-tightly bound and the least-tightly bound electron with the same value of n. Except for $n = 1$, more than one orbital angular momentum state is possible for each shell. Each such state is described by a quantum number l, which can have only whole-number values between zero and $n - 1$. The number n is usually called the principal quantum number and l the orbital angular momentum, or sometimes azimuthal, quantum number. In addition to its characteristic angular momentum, each electron spins on an axis, such that it also has a spin angular momentum, described by a quantum number s. Because all electrons are identical, s has only one value, $\frac{1}{2}$.

In the development of the concepts of atomic structure much of the experimental evidence came from optical and x-ray spectroscopy. From this work certain notations have arisen that are now an accepted part of the language. For example, the $n = 1$ shell is sometimes known as the K-shell, the $n = 2$ shell as the L-shell, the $n = 3$ shell as the M-shell, etc., with consecutively following letters of the alphabet being used to designate those shells with successively higher principal quantum numbers. A Roman numeral subscript further subdivides the shells in accordance with the n, l, and j quantum numbers of the electrons, as shown in Table 4.

TABLE 4. IDENTIFICATION OF ATOMIC SHELLS

X-ray Notation	Corresponding Quantum Numbers n	l	j	X-ray Notation	Corresponding Quantum Numbers n	l	j
K	1	0		M_{V}	3	2	
L_{I}	2	0		N_{I}	4	0	
L_{II}	2	1		N_{II}	4	1	
L_{III}	2	1		N_{III}	4	1	
M_{I}	3	0		N_{IV}	4	2	
M_{II}	3	1		N_{V}	4	2	
M_{III}	3	1		N_{VI}	4	3	
M_{IV}	3	2		N_{VII}	4	3	

A letter notation has been given to the different orbital angular momentum states by optical spectroscopists. In this notation an $l = 0$ state is called an s state (not to be confused with the s used as a quantum number for spin, and which can usually be distinguished from the way it is used), an $l = 1$ state is a p state an $l = 2$ a d state, an $l = 3$ state an f state, with consecutively higher letters above f in the alphabet designating each succeeding value of l. A number often accompanies the state designation to indicate the appropriate value of n. For example, a $3p$ level is an $n = 3$, $l = 1$ state.

Electrically neutral atoms with nuclear charge $Z > 1$ are not hydrogen-like, but have more than a single orbital electron. With more than one electron in an atom, it is necessary to determine the relationship of one electron to its neighbors. A clue to this relationship is found from the observation that the energy required to remove a second electron from an atom is greater than that required to remove the first electron and the energy so required increases with each succeeding electron that is removed. In other words, the potential energy that holds some electrons in an atom is much greater than the energy that holds other electrons in the same atom. From the results of the detailed observations, Pauli formulated a principle, the Pauli Exclusion Principle, which states that no two electrons within the same atom may have exactly the same wave function and, on this basis, that no two electrons in the same atom may have the same set of quantum numbers. Thus, if a particular configuration state in an atom is occupied by an electron, that state is forbidden to all other electrons. If each electron falls into the lowest possible energy state, the next electron to enter must remain in some higher energy state. Acceptance of this principle allows ones to classify observed spectral characteristics of the radiation emitted by atoms in such a way that within reasonable limits the number of electrons in each shell or subshell of the atom producing the radiation can be determined. The electron configurations in the known atomic species are shown in Table 5, in which the atoms are ordered in accordance with their atomic numbers Z. Generally the innermost (lower quantum number) shells are filled with all the electrons allowed. For example, neon has two $1s$ electrons, two $2s$ electrons, and six $2p$ electrons, such that its $K(n = 1)$ and L $(n = 2)$ shells are both filled. An atom with Z having a magnitude one greater than neon, which is sodium, also has both the K and L shells filled; thus, there is no space for another electron to go into either of these shells, and its additional electron must go into the M $(n = 3)$ shell. Shells with higher values of the orbital angular momentum quantum number l are sometimes partially shielded electrically from the nucleus by other electrons in such a way that their binding energies are not as great as the lower orbital angular momentum subshells associated with the next higher principal quantum number. Thus, as can be seen in Table 5, the $5s$ subshell is filled in atomic species of lower Z than any of those that have any $4f$ electrons.

The periodic table of elements can be described in terms of the similarities and differences of the angular momentum characteristics of the various atomic species. For example, similar but not identical chemical properties are observed for a number of elements that have all but one of their electrons in filled shells, with the extra electron being a single s electron. In the periodic table, lithium, sodium, potassium, rubidium, and cesium all have this characteristic and thus are placed in a single column. Other groups of atomic species that have similar electron configurations in their outermost shell are arranged in the periodic table in the same chemical grouping. See also **Periodic Table of the Elements**.

Motions of charged particles are expected to establish magnetic fields that interact with each other. As a result, coupling between spin and orbital angular momenta of a single electron or coupling between angular momenta of different electrons in a single atom is expected. The spin-orbit coupling of a single electron results in a total angular momentum state, described by a total quantum number j, such that either $j = l + \frac{1}{2}$ or $j = l - \frac{1}{2}$. Quantum-mechanical solutions show that the magnitude of the orbital angular momentum is $l^*h = [l(l + 1)]1/2h$, not l, as would be expected if the simpler assumption of the Bohr model. Similarly, the magnitude of the spin and total angular momenta are $s^* = [s(s + 1)]1/2$ and $j^* = [j(j + 1)]1/2$, respectively. Coupled spin and orbital angular momenta thus do not align themselves in a linear pattern, but in such a way that the spin and orbital angular momenta precess around the direction of the total angular momentum, as shown in Fig. 3. A similar precession around the direction of the resultant angular momentum state is found, as we shall find later, in the coupling of any two or more angular momentum states into a single common system.

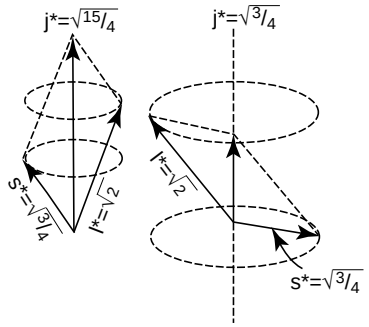

Fig. 3. Magnitudes and directions of the angular momentum vectors for an $l = 1$, $s = \frac{1}{2}$ electron in an atomic energy state.

Without some external influence, angular momentum states have no preferred orientation in space because the only interacting magnetic fields are entirely within the individual atom. An external magnetic field, however, may couple to the magnetic field of an atomic angular momentum state of the type described in the preceding paragraphs. In coupling to the total angular momentum, for example, only a limited number of orientations of j^*h are possible, these being such that their projections in the direction of the magnetic field have magnitudes m_j in which m_j, a magnetic quantum number, can have only those whole-number values for which $m_j \leq j$. Thus $2j + 1$ orientations, as illustrated in Fig. 4 for $j = \frac{3}{2}$, are possible. Note that the vector representing the total angular momentum is not parallel to the direction of the applied magnetic field. As a result, the total angular momentum vector processes around the direction of the magnetic field such that the component of the total angular momentum that is perpendicular to the direction of the magnetic field has a time-averaged value of zero and the only component that can be observed with an external detecting device is that component parallel to the direction of the external magnetic field. A magnetic field of this type splits a set of levels characterized by a quantum number j, all of which initially have the same energy, into $2j + 1$ components. The nature of this level splitting is deduced from observations of the splitting of characteristic line spectra, in which case an originally monoenergetic radiation is split by the magnetic field into several components that are usually relatively closely spaced in wave length. The observed effect is known as the Zeeman effect. See also **Zeeman Effect**.

The use of axial vectors to describe states of an atom in terms of a coupling between the angular momentum inherent in the electrons of the atom forms what is commonly called the *vector model* of the atom. The type of coupling just described forms the basis for the *j-j* coupling model. Such coupling is found between electrons that produce the optical radiation in the higher Z atomic systems. In these systems the total angular momentum j^* formed by the coupling of the spin and orbital angular momentum states of individual electrons are further coupled within any single shell of an atom to form a total angular momentum j^*, characterized by a quantum number J, which then is the angular momentum for the system of several electrons. According to customary usage, a lower case letter as a designator for a quantum number indicates that the quantum number is that of a single electron, while a capital letter indicates that the quantum number represents a state formed by several electrons.

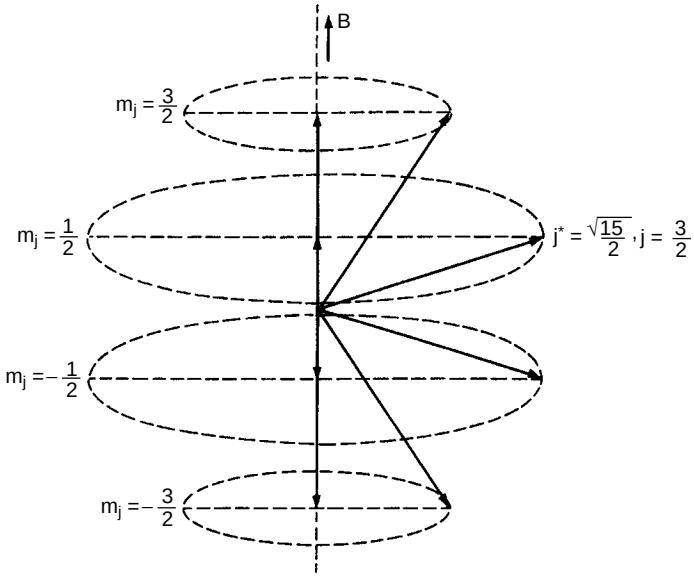

Fig. 4. Possible orientations of the total angular momentum vector **i** relative to the direction of an externally applied magnetic field B and the magnitudes of the associated magnetic quantum state vectors $\mathbf{m}_j$.

For the lower Z part of the periodic table of elements, the appropriate coupling system for angular momentum states in an atom is the *L-S*, or Russell-Saunders, coupling. In this description, the orbital angular momenta of individual electrons in any single shell of an atom are coupled to form a resultant orbital angular momentum, described by the quantum number L, and the spin angular momenta of the same individual electrons are coupled to form a resultant spin angular momentum, described by the quantum number S. Coupling of the individual orbital angular momentum states is not shown but possible coupling schemes for the spins of 2, 3, and 4 electrons are shown in Fig. 5. Note that as many possible couplings exist as there are electrons. Only one of these possible schemes will be the lowest energy state, the others being at higher energies. The resultant spin and orbital angular momentum vectors for a group of electrons in a single shell of an atom can then be used to describe the coupling that gives the total angular momentum J^* for these electrons. In Fig. 6 is

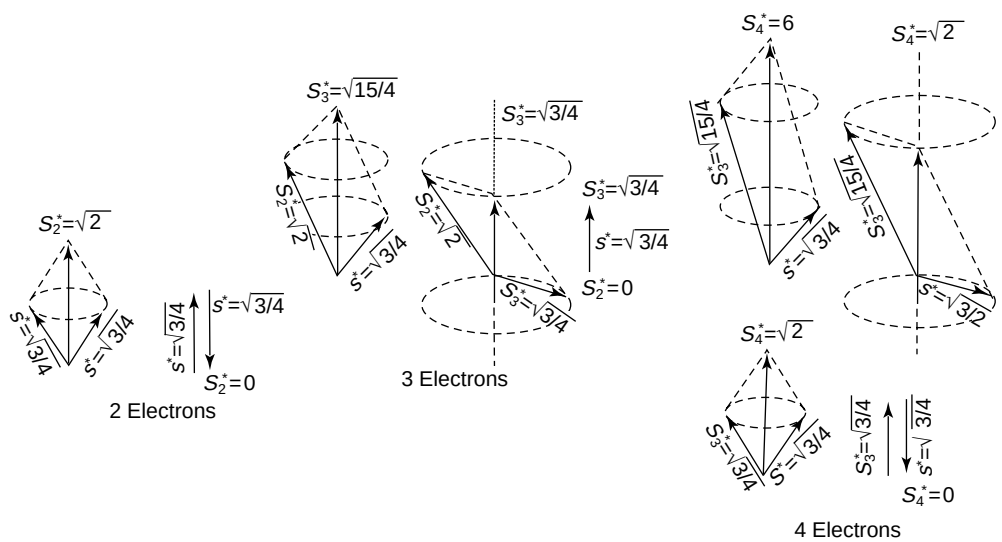

Fig. 5. Vector model coupling of the spin angular momenta of two, three, and four electrons.

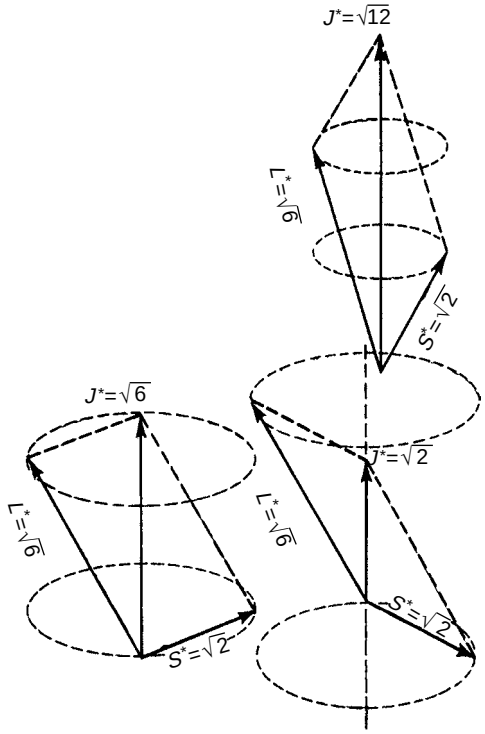

Fig. 6. Vector model coupling of spin and orbital angular momenta for which $L = 2$, $S = 1$.

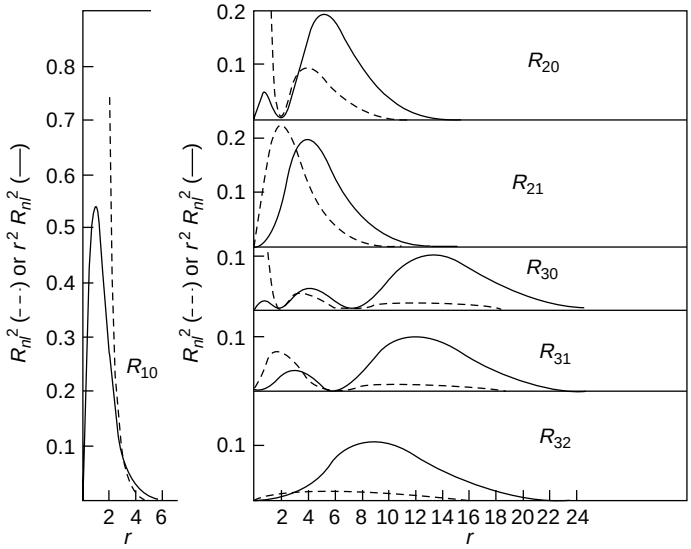

Fig. 7. Probability density distributions as a function of radial distance from the nucleus for several states of a hydrogen atom. The solid lines are proportional to the probability for finding the electron in an incremental shell of volume $4\pi r^2 dr$ at the indicated radius.

shown the coupling according to the vector model between the orbital and spin angular momenta for which $L = 2$ and $S = 1$. There are $2J + 1$ possible states. All $2J + 1$ states have the same energy unless under the influence of an external magnetic field, in which case they are broken into components, each of which is designated by a magnetic quantum number M_j. In principle this splitting is the same as for the splitting of the total angular momentum states for a single electron, as shown in Fig. 3, except for the use of capital letters M_j and J.

The Pauli Exclusion Principle states that no two electrons of any single atom may simultaneously occupy a state described by only a single set of quantum numbers. Five such numbers are needed to describe fully the quantum-mechanical conditions of an electron. For *j-j* coupling this set is generally n, l, s, j, m_j, and for *L-S* it is n, l, s, m_l, m_s. From the coupling of the angular momentum associated with the latter sets a full description of the multielectron state, described by n, L, S, J, M_j, is determined.

Part of the outgrowth of the determination that atomic particles have wave properties, and of the subsequent development of quantum mechanics, is the Heisenberg Uncertainty Principle, which states that an electron cannot be located exactly in terms of both its space and momentum coordinates, or in terms of both its time and energy coordinates. See also **Uncertainty Principle**. If the energy of a particular atomic state is precisely defined, the time at which an electron is found in that energy state cannot be so defined. Likewise, if the momentum of an electron is precisely defined, its position in space cannot be so defined. On the other hand, the probability for finding an electron in a particular location relative to the atomic nucleus can be determined. After substitution of the appropriate potential energy terms needed to describe the atomic system, these probability density distributions may be found from solutions of the Schroedinger wave equation, which is a quantum-mechanical description of the system. This distribution, which is directly related to the wave function that describes the atomic state in a quantum-mechanical manner, must be distributed through a region of space and is hence a function of all three spatial variables, which are r, θ and ϕ in the spherical coordinate system. Because only two variables are available on the plane of a page to describe these functions, they are usually described by a series of graphs, which must then be assembled in the imagination of the reader to picture the complete three-dimensional distribution. The radial part of the distribution is dependent only on the quantum numbers n and l and is usually represented by the terminology $R_{nl}{}^2$. The radial distribution for selected states of a hydrogen atom are shown in Fig. 7. The dashed lines are proportional to the probability of finding the electron in the appropriate *nl* state in an incremental volume *dv* of constant magnitude at the indicated radial distance from the atomic nucleus. The solid lines are proportional to the probability of finding the electron in an incremental shell between the radial distances r and $r + dr$, with a volume $4\pi\ r^2 dr$ at the indicated radius. Radial distances in Fig. 7 are given in units of Bohr radii, the distance from the nucleus of the $n = 1$ orbit in the Bohr planetary model of the hydrogen atom.

In the quantum-mechanical description of a hydrogen atom, the radial portion of the probability density distribution is the same in all directions from the nucleus, but only for the case $l = 0$ is the magnitude of the distribution the same in all radial directions. For all other values of l, the magnitude of the distribution is a function of the angular direction, defined by the coordinates θ and ϕ. However, as in the case of the discussion of the vector model of an atom, we cannot define an angular direction unless an axis exists to provide a reference direction. To provide this axis some force or torque external to the electron configuration must be found. The only external force strong enough to interact with the electron configuration is that provided by certain magnetic fields. The interaction with the magnetic moment of the electron configuration can then be described in terms of a magnetic quantum number m_l, which is the magnetic quantum number associated with orbital angular momentum quantum number. When $l = 1$, m_l may have any of three values, +1, 0, or −1. Three possible angular distributions are then possible for the electrons described by a quantum number $l = 1$, but the distributions for $m_l = +1$ and $m_l = -1$ are identical, thereby providing some simplification. If we define $\theta = 0$ in the direction of the applied magnetic field, the probability density distribution in the $r\theta$-plane for an electron of a hydrogen atom described by $l = 1$, $m_l = 0$ is given in the $2p$, $m = 0$ part of Fig. 8. This distribution is symmetric in ϕ; it may thus be rotated around an axis perpendicularly directed through the center of the figure (the $\theta = 0$ axis) to give the full three-dimensional distribution. For either $m_l = +1$ or $m_l = -1$ the distribution is given by that part of Fig. 8 labeled $2p$, $m = 1$. When rotated about the $\theta = 0$ axis the $m_l = 0$ distribution gives a dumbbell-like distribution and the $m_l = 1$ distributions give ring-like distributions, all of which fade away to negligible magnitude at large distances from the center of the distribution. For the $2p$, $m_l = 0$ configuration, the angular distribution in the $r\theta$-plane is given by the equation $\frac{3}{2}\cos^2\theta$, and for the $2p$, $m_l = \pm 1$ configuration by the equation $\frac{3}{4}\sin^2\theta$. Since two $m_l = 1$ configurations exist for each $l = 1$, the distributions for all three m_l configurations, when summed, give a resultant distribution that is independent of the angle θ, as well as of the angle ϕ. This condition is reached when all possible electron states in the $2p$ subshell are filled. A similar situation, a complete symmetry of the electron distribution, exists for all filled subshells. Hence an external magnetic field

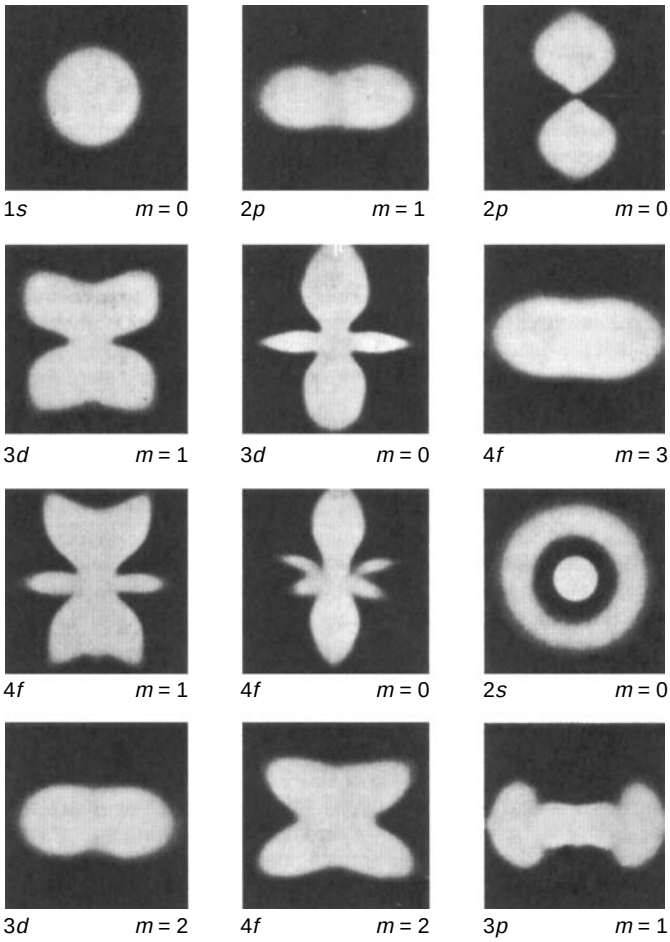

Fig. 8. Electron wave density figures representing the single electron states of the hydrogen atom.

interacts only with partially filled shells. In multielectron atoms only one shell is usually partially filled; thus interactions with external magnetic fields, such as those introduced artificially, by the atomic nucleus, or by neighboring atoms, occur only in one shell of the atom, sometimes called in chemical terminology the valence shell. For specific elements, the unfilled shell can be determined from Table 5. Probability density distributions for several other electron configurations besides $2p$ is given in Fig. 8.

The radial probability density distributions for individual electron configurations in atoms other than hydrogen are generally similar to those of Fig. 7, but, since the nuclear charge Z of these atoms is larger than for hydrogen, the electrostatic attractive force exerted by the nucleus on the innermost electron is stronger than for hydrogen and hence pulls its distribution closer to the nucleus. Outer electrons, however, are partially shielded electrostatically from the nucleus by the inner electrons and hence are influenced by a weaker force than that which would be provided by a bare nucleus. The least tightly-bound electron is held by a force that has an effective Z of about 1 but for the more tightly bound electrons the effective Z is much higher. The probability density distribution for the least tightly bound electron then extends to a distance comparable to the distribution for hydrogen, but the main part of the distribution is much closer to the nucleus. A typical distribution for all the electrons of a multielectron atom, in this case rubidium, is shown in Fig. 9.

As stated earlier in this entry, there are three p orbitals, with magnetic quantum numbers of 0, 1 and -1. The orbital for which $m = 0$ corresponds to the direction of the applied magnetic field, so that its effect is zero. This direction is conventionally taken as that of the z-axis, so that p_z, which is symmetrical about that axis, coincides with p_0. The other p orbitals, p_x and p_y, are perpendicular to p_z and to each other and correspond to standing waves built up by mixing of p_{+1} and p_{-1} which are oppositely directed waves.

An analogous situation for the d orbitals, for which $l = 2$, and hence $m_l = 2$, 1, 0, -1 and -2, gives rise to five d orbitals, designated as d_{xy}, d_{yz}, d_{x2-y2} and d_{z2}.

For further discussion of atomic orbitals see also **Orbitals**.

It follows from the earlier discussion that each orbital may be occupied, in accordance with the Pauli Exclusion Principle, by two electrons of opposed spin.

See also **Pauli Exclusion Principle**.

Atomic Radius

The radius of an atom may be defined as the distance of closest approach to another atom; it is the distance at which the mutual repulsion of the electron clouds and the mutual attraction of the nuclear charge of each for the electrons of the other are in equilibrium under specified circumstances. If the two atoms are the same, the radius of each is one half the internuclear distance; if they are unlike, the internuclear distance is the sum of the individual radii. Atomic radii fall roughly into four categories, which, however, merge into one another. These are Van der Waals and ionic radii, which are radii of equilibrium approach for mutually nonbonded atoms (neutral and charged, respectively), and covalent and metallic radii, which are for mutually bonded atoms (where the bonding electrons are, respectively, largely localized between the bonded atoms, or highly delocalized). Radii of all types vary in essentially the same manner from one part of the periodic table to another. In general, the radii decrease from the beginning to the end of any period, the rate of decrease being less the higher the number of the period. There are discontinuities in the decrease at points at which the quantum levels become half or completely filled. For example, Mn^{2+} ($r = 0.83$ Å) is larger than either Cr^{2+} (0.80 Å) or Fe^{2+} (0.80 Å), and Zn^{2+} (0.75 Å) is larger than Cu^{2+} (0.72 Å). (In this description, angstroms, Å, are used for convenience of notation. 1 angstrom = 10^{-10} meter.) Again, in general, the radii increase going down any column in the periodic table except in the region of hafnium. This last exception is caused by the lanthanide contraction occurring for the series of 14 elements between lanthanum and hafnium, which results in a far greater decrease between these two elements (average metallic radii: La 1.87 Å, Hf 1.58 Å) than between yttrium and zirconium (Y 1.80 Å, Zr 1.60 Å), where no such series intervenes. Because of the slower rate of decrease of the radius in the sixth period as compared to the fifth, however, the radii in the sixth period soon become larger again than those in the fifth (cf. Nb 1.429 Å, Ta 1.43 Å; Mo 1.36 Å, W 1.37 Å).

Van der Waals Radius. This is the radius of closest approach of one atom to another with which it does not form a chemical bond. It represents the distance at which the mutual repulsion of the nonbonding electrons of each exactly balances the attraction of the nucleus of each for the electrons of the other.

Ionic Radius. This is the radius of closest approach of a charged atom or group (i.e., an ion) to another atom or group with which it does not form a covalent bond. It represents the distance at which the

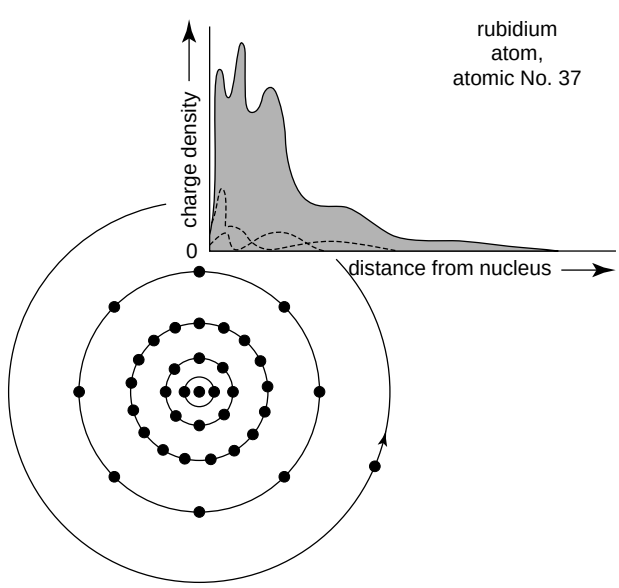

Fig. 9. Radial probability density distribution, derived from quantum-mechanical predictions, for rubidium, along with Bohr planetary model for the same atom.

mutual repulsion of the nonbonding electrons of each exactly balances the mutual attraction of oppositely charged ions, or the attraction of a positive ion for the electrons of a neutral atom or group or the attraction of a negative ion for the nucleus or nuclei of a neutral atom or group. Ionic radii for the cations of the least electronegative metals and of the most electronegative nonmetals are clearly defined, but for the elements of intermediate electronegativity (including the transition elements) they are much more doubtful because of the varying degrees of covalency in the compounds of these elements. Published ionic radii for these latter elements can therefore not be considered to be accurate measures of the true sizes of the ions, but are useful for comparison of relative sizes. In particular, there are certainly no simple cations of charge greater than 4+, and the simple tetrapositive cations are limited to Th^{4+}, probably the other tetrapositive actinide cations, and possibly Ce^{4+}. "Ionic radii" cited for such "cations" as Si^{4+}, P^{5+}, S^{6+}, Cl^{7+}, etc., are fictions arrived at by subtracting from an observed interatomic distance an arbitrary anionic radius for the second atom or else are extrapolated or theoretically calculated radii. However, inasmuch as all compounds of such elements have a high degree of covalency, such radii have no real meaning in normal compounds. Simple anions of absolute charge greater than 3 undoubtedly do not exist and the existence of monatomic trinegative ions is open to question. However, in their binary compounds with the lanthanide elements, phosphorus, arsenic, antimony and possibly nitrogen and bismuth apparently have radii very close to their Van der Waals radii and may therefore be considered essentially ionic. (See Table 6.)

The monatomic ionic radii of a given element become smaller as the oxidation state increases, provided this implies actual removal of electrons. For example, the radius of Fe^{2+} is 0.80 Å, whereas that of Fe^{3+} is 0.67 Å; $Cu^{+} = 0.96$, $Cu^{2+} = 0.72$.

The ionic radii discussed above are properly "crystal radii," i.e., the radii exhibited by the ions in ionic crystals. Although these radii are probably reasonable representations of the radii of contact of the ions in solution with the nearest atoms of solvate molecules, especially for ions of low charge density, nevertheless, most ions in solution have far larger effective radii because they carry with them a sheath of solvent molecules, the tenacity and thickness of which is a function of the charge density and electronic structure of the ion. In consequence, ions of small crystal radius (e.g., Li^+) may act larger (e.g., have lower mobility) in solution than ions of large crystal radius (e.g., Cs^+).

The effective radius of an ion changes with coordination number. An ion of coordination number 4 (tetrahedral) has a radius 0.93–0.95 times as large as the same ion with coordination number 6, while an ion of coordination number 8 is about 1.03 times as large as the same ion with coordination number 6.

Effective spherical crystal radii for some polyatomic ions are given in Table 7.

Metallic Radius. Metals may be considered to be composed of cations bonded together by a cement of mobile electrons which are located in the conduction bands. Since the number of available energy levels in the conduction bands is a function of the number of available orbitals of the atoms making up the metal, and since the electron population of the nonbonding orbitals of the atoms and of the conduction band is a function of the number of valence electrons of the metal, the number and distance of nearest neighbors and the strength of the metal-metal bond varies in a fairly regular way across the periodic table. In particular, bond lengths are

*1 angstrom = 10^{-10} meter.

shortest and bond strengths are greatest in the vicinity of cobalt, rhodium and iridium, where the number of valence electrons and the number of available orbitals (nine) exactly match. Below this number there are too few electrons and above, too many, for maximum sharing and use of the bonding orbitals. The interatomic distances and coordination numbers of the elements in their metallic states are given in Table 8.

Covalent Radius. This is the radius of closest approach for atoms bonded together by electrons that are localized in the region between the atoms. It represents the distance at which the attraction of each nucleus for the bonding electrons is in equilibrium with the mutual repulsion of the two nuclei and the repulsion of the inner electrons of each atom for the inner electrons of the other.

The length of the covalent radius is a function of several factors, among which are (1) bond order (multiplicity), (2) electronegativity, (3) hybridization, (4) orbital overlap, (5) steric factors, and (6) special electronic effects.

1. The effect of bond order is exemplified by the familiar shortening of the carbon-carbon bond in ethane (1.543 Å), graphite (1.4210 Å), benzene (1.397 Å), ethylene (1.353 Å), and acetylene (1.207 Å) as the bond order goes from 1 to $1\frac{1}{3}$ to $1\frac{1}{2}$ to 2 to 3. Bond orders affect the covalent radii of other elements similarly. The determination of the standard single bond radius is not always a simple matter. In those cases where two like atoms are joined by an unquestionable single bond (as the carbon atoms in ethane) the standard single bond radius is one-half the internuclear distance. Similarly the single bond radii for nitrogen, oxygen, and fluorine are half the interatomic distances in N_2H_4, H_2O_2 and F_2. On the other hand, acceptance of half the interatomic distances in P_4, H_2S_2 and Cl_2 for the corresponding single bond radii is open to question, since in these and similar cases the possibility exists of multiple bond formation by overlap of the electron-filled p-orbitals of each atom with the empty d-orbitals of the other. This will result in an increase in strength and a decrease in length for these bonds compared with what they would have if they were exactly single bonds. In support of this idea, it can be seen from Table 9 that, although the homoatomic bond energy for silicon (where no electrons are available for multiple bonding) is less than that for carbon, the bond energies for phosphorus, sulfur, and chlorine are significantly greater than for nitrogen, oxygen, and fluorine, respectively. Representative bond strength s are given in Table 10. In consequence of this effect, the single bond radii for such elements are better derived from the alkyl derivatives (with an electronegativity correction) in which only single bonding is possible. The single bond radii in Table 11, Covalent Radii of the Elements, were derived insofar as possible from such compounds. The multiple bond radii were derived similarly. For example, the oxygen double bond radius may be obtained from acetone by using the double bond radius for carbon taken from ethylene and applying the electronegativity correction discussed in the following paragraph.

TABLE 8. INTERATOMIC DISTANCES IN METALS (IN ANGSTROM UNITS)[a]

TABLE 9. HOMOATOMIC SINGLE BOND ENERGIES (KCAL/MOLE)

C−C	78.9	Si−Si	53
N−N	39	P−P (in P_4)	48
O−O	35	S−S	58.1
F−F	38	Cl−Cl	57.87

2. When two atoms of different electronegativity are connected by a covalent bond, the bond length is always shorter than the sum of the individual homoatomic covalent radii for the atoms in question. The shortening is proportional to the difference in electronegativity of the two elements and is expressed by the relationship due to Stevenson and Schomaker.

$$R = (r_A - r_B) - 0.09\,|x_A - x_B|$$

where R = observed bond length
r_A, r_B = standard covalent radii of atoms A and B
x_A, x_B = electronegativities of A and B.

3. It has been pointed out by a number of workers that for bonds of the same multiplicity, the lower the average value of the l quantum number in a hybrid bonding orbital, the shorter the bond should be. For example, the carbon-carbon single bond in HC≡C−C≡CH which involves orbitals of *sp* hybridization is 1.37 Å long compared with the carbon-carbon bond in ethane (sp^3 hybridization) which is 1.543 Å long. Similarly the B−C bond in $B(C_6H_5)_3$ (sp^2) is shorter than in $B(C_6H_5)_4^-$ (sp^3). Thus it is found that a bond of given multiplicity has a length which is characteristic not only of the bond order, but also of the individual states of hybridization of the atoms. For example, the C−C bond in CH_3CN ($sp^3 + sp$) (1.46 Å) is almost exactly the average of the bonds in CH_3CH_3 (sp^3) and N≡C−C≡N (*sp*) (1.37 Å). Though the data for other elements are less extensive than for carbon, and the interpretation frequently is much more complicated, the same general principles seem to apply to other elements as well.
4. The effectiveness of overlap of bonding orbitals of the same symmetry appears to decrease as the principal quantum number

increases and as the difference between the principal quantum numbers increases. This is reflected in the bond strengths shown in Table 10, The covalent radius of hydrogen is especially subject to effects of this kind, and has the values 0.3707, 0.362, 0.306, 0.284 and 0.293 Å respectively in H2, HF, HCl, HBr and HI. The apparent anomaly of the P−P, S−S, and Cl−Cl bonds being stronger than the N−N, O−O, and F−F bonds has been considered in paragraph (1).

5. In the case of very large atoms or groups bonded to small atoms, the spatial requirements of the large groups may result in a bond lengthening. For example, it is probable that the C−I bond in CI_4 is longer and weaker than in CH_3I because of the steric repulsions of the large iodine atoms. Again, the N−N bond in $[(CH_3)_3NN(CH_3)_3]^{2+}$ may be longer than in $H_3\ NNH_3^{2+}$.
6. Special effects of electronic or orbital structure may result in either lengthening or shortening a bond. The first situation is exemplified by such compounds as O_2N-NO_2, O_2N-X, $(C_6H_5)_3\ C-C\ (C_6H_5)_3$ and the like, where the long bond is indicated in the formula. Cases of this sort involve molecules having a pi-electron system capable of accepting additional electrons (frequently in low-lying antibonding orbitals) so that the electrons required for the bond in question are partially drained away from it, leaving the bond weak and long. Thus the N−N bond in N_2O_4 has a length of 1.75 Å and a dissociation energy of 12.9 kcal compared with 1.47 Å and 60 kcal for N_2H_4.

Bond shortening, on the other hand, may occur in compounds of the most electronegative elements, notably fluorine. Typical examples are the fluoromethanes, in which the C−F bond lengths are: CH_3F 1.391 Å, CH_2F_2 1.358 Å, CHF_3 1.332 Å, and CF_4 1.323 Å. This has been explained in terms of electronegativity; i.e., that the polar C−F bond requires a high degree of *p*-character, thus releasing the *s*-orbital for the bonds to the less electronegative atoms, making them shorter and stronger. As more fluorine atoms are added, the *s*-orbital is more equally divided among the bonds, resulting in a regular shortening of the C−F bonds. This theory has been used to explain the supposed shortening of the C−C bond from 1.543 Å in C_2H_6 to 1.52 Å in C_2F_6. However, the experimental error attached to the latter value does not allow it to be considered really different from the former (a more recent value is 1.56 Å), and furthermore, the effect is not observed in other halo-substituted ethanes for which more accurate data are available: e.g., the C−C bond length in CF_3CN (1.464 Å) is if anything slightly longer than that in CH_3CN (1.458 Å), and microwave determinations on, C_2H_5 Br, C_2H_5Cl and C_2H_5 give 1.5508, 1.5508 and 1.540, respectively, for the C−C bonds. In addition, the C−H bond lengths in the fluoromethanes appear to be essentially constant: CH_4 1.092, CH_3F 1.109, CH_2F_2 1.092 and CHF_3 1.093. It should also be noted that the C−C stretching force constants in the two cyanides (4.50×10^{-5} and 4.55×10^{-5} dyne cm^{-1}, respectively) do not differ appreciably.

A theory that more satisfactorily explains all the known facts has been suggested by J.F.A. Williams [*Trans. Faraday Soc.*, **57**, 2089 (1961)]. This proposes that the highly electronegative fluorine atom drains electron density away from the carbon atom in a C−F group sufficiently to make the lobe of the σ-antibonding (σ^*) orbital which is concentrated beyond the carbon atom available for π-bonding. In CH_3F where the hydrogen atoms have no nonbonding electrons to interact with the σ^* orbital, there is little or no effect. However, in CH_2F_2, where each fluorine atom has nonbonding electrons in *p*-orbitals of favorable disposition, the *p*-electrons of each interact with the σ^* orbital associated with the other to give a $p_\pi - \sigma_\pi^*$ bond, which results in a strengthening and shortening of both bonds.

This effect is observed in the shortening of such bonds as C−N in CCl_3NO_2 and $(CF_3)_3N$, C−P in $(CF_3)_3P$, C−S in $(CF_3)_2S$ and so forth. Such a mechanism, on the other hand, could not result in a shortening of the C−C bond in C_2F_6.

Table 11 gives standard covalent radii for most of the elements of the periodic table. Most of these have been calculated from the best data available in the literature using the considerations of paragraphs 1–3 above. Thus when radii of the appropriate multiplicity and hybridization are added and corrected for difference in electronegativity by the Stevenson and Schomaker relationship, the observed bond length will be obtained. For example, the O−F bond in OF_2 would have the value $0.745 + 0.709 - 0.9(0.5) = 1.409$ Å. The experimental value is 1.41 Å.

The sp^3 double bond radii for Si, P, S and Cl are taken from the paper of D.W.J. Cruickshank, *J. Chem. Soc.*, **5486** (1961). A calculation of the Cl=O bond length gives

$$0.681 + 0.654 - 0.9(0.5) = 1.290 \text{ Å}$$

while for the Cl−O bond we calculate

$$1.050 + 0.745 - 0.9(0.5) = 1.750 \text{ Å}$$

The observed Cl−O bond length in ClO_4^- (1.48 Å) indicates that it has a bond order somewhat greater than 1.5.

The hybridization designations given in the table are not intended to be exact. In particular it must be recognized that the nitrogen bonding orbitals in the ammonia molecule, for example, have considerable *s* character. Nevertheless, such orbitals, for simplicity's sake, have been designated merely as *p*. This practice has been used uniformly when a nonbonding pair of electrons is found in the valence level. In the case of "sp^3d" hybridization, the radii are given as "sp^3d" if only average lengths were available, but are separated into sp^2 and *pd* if the data differentiated the two types of bonds. The values given for radii of the transition elements and for the less common hybridization states of the other elements, especially where the bond order is not accurately known, must be considered to be only approximate.

Valence

Valence is the capacity of an atom to combine with other atoms to form a molecule. Valence is specified as the number of hydrogen atoms or twice the number of oxygen atoms with which one atom of the element under question will combine. Thus, nitrogen has the valence 3,2,4,5 in the compounds NH_3, NO, NO_2, N_2O_5. A further distinction is made by considering positive and negative valences. If the hydrogen is assigned the valence of plus one, and oxygen that of minus two, and if the valences in a compound are made to total up to zero, we have a formal scheme of positive and negative valences. In ammonia, NH_3, the three hydrogen atoms each with a valence of plus one exactly balance the one nitrogen atom with the valence of negative three. Many atoms possess more than one valence but the principal valence is correlated with the periodic table and the atomic structure of the atom. The principal positive valence is the number of the group in which the element falls in the periodic table. Thus hydrogen is one, lithium also one, boron three, etc. The negative valence is eight minus the number of the group in the periodic table. Negative valences greater than four do not occur. For example, oxygen has the valence of eight minus six, that is two negative in H_2O (water): and nitrogen has the valence of eight minus five, that is three negative in NH_3 (ammonia).

On the basis of contemporary electronic theory of atomic structure we can classify the different types of valence. The guiding principle is that the atoms tend to assume an inert gas electronic structure of eight electrons in the outer shell (in the case of hydrogen it is two). To do this, the atom either loses to, gains from, or shares with other atoms, electrons. This process leads to molecule formation. The following are the principal types of valences and their electronic interpretation.

Electrovalence or polar valence is associated with a transfer of an electron from one element to the other in order to complete by such a transfer the octet of each element. Thus in sodium chloride the sodium atom has one valence electron outside a closed octet of eight. By loss of this electron the sodium atom becomes positively charged sodium ion because the nuclear positive charge exceeds that of the electrons by one. On the other hand, the chlorine atom has a grouping of seven electrons in the outer shell. It picks up another electron to complete its outer shell to an octet, but in so doing obtains a total charge of one minus, becoming a chloride ion. The result is that in sodium chloride we are not dealing with sodium atoms and chlorine atoms, but with sodium and chloride ions. This is experimentally substantiated. The forces holding the ions together are the electrostatic forces, which are equal to the product of the electronic charges on the ions divided by the product of the separation squared times the dielectric constant of the medium. Thus when the sodium chloride crystal is placed in solvent of high dielectric constant such as water, the forces between the ions are weakened and the ions float away from each other. In other words, electrolytic dissociation takes place. It must be noted that polar valences have no specific directional effects in space. The electrostatic attraction is best satisfied by a close packing of the ions. Inasmuch as there are large stray electric fields present in polar compounds, they possess a high melting point and considerable hardness.

[a] 1 angstrom $= 10^{-10}$ meter.

Homopolar or covalent bonds are formed by a different mechanism. Here again we have as the basis the tendency of each atom to complete its outer shell of electrons to eight, or in the case of hydrogen to a doublet. In contrast to polar valence, in covalence we have no direct transfer of electrons, but merely a sharing. In the case of molecular hydrogen each hydrogen atom with its one electron shares this electron with the other hydrogen. The result is that each atom in the molecule has at least part of the time a complete shell of two electrons. The electrons can be visualized as traveling in orbits encompassing the two hydrogen nuclei. It is a property of the covalent bond that it is not weakened by electrolytic solvents and that it has a definite direction in space. These directional effects of covalent bonds are expressed in stereochemistry. Thus, for example, the four valence bonds of the carbon atoms are arranged to extend from the center of a tetrahedron to the four corners. Furthermore, since there is a one-to-one saturation of the electron forces, the stray electric fields are negligible, the melting points are low, and the crystals are soft.

Intermediate in properties between the electrovalent and covalent bonds discussed above is the *semi-covalent bond* (also called *dative* or *polarized ionic bond*). It is formed when both electrons that constitute the bonding pair are supplied by one of the atoms. An example is the formation of amine oxides between tertiary amines and oxygen, in which both electrons are donated by the nitrogen atom. Such bonds naturally exhibit electrical polarity. They are members of the large class of heteropolar bonds characterized by an unequal distribution of charge due to a displacement of the electron-pair so that the effect of the bond is to make the atoms differ in polarity. In fact, atomic bonds are best described, not qualitatively, but in terms of bond angles and distances. In water, for example, the bond angle is 109.5°, indicating that the lines joining the two hydrogen atoms to the oxygen atom meet at this angle. However, there are two special types of bonds that deserve individual mention.

The *hydrogen bond* is actually two bonds, whereby two electronegative atoms are joined through a hydrogen atom. Since a stable hydrogen atom cannot be associated with more than two electrons, the hydrogen bond may be regarded as a resonance phenomenon, whereby the hydrogen atom is periodically attached to each of the two other atoms in turn, so that its behavior is a composite of the two structures.

Another type of bond that occurs in solids is the metallic bond. It can be considered as an extreme case of sharing of electrons in that an electron gas (present in the crystal lattice) is shared not by two ions but by all the ions in the lattice. This electron gas is responsible for the metallic properties of certain solids, especially for thermal and electrical conductivity.

As a consequence of the fact that many valence bonds leave residual electrical fields, many molecules in which the "primary" valences are satisfied can combine further with other molecules or with atoms. These higher combinations enter into many important areas of chemical science. They are the basis of the formation of coordination compounds, discussed under that heading. They cause molecular association. They are responsible for the formation of hydrates. They are in many cases the binding forces in nonionic solids, and are of great importance in explaining the structure of larger material aggregates.

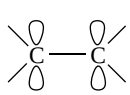
The foregoing discussion of valence is, of course, a simplified one. From the development of the quantum theory and its application to the structure of the atom, there has ensued a quantum theory of valence and of the structure of the molecule, discussed in this book under ***Molecule***. Topics that are basically important to modern views of molecular structure include, in addition to those already indicated: the Schroedinger wave equation; the molecular orbital method (introduced in the article on ***Molecule***) as well as directed valence bonds; bond energies, hybrid orbitals, the effect of Van der Waals forces; and electron-deficient molecules. Some of these subjects are clearly beyond the space available in this book and its scope of treatment. Even more so is their use in interpretation of molecular structure. (However, see **Crystal Field Theory**; and **Ligand**.)

There are a number of terms used in describing the individual valence bonds. The *bond angle* is the angle between two bonds in a molecule, e.g., in water the bond angle is 109.5°, indicating that the lines joining the two hydrogen atoms to the oxygen atom meet at this angle.

The term *bond direction* arises from the fact that certain covalent bonds prefer to lie in particular directions with respect to the bonded atoms. For example, the bonds from carbon point from the center to the vertices of a regular tetrahedron.

Atoms sharing the two pairs of electrons are described as connected by a *double bond*. The bond energy of the C−C bond is 80 kcal and that of the C=C bond is 145 kcal. The second bond is formed by p-electrons and, while its energy effect is considerable, it does not produce a double bond having twice the energy of the single bond. Moreover, its electrons, being less firmly held between the carbon atoms, are available for addition reactions. These bonds between p-electrons, or π-bonds, tend to delocalize in many cases, i.e., the electronic charges "spread" over other atoms than those furnishing them.

The diagram below, which shows the bonding of the carbon atoms in the ethylene molecule, shows the carbon atoms connected by one of the sp^2 hybrid bonds (solid line), the other two being used for the hydrogen atoms. The dotted lines show the π-bond formed between the two p-electrons. Since they occupy p-orbitals that are perpendicular to the plane of the sp^2 bonds, they cannot form a bond without considerable overlapping. From the figures of 80 and 145 kcal for single and double bonds, the π-bond accounts for 44% of the energy of the double bond, indicating extensive overlapping.



Conjugated double bonds are two double bonds in positions connecting alternate pairs of carbon atoms. For example, the compound

$$CH_2{=}CH{-}CH{=}CH_2$$

has conjugated double bonds. In addition reactions, the conjugated double bond system commonly changes to a single double bond between the second and third carbon atoms, accompanied by the addition of atoms or groups to the first and fourth carbon atoms.

Triple Bond

A single C−C bond involves *sp*-*sp* overlapping of orbitals, while a C−H bond is the result of *sp*-*s* overlapping. The other two valences on

carbon atoms are represented by two remaining π-electrons, occupying mutually perpendicular *p*-orbitals. In the case of *triple bonding*, $-C\equiv C-$, overlapping of these four *p*-orbitals gives two π molecular orbitals. Thus the carbon-carbon *triple bond* is conveniently represented as $-C{:}C-$, in which the π-electrons are shown occupying positions on the periphery of the carbon-carbon single bond. Their mutual repulsion reduces their bonding effectiveness, so that the bond energies for single, double and triple carbon-carbon bonds are 80, 145, and 198 calories, respectively.

Bond Energies

It has been suggested that ΔH^0_{298}, the heat of formation of a molecule from its constituent atoms (see also **Atomic Heat of Formation**), could be computed from a table of average bond energies, and the assumption of additivity:

$$\Delta H^0_{298} = \sum_{\substack{\text{all types}\\ \text{of bonds}}} n_{Xi-Xj} \cdot E_{Xi-Xj}$$

where n_{Xi-Xj} is the number of bonds between the two atomic species, X_i and X_j, in the molecule. E_{Xi-Xj} is the average bond energy associated with each of these bonds. Fairly accurate predictions of the heats of formations of organic molecules can be made in this way, particularly for the *larger* hydrocarbons, alcohols and other aliphatic derivatives.

The differences between the observed heats of formation of *cis-trans* isomers and of branched and unbranched hydrocarbon chains show that the additivity rule is not strictly rigorous. Various improvements have been suggested.

Single bond energies are given directly by the heat of dissociation of the corresponding molecules into neutral atoms. In cases where the molecule has no independent existence, other data may often be used. For example, the complete dissociation energy of a binary compound containing more than two atoms may be divided by the number of bonds broken in the dissociation, that is, the energy of the A−B bond may be taken as $\frac{1}{2}$ the dissociation energy of A−B−A into 2A and B, or as $\frac{1}{3}$ the dissociation energy of  into 3A and B. This multiple bond calculation yields, of course, an average value for the energy of the bonds involved. In the simple case of the H_2O molecule, the dissociation energies of the two successive steps $H_2O \rightarrow H + OH \rightarrow H + H + O$ differ by about 10%.

Representative single bond values were given in Table 10. Summation of such energies to obtain *average* values for molecules applies only when the constituent atoms exhibit their normal covalences and is subject to the exceptions already stated.

Pseudopotential Theory

It has been assumed for many years that the properties of matter (the chemical elements and the compounds that are built up from the atoms of the specific chemical elements) will follow the laws of quantum mechanics. Although the fundamental principles have been acknowledged, until recently it has been difficult to scale up these principles to aggregates of particles and to effectively apply fundamental theory to the prediction of materials properties, such as electrical conductivity, optical reflectivity, hardness, malleability, elasticity, and a number of chemical qualities. With a simple atom like hydrogen where its single electron is obviously a valence electron, calculations can be based on the potential energy of the electron. However, for atoms that contain two or more electrons, quantum scientists have found a mathematical approach impractical because the potential energy of a valence electron is affected by interactions with the more tightly bound core electrons of the atom. Further, these interactions are governed by the potential energy of each core electron. Consider, for example, the calculations that would be needed in connection with an electronic structure that may contain upward of 10^{20} particles or more. Some researchers have found that the interactions of the core and valence electrons have little effect outside the core. Thus, there is no requirement to know the true potential energy of all the electrons.

What is needed is a good approximation to the configuration of the valence electrons. Thus, as pointed out in a scholarly and detailed paper, Cohen, Heine, and Phillips observe, "The new method regards the core electrons and the atomic nucleus as if they constitute a single particle without internal structure. The method is called the *pseudopotential theory*." In their article, the authors review early computational strategy and problems, electron waves and standing wave patterns, the Fermi momentum, quantum momentum change, scattering in crystals, and applications to elemental solids and binary compounds. The authors conclude, "Perhaps the most remarkable aspect of pseudopotential theory is its capacity for steady growth through increasing physical and mathematical sophistication. The cumulative development has enabled pseudopotential theorists to keep basic physical issues as well as technical details in mind in describing the quantum structure of materials."

Among recent practical accomplishments from applying the theory are: (1) explanation of the properties of interfaces between metals and semiconductors and between two semiconductors; (2) calculation of the total energy of semiconducting materials with an accuracy of about 0.2 eV per atom for a variety of densities or volumes; and (3) forecasting the properties of light or heavy elements and covalent, ionic or metallic compounds throughout the periodic table more accurately, more rapidly, and more reliably than appraisal of any one light element a quarter of a century ago.

In the late twentieth century, a number of new instrumental techniques were developed for determining atomic properties with increased precision and reliability. Of marked importance is the increased facility for measuring minute dimensions and units of time at the respective nanometer and nanosecond levels. Laboratory techniques include laser atom probes, cold neutron research, scanning-tunneling microscopy, and atom trapping, among others.

CHEMICAL ELEMENTS: HISTORY OF THE ORIGIN. A chemical element is matter, all of whose atoms are alike in having the same positive charge on the nucleus and the same number of extra-nuclear electrons. The origin of the chemical elements show a wide diversity with some of these elements having an origin in antiquity, other elements having been discovered within the past few hundred years and still others have been synthesized within the past fifty years via nuclear reactions on heavy elements since these other elements are unstable and radioactive and do not exist in nature.

The names of the various chemical elements come from many sources including mythological concepts or characters; places, areas or countries; properties of the element or its compounds, such as color, smell or its inability to combine; and the names of scientists. There are also some miscellaneous names as well as some obscure names for particular elements.

The basis for the claim of discovery of an element has varied over the centuries. The method of discovery of the chemical elements in the late eighteenth and the early nineteenth centuries used the properties of the new substances, their separability, the colors of their compounds, the shapes of their crystals and their reactivity to determine the existence of new elements. In those early days, atomic weight values were not available, and there was no spectral analysis that would later be supplied by arc, spark, absorption, phosphorescent or x-ray spectra. Also in those days, there were many claims, e.g., the discovery of certain rare earth elements of the lanthanide series, which involved the discovery of a mineral ore, from which an element was later extracted. The honor of discovery has often been accorded not to the person who first isolated the element but to the person who discovered the original mineral itself, even when the ore was impure and that ore actually contained many elements. The reason for this is that in the case of these rare earth elements, the "earth" now refers to oxides of a metal not to the metal itself. This fact was not realized at the time of their discovery, until the English chemist Humphry Davy showed that earths were compounds of oxygen and metals in 1808.

Although the atomic weight of an element and spectral analysis of that element were not available in the early days, both of these elemental properties would be required before discovery of the element would be accepted by the latter part of the nineteenth century. In general, the requirements for discovery claims have tightened through the years and claims that were previously accepted would no longer meet the minimum constraints now imposed. There are also cases where the honor of discovery is not given to the first person who actually discovered the element but to the first person to claim the discovery in print. If a publication was delayed, the discoverer has often historically been "scooped" by another scientist.

This leads to the question of who should be considered the ultimate discoverer of a chemical element. Should it be the first person to describe the initial properties, the one who found the oxide or the metal, the one who separated the element or the first one to publish their results? On the matter of publication, the Swedish chemist Jons Jacob Berzelius published an annual review (equivalent to our present abstract service) during the early nineteenth century. Berzelius usually cited articles published in other journals, but he also reported on the work in his laboratory which had not yet been published. This enabled his assistant Carl-Gustav Mosander to receive early credit for work that Mosander chose not to formally publish until many years later after he had worked out all of the details. In the element review, we shall see that the answer to the above questions would be any of the above criteria could qualify for discovery of particular elements.

Determining the Names of the Chemical Elements

Names of the chemical elements are determined by the acceptance of the chemical community, the priority rights of the discoverer not withstanding. We shall see long-standing disputes among a number of elements. For some of these elements, this involved both national pride and rivalry between French and German scientists for some of the older elements and Russian and American scientists in more recent times.

At the beginning of the twentieth century, the International Committee on Atomic Weights (ICAW) was formed. Although the ICAW did not set internationally approved names, a name with an atomic weight value in their table lent support for the adoption of that name by the chemical community. Twenty years later, the ICAW became a part of the International Union of Pure and Applied Chemistry (IUPAC) when it was formed, IUPAC was called the International Union of Chemistry in early days between 1930 and 1950. When the IUPAC Commission on Atoms officially disbanded in 1949, the responsibility for acceptance of the name of a chemical element was given by IUPAC to its Commission on Nomenclature of Inorganic Chemistry (CNIC). See also http://www.iupac.org/publications/ci/2004/2601/1_holden.html (*Atomic Weights and the International Committee: A Historical Review*); and http://www.iupac.org/index_to.html.

The CNIC does not deny the right of a discoverer to propose a name for a new chemical element. However, the approved names of the elements should differ as little as possible in different languages; the names should be based on practicality and prevailing usage and finally the choice of the name carries no implication at all about the priority of discovery. A number of examples of this last point will be seen in the element review. See also http://www.iupac.org/publications/ci/2002/2402/news_nomenclature.html.

Systematic Naming of Elements with Atomic Numbers Greater than 110

Elements of atomic numbers greater than 110 are often referred to in the scientific literature but receive names only after they have been 'discovered'. Names are needed for indexing and other purposes and the Commission on Nomenclature of Inorganic Chemistry was asked to make recommendations concerning names and symbols of the heavy 'unknown' elements. The Commission decided that these elements would be best named systematically and that names should accord with the following principles:

i. The names should be short and obviously related to the atomic numbers of the elements.
ii. The names should end in 'ium' whether the element was expected to be a metal or otherwise.
iii. The symbols for the systematically named elements should consist of three letters.
iv. The symbols should be derived directly from the atomic numbers and be visually related to the names as far as possible.

The reasons for principles (i), (ii), and (iv) are obvious but those for (iii) are not so immediately apparent. The Commission recommends the use of three-letter symbols because any systematically derived set of two-letter symbols will tend to duplicate some of the two-letter symbols of elements of atomic numbers less than 110. Any ad hoc method of removing such duplication will destroy the systematic derivation of the symbol.

The existence of a systematic nomenclature for the unknown elements does not deny the right of 'discoverers' of new elements to suggest other names to the Commission after their discovery has been established beyond all doubt in the general scientific community.

Nomenclature of Elements of Atomic Numbers Greater than 110

1. The name is derived directly from the atomic number of the element using the following numerical roots:

0=nil	5=pent
1=un	6=hex
2=bi	7=sept
3=tri	8=oct
4=quad	9=enn

2. The roots are put together in the order of the digits which make up the atomic number and terminated by 'ium' to spell out the name. The final 'n' of 'enn' is elided when it occurs before 'nil', and the final 'i' of 'bi' and of 'tri' when it occurs before 'ium'.
3. The symbol of the element is composed of the initial letters of the numerical roots which make up the name.
4. The root 'un' is pronounced with a long 'u', to rhyme with 'moon'. In the element names each root is to be pronounced separately.

Special Difficulties with the Rare-Earth Elements

The discovery of the rare earth elements provide a long history of almost two hundred years of trial and error in the claims of element discovery starting before the time of Dalton's theory of the atom and determination of atomic weight values, Mendeleev's periodic table, the advent of optical spectroscopy, Bohr's theory of the electronic structure of atoms and Moseley's x-ray detection method for atomic number determination. The fact that the similarity in the chemical properties of the rare earth elements make them especially difficult to chemically isolate led to a situation where many mixtures of elements were being mistaken for elemental species. As a result, atomic weight values were not nearly as useful because the lack of separation meant that additional elements would still be present within an oxide and lead to inaccurate atomic weight values. Very pure rare earth samples did not become a reality until the mid twentieth century.

Prior to the proposal of the Periodic Table, there was no information available on how many chemical elements could possibly exist. Even after the appearance of the numerous periodic tables of chemical elements, the rare earth elements were an especially difficult case because they could not be properly arranged into any of the Tables. Until the twentieth century, fractional crystallization was the only method of purification of elements. In most cases, this required thousands of recrystallizations involving months of work. As a result, there is a long list of various false claims among the rare earth elements, some of which are detailed below. See also **Periodic Table of the Elements**.

The erroneous element names include: junonium, thorine, vestium, sirium, didymium, donarium, wasmium, mosandium, philippium, decipium, ytterbium, columbium, rogerium, austrium, russium, mssrium, demonium, metacerium, damarium, lucium, kosmium, neokosmium, glaucodymium, monium, victorium, euxenium, carolinium, berzelium, incognitium, ionium, celtium, denebium, dubhium, eurosamarium, welsium, nipponium and moseleyum.

Of course, mistaken elements are not restricted to the rare earth elements only. Other elemental errors produced such names as polinium, ilmenium, neptunium, pelopium and davyum.

It should be noted that the ytterbium listed above was a mixture discovered in the mineral erbia by de Marignac in 1878 and not the neoytterbium/aldebaranium element renamed ytterbium that was found in the mineral ytterbia. The columbium was a mixture found in the mineral samarskite and was not the present day columbium/niobium. The ionium listed above was a mixture of terbium and gadolinium that was found in the mineral yttria and does not refer to 230Th. Finally, the neptunium refers to material found in niobium/tantalum minerals and does not refer to the 1940 discovery of the trans-uranium element produced via a neutron capture reaction on a uranium sample. See also **Rare-Earth Elements and Metals**.

Controversial Heavy Elements

During the last half of the twentieth century, there were many opposing claims, which have taken on a nationalistic rivalry and a fight over when and where an element was "actually discovered" and who has the right to name that element. As mentioned above, IUPAC has taken the position that the name IUPAC proposes for an element carries no implication regarding the priority of the discovery but is merely related to the general usage of a name in the literature. Elements exist where the accepted name was proposed on the basis of an erroneous discovery of that element but widespread usage has dictated the continued use of the original name, even after the error has been discovered (see nobelium in the element list). Historically, new elements have been proposed and accepted in the past on the basis of evidence that would not meet the criteria of today.

Controversy about the first synthesis of new chemical elements in the trans-lawrencium region has recently been resolved by a joint IUPAC and IUPAP (International Union of Pure and Applied Physics) committee. CNIC has assigned names that appear to have been internationally accepted for these elements.

Element Names and History

Actinium [CAS: 7440-34-8], the atomic number is 89 and the chemical symbol is Ac. The name derives from the Greek, *aktis* or *akinis* for "beam or ray" because in equilibrium with its decay products, actinium is a powerful source of alpha radiation. The discovery has been credited to the French chemist Andre-Louis Debierne in 1899. It was independently discovered by German chemist Friedrich Oskar Giesel in 1902, who called it *emanium*. It is thought that Debierne's original preparation actually consisted of two thorium isotopes, ^{227}Th and ^{230}Th, but there was confusion in those early discoveries in radioactivity and Debierne's claim prevailed and his name of actinium has been retained to this day. The longest half-life associated with this unstable element is 21.77 year ^{227}Ac. See also **Actinium**.

Aluminium [CAS: 7429-90-5], the atomic number is 13 and the chemical symbol is Al. Although the name was originally called *alumium*, it was later changed to aluminum. Internationally, the element is referred to as aluminium, to conform with the "ium" ending of most metallic elements. The name derives from the Latin, *alum* and *alumen* for "stringent", since the early Romans called any substance with a stringent taste alum. The element was known in prehistoric times. In 1825, the Danish physicist, Hans Christian Oersted, isolated impure aluminium. The pure metal was first isolated by the German chemist Friedrich Wohler in 1827. See also **Aluminum**.

Americium [CAS: 7440-35-9], the atomic number is 95 and the chemical symbol is Am. The name derives from "America" where it was first synthesized in a series of successive neutron capture reactions in the element plutonium, ^{239}Pu, in a nuclear reactor in 1944 by American scientists under Glenn T. Seaborg at the University of California lab in Berkeley, California, using the nuclear reaction ^{239}Pu (n,γ) ^{240}Pu (n,γ) $^{241}\text{Pu} \rightarrow \beta^- \rightarrow {}^{241}$ Am. Americium is the sixth element in the Actinide series of elements and is named in analogy to Europium, which is the sixth element in the Lanthanide series of elements. The longest half-life associated with this unstable element is 7370 year ^{243}Am. See also **Americium**.

Antimony [CAS: 7440-36-0], the atomic number is 51 and the chemical symbol is Sb. The name derives from the Greek, anti + monos for "not alone or not one" because it was found in many compounds. The chemical symbol, Sb, comes from the original name, *stibium*, which is derived from the Greek *stibi* for "mark", since it was used for blackening eyebrows and eyelashes. The name was changed from stibium to antimonium to antimony. The minerals stibnite (Sb_2S_3) and stibine (SbH_3) are two of more than one hundred mineral species, which were known in the ancient world.

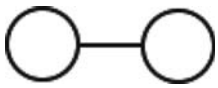
Antimony is one of the elements which has an alchemical symbol, shown below (alchemy is an ancient pursuit concerned with, for instance, the transformation of other metals into gold). See also **Antimony**.

Argon [CAS: 7440-37-1], the atomic number is 18 and the chemical symbol was originally just "A" but this symbol was changed to "Ar" in 1957. The name is derived from the Greek *argos* for "lazy or inactive"

because it did not combine with other elements. It was discovered in 1894 by the Scottish chemist Sir William Ramsay (Bristol, England) and the English physicist Robert John Strutt (Lord Rayleigh London, England) in liquefied atmospheric air. Rayleigh's initial interest was generated when he followed up on a problem posed by the English physicist Henry Cavendish in 1785, i.e., when oxygen and nitrogen were removed from air, there was an unknown residual gas remaining. See also **Argon**.

Arsenic [CAS: 7440-38-2], the atomic number is 33 and the chemical symbol is As. The name derives from the Latin *arsenicum* and the Greek *arsenikos* for the arsenic ore "yellow orpiment" (As_2S_3, an ancient dye stuff) and sounds similar to the Greek *arsenikon* for "male or potent", perhaps referring to its poisonous properties. The term orpiment is perhaps a corruption of auripigmentum meaning gold color. Arsenic was also known in prehistoric times for its poisonous sulfides. German scientist and philosopher, Albert von Bollstadt (Albert the Great/Albertus Magnus) is thought to have obtained the metal around 1250 but this is uncertain.

Arsenic is one of the elements which has an alchemical symbol, shown below. See also **Arsenic**.



Astatine [CAS: 7440-68-8], the atomic number is 85 and the chemical symbol is At. The name derives from the Greek *astatos* for "unstable" since it is an unstable element. It was first thought to have been discovered in nature in 1931 and was named alabamine. When it was determined that there are no stable nuclides of this element in nature, that claim was discarded. It was later shown that astatine had been synthesized by the physicists Dale R. Corson, Kenneth R. Mackenzie and Emilio Segre at the University of California lab in Berkeley, California in 1940 who bombarded bismuth with alpha particles, in the reaction ^{209}Bi(^{4}He, 2n) ^{211}At. Independently, a claim about finding some x-ray lines of astatine was the basis for claiming discovery of an element helvetium, which was made in Bern, Switzerland. However, the very short half-life precluded any chemical separation and identification. The longest half-life associated with this unstable element is 8.1 hour ^{210}At. See also **Astatine**.

Barium [CAS: 7440-39-3], the atomic number is 56 and the chemical symbol is Ba. The name is derived from the Greek *barys* for "heavy" since it was found in the mineral heavy spar (BaSO_4). It was discovered by the Swedish pharmacist and chemist Carl Wilhelm Scheele in 1774 and it was first isolated by the British chemist Humphry Davy (London, England) in 1808. See also **Barium**.

Berkelium [CAS: 7440-40-6], the atomic number is 97 and the chemical symbol is Bk. The name is derived from Berkeley, the town in California where the element was first synthesized in 1949 by the American scientific team Stanley G. Thompson, Albert Ghiorso, and Glenn T. Seaborg at the University of California, Berkeley, CA., using the nuclear reaction ^{241}Am(^{4}He, 2n) ^{243}Bk. It is the eighth element in the Actinide series of the elements and was named in analogy with Terbium (for Ytterby the town in Sweden whose mine produced the ore), which is the eighth element in the Lanthanide series of the elements. The longest half-life associated with this unstable element is 1400 year ^{247}Bk. See also **Berkelium**.

Beryllium [CAS: 7440-41-7], the atomic number is 4 and the chemical symbol is Be. The name derives from the Greek word *berryllos* for "Beryl" (3BeO.Al_20_3.6Si0_2) the gem-stone in which it is found. It was discovered by the French chemist and pharmacist Nicholas-Louis Vauquelin (Paris, France) in beryl and emerald in 1797. The element was first separated in 1828 by the French chemist Antoine-Alexandre Brutus Bussy (Paris, France) and independently by the German chemist Friedrich Wohler (Berlin, Germany). Since the salts of beryllium have a sweet taste, the element was also known for many years by the symbol GI and the name glucinium from the Greek *glykys* for "sweet", until IUPAC's CNIC selected the name beryllium in 1949 based on consideration of prevailing usage. See also **Beryl**; and **Beryllium**.

Bismuth [CAS: 7440-69-9], the atomic number is 83 and the chemical symbol is Bi. The name derives from the German *weisse masse* for "white mass" (the name later altered to wismuth and bisemutum) from the color of its oxides. The ancients did not distinguish bismuth from lead. The French chemist Claude-Francois Geoffroy (the younger) showed that bismuth was distinct from lead in 1753. See also **Bismuth**.

Bohrium [CAS: 54037-14-8], the atomic number is 107 and the chemical symbol is Bh. The name derives from the Danish physicist Niels Bohr, who developed the theory of the electronic structure of the atom. The first synthesis of this element is credited to the laboratory of the GSI (Center for Heavy-Ion Research) under the leadership of the German scientists Peter Armbruster and Gunther Miinzenberg at Darmstadt, Germany in 1981, using the reaction ^{209}Bi(^{54}Cr, n) ^{262}Bh. The longest half-life associated with this unstable element is 17 second ^{267}Bh. See also **Chemical Elements**.

Boron [CAS: 7440-42-8], the atomic number is 5 and the chemical symbol is B. The name derives from the Arabic *buraq* for "white". Although its compounds were known for thousands of years, it was not isolated until 1808 when the French chemists Louis-Joseph Gay-Lussac and Louis-Jacques Thenard (Paris, France) obtained boron in an impure state and the English chemist, Humphry Davy (London, England), prepared pure boron by electrolysis. See also **Boron**.

Bromine [CAS: 7726-95-6], the atomic number is 35 and the chemical symbol is Br. The name derives from the Greek *bromos* for "stench or bad odor". It was first prepared by the German chemist Carl Lowig (Heidelberg, Germany) in 1825 but it was first publicly announced in 1826 by Balard and so the discovery is therefore credited to the French chemist and pharmacist Antoine-Jerome Balard Montpellier, France). See also **Bromine**.

Cadmium [CAS: 7440-43-9], the atomic number is 48 and the chemical symbol is Cd. The name derives from the Greek *kadmeia* for "calamine (zinc carbonate)" with which it was found as an impurity in nature. It may have been found in furnace flue dust in Thebes. Kadmeia was also the name of the fortress of Thebes, a city in the Boeottia region of central Greece. The fortress was named after its founder, Cadmus, who was the son of the Phoenician king, Agenor, and brother of Europ and would be a possible source for the name of the ore. The element was discovered and first isolated by the German physician Friedrich Stromeyer in 1817. See also **Cadmium**.

Caesium or **(Cesium)** [CAS: 7440-46-2], the atomic number is 55 and the chemical symbol is Cs. The internationally accepted name is caesium because it is derived from caesius but the name is often given in English as cesium. The name caesium derives from the Latin *caesius* for "sky blue color" or "heavenly blue", which was the color of the caesium line in the spectroscope. It was discovered by the German chemist Robert Wilhelm Bunsen and the German physicist Gustav Robert Kirchhoff (Heidelberg, Germany) in 1860. It was first isolated by the German chemist Carl Setterberg in 1882. See also **Cesium**.

Calcium [CAS: 7440-70-2], the atomic number is 20 and the chemical symbol is Ca. The name derives from the Latin *calx* for "lime (CaO) or limestone (CaCO_3)" in which it was found. It was first isolated by the British chemist Humphry Davy (London, England) in 1808 with help from the Swedish chemist Jons Jacob Berzelius and the Swedish court physician M.M. af Pontin, who had prepared calcium amalgam. See also **Calcium**.

Californium [CAS: 7440-71-3], the atomic number is 98 and the chemical symbol is Cf. The name derives from the state and the University of California, where the element was first synthesized. Although the earlier members of the actinide series were named in analogy with the names of the corresponding members of the lanthanide series, the only connection with the corresponding element dysprosium (Greek for hard to get at) that was offered by the discoverers was that searchers for another element (gold about a century before in 1849) found it difficult to get to California. An American scientific team Stanley G. Thompson, Kenneth Street, Jr., Albert Ghiorso, and Glenn T. Seaborg at the University of California lab in Berkeley, California used the nuclear reaction ^{242}Cm(^{4}He, n) ^{245}Cf to first detect the element californium in 1950. The longest half-life associated with this unstable element is 900 year ^{251}Cf. See also **Californium**.

Carbon [CAS: 7440-44-0], the atomic number is 6 and the chemical symbol is C. The name derives from the Latin *carbo* for "charcoal". In 1797, the English chemist Smithson Tennant proved that diamond is pure carbon.

Carbon as charcoal, soot and coal has been used since prehistoric times. Carbon as diamond has also been known since very ancient times. The recognition that soot (amorphous carbon), graphite (another form of carbon) and diamond are all forms of carbon. See also **Carbon**.

A fourth form, buckminsterfullerene, formula C_60, whose framework is reminiscent of the seams in an Association Football ("soccer") ball, is the subject of considerable interest at present and was only discovered a few years ago in work involving Harry Kroto, http://www.kroto.info/, a Sheffield graduate.

Cerium [CAS: 7440-45-1], the atomic number is 58 and the chemical symbol is Ce. The name, which was originally cererium but was shortened

to cerium, derives from the planetoid Ceres, which was discovered by the Italian astronomer Guiseppe Piazzi in 1801 and named for Ceres, the Roman goddess of agriculture. Two years later in 1803, the element was discovered by the German chemist Martin-Heinrich Klaproth, who called the element *ochroeite earth* because of its yellow color. This rare earth was independently discovered at the same time by the Swedish chemist Jons Jacob Bezelius and the Swedish minerologist Wilhelm von Hisinger, who called it *ceria*. It was first isolated in 1875 by the American mineralogist and chemist William Frances Hillebrand and the American chemist Thomas H. Norton (Washington, DC.). See also **Cerium**.

Chlorine [CAS: 7782-50-5], the atomic number is 17 and the chemical symbol is Cl. The name derives from the Greek *chlooros* for "pale green or greenish yellow color" of the element. It was discovered by the Swedish pharmacist and chemist Carl-Wilhelm Scheele (Uppsala, Sweden) in 1774. He obtained it through the reaction of the mineral pyrolusite (manganese dioxide, MnO_2) with hydrochloric acid (HCl, then known as muriatic acid). Scheele thought the resulting gas contained oxygen. In 1810, the English chemist Humphry Davy proved it was an element and gave it the name chlorine. See also **Chlorine**.

Chromium [CAS: 7440-47-3], the atomic number is 24 and the chemical symbol is Cr. The name derives from the Greek *chroma* for "color", from the many colored compounds of chromium. It was discovered in 1797 by the French chemist and pharmacist Nicolas-Louis Vauquelin (Paris, France). Vauquelin also isolated chromium in 1798.

A year or two after Vauquelin's discovery, a German chemist named Tassaert working in Paris found chromium in an ore now called chromite. This ore, Fe(CrO_2)_2, is now an important source of chromium. See also **Chromium**.

Cobalt [CAS: 7440-48-4], the atomic number is 27 and the chemical symbol is Co. The name derives from the German *kobold* for "evil spirits or goblins", which were superstitiously thought to cause trouble for miners, since the mineral contained arsenic which injured their health and the metallic ores did not yield metals when treated with the normal methods. The name could also be derived from the Greek *kobalos* for "mine". Cobalt was discovered in 1735 by the Swedish chemist Georg Brandt (Stockholm, Sweden). See also **Cobalt**.

Copper [CAS: 7440-50-8], the atomic number is 29 and the chemical symbol is Cu. The name derives from the Latin *Cuprum* for "Cyprus", the island where the Romans first obtained copper. The chemical symbol, Cu, also comes from the Latin *cuprum*. The discovery of copper dates from prehistoric times. There are reports of copper beads dating back to 9000 BC found in Iraq. Methods for refining copper from its ores were discovered around 5000 BC and a 1000 or so years later it was being used in pottery in North Africa. See also **Copper**.

Part of the reason for it being used so early is simply that it is relatively easy to shape. However it is somewhat too soft for many tools and around 5000 years ago it was discovered that when copper is mixed with other metals the resulting alloys are harder than copper itself. As examples, brass is a mixture of copper and zinc while bronze is a mixture of copper and tin.

Copper is one of the elements which has an alchemical symbol, shown below.

Curium [CAS: 7440-51-9], the atomic number is 96 and the chemical symbol is Cm. The name derives from "Pierre and Marie Curie", the French physicist and Polish-born French chemist, who discovered radium and polonium. It was first synthesized in 1944 by the American scientists Glenn T. Seaborg, Ralph A. James, and Albert Ghiorso at the University of California lab in Berkeley, California, using the nuclear reaction $^{239}Pu(^{4}He, n)\ ^{242}Cm$. It was chemically identified at the Metallurgical Laboratory (now Argonne National Laboratory) at the University of Chicago. Since it is the ninth member of the actinide series, curium was named in analogy with its homologue the ninth member of the lanthanide series, gadolinium, which had been named after the Finnish rare earth chemist Johan Gadolin. The longest half-life associated with this unstable element is 15.6 million year ^{247}Cm. See also **Curium**.

Darmstadtium [CAS: 54083-77-1], the atomic number is 110 and the chemical symbol is Ds. The name derives from Darmstadt, the region where the research center GSI is located. This element was first synthesized in a November 1994 experiment by a multi-national team of scientists (Sigurd Hofmann, Victor Ninov, Fritz Peter Heberger, Peter Armbruster, H. Folger, Gottfried M unzenberg, H.J. Sch ott and others) working at the Gesellschaft f ur Schwerionenforschung (GSI) in Darmstadt, Germany. The scientific teams were from the GSI (Heavy Ion Research Center), Daiinstadt, the Joint Institute for Nuclear Research (JINR), Dubna, Russia, Comenius University, Bratislava, Slovakia and the University of Jyvaskyla, Finland. They used the nuclear reaction $^{208}Pb\ (^{62}Ni, n)\ ^{269}110$. The longest half-life associated with this unstable element is 1.1 minute $^{281}110$. See also **Chemical Elements**.

Dubnium [CAS: 53850-35-4], the atomic number is 105 and the chemical symbol is Db. The name derives from the location of the Russian research center, the Joint Institute for Nuclear Research lab in "Dubna", Russia. The first synthesis of this element is jointly credited to the American scientific team, Albert Ghiorso, M. Nurmia, K. Eskola, J. Harris, and P. Eskola at the University of California in Berkeley, CA, in 1970 and the Russian scientific team, Georgi N. Flerov, V. A. Druin, A. G. Demin, Y. V. Lobanov, N. K. Skokelev, G. N. Akap'ev, B. V. Fefilov, I. V. Kolesov, K. A. Gavrilov, Y. P. Kharitonov, and L. P. Chelnokov at the JINR (Joint Institute for Nuclear Reactions) lab in Dubna, Russia, in 1968. The longest half-life associated with this unstable element is 34 second ^{262}Db. See also **Chemical Elements**.

Dysprosium [CAS: 7429-91-6], the atomic number is 66 and the chemical symbol is Dy. The name derives from the Greek *dysprositos* for "hard to get at", due to the difficulty in separating this rare earth element from a holmium mineral in which it was found. Discovery was first claimed by the Swiss chemist Marc Delafontaine in the mineral samarskite in 1878 and he called it philippia. Philippia was subsequently found to be a mixture of terbium and erbium. Dysprosium was later discovered in a holmium sample by the French chemist Paul-Emile Lecoq de Boisbaudron (Paris, France) in 1886, who was then credited with the discovery. It was first isolated by the French chemist George Urbain in 1906. See also **Dysprosium**.

Einsteinium [CAS: 7429-92-7], the atomic number is 99 and the chemical symbol is Es. The name derives from "Albert Einstein", the Geituan born physicist who proposed the theory of relativity. A collaboration of American scientists G. R. Choppin, S. G. Thompson, A. Ghiorso, and B. G. Harvey, from the Argonne National Laboratory near Chicago, Illinois, the Los Alamos Scientific Laboratory in Los Alamos, New Mexico and at the University of California lab in Berkeley, CA, first found ^{252}Es in the radioactive debris from the first large thermonuclear bomb explosion, nicknamed "Mike," which took place at Enewetak atoll, Marshall Islands in the Pacific on November 1, 1952. The longest half-life associated with this unstable element is 472 day ^{252}Es. See also **Einsteinium**.

Erbium [CAS: 7440-52-0], the atomic number is 68 and the chemical symbol is Er. The name derives from the Swedish town of "Ytterby" (about 3 miles from Stockholm), where the ore gadolinite (in which it was found) was first mined. It was discovered by the Swedish surgeon and chemist Carl-Gustav Mosander (Stockholm, Sweden) in 1843 in an yttrium sample. He separated the yttrium into: yttrium, a rose colored salt he called terbium and a deep yellow peroxide that he called erbium. In 1860, an analysis of yttrium by the German chemist Berlin found only the yttrium and the rose colored salt, which was now called erbium not terbium. All subsequent workers followed Berlin in designating the rose colored rare earth as erbium. See also **Erbium**.

Europium [CAS: 7440-53-1], the atomic number is 63 and the chemical symbol is Eu. The name derives from the continent of "Europe". It was separated from the mineral samaria in magnesium-samarium nitrate by the French chemist Eugene-Anatole Demarcay (Paris, France) in 1896. It was also first isolated by Demarcay in 1901. See also **Europium**.

Fermium [CAS: 7440-72-4], the atomic number is 100 and the chemical symbol is Fm. The name derives from the Italian born physicist "Enrico Fermi", who built the first man made nuclear reactor. The nuclide ... Fm was found in the debris from the first thermonuclear weapon's explosion, nicknamed "Mike," on November 1, 1952, at Enewetak atoll, Marshall Islands, by a collaboration of American scientists G.R. Choppin, S.G.Thompson, A. Ghiorso and B.G. Harvey from the Argonne National Laboratory near Chicago, Illinois, the Los Alamos Scientific Laboratory in

Los Alamos, New Mexico and the University of California lab at Berkeley, CA. The longest half-life associated with this unstable element is 100 day ^{257}Fm. See also **Fermium**.

Fluorine [CAS: 7782-41-4], the atomic number is 9 and the chemical symbol is F. The name derives from the Latin *fluere* for "flow or flux" since fluorspar (CaF_2) was used as a flux in metallurgy because of its low melting point. It was discovered in hydrofluoric acid by the Swedish pharmacist and chemist Carl-Wilhelm Scheele in 1771 but it was not isolated until 1886 by the French pharmacist and chemist Ferdinand-Frederic-Henri Moisson (Paris, France) who used an apparatus constructed from platinum. His reward was the Nobel Prize for chemistry in 1906. See also **Fluorine**.

Francium [CAS: 7440-73-5], the atomic number is 87 and the chemical symbol is Fr. The name derives from the country "France", where the French physicist Marguerite Perey from the Curie Institute in Paris, France discovered it in 1939 in the alpha particle decay of actinium, $^{227}\text{Ac} \rightarrow {}^{4}\text{He} \rightarrow {}^{223}\text{Fr}$, which was known as actinium-K and has a half-life of 22 minutes. An earlier claim of discovery in 1930 with the element name Virginium was determined to be incorrect. A similar claim for discovery of the element with atomic number 87 and named moldavium was also determined to be incorrect. The longest half-life associated with this unstable element is 22 minute ^{223}Fr. This is the only isotope of francium occurring in nature, but at most there is only 20-30 g of the element present in the earth's crust at any one time. No weighable quantity of the element has been prepared or isolated. There are about 20 known isotopes. See also **Francium**.

Gadolinium [CAS: 7440-54-2], the atomic number is 64 and the chemical symbol is Gd. The name derives from the mineral gadolinite, in which it was found, and which had been named for the Finnish rare earth chemist "Johan Gadolin". It was discovered by the Swiss chemist Jean-Charles Galissard de Marignac (Geneva, Switzerland) in 1880, who produced a white oxide he called Y_α in a samarskite mineral. In 1886, the French chemist Paul-Emile Lecoq de Boisbaudran (Paris, France) gave the name gadolinium to Y_α. See also **Gadolinium**.

Gallium [CAS: 7440-55-3], the atomic number is 31 and the chemical symbol is Ga. The name derives from the Latin *gallia* for "France" or perhaps from the Latin *gallus* for "le coq or cock", since it was discovered in zinc blende by the French chemist Paul-Emile Lecoq de Boisbaudan (Paris, France) in 1875. It was first isolated in 1878 by Lecoq de Boisbaudran and the French chemist Emile-Clement Jungflesch. This element had previously been predicted as "eka-aluminum" by Mendeleev, along with its properties and its location in the Periodic Table. See also **Gallium**.

Germanium [CAS: 7440-56-4], the atomic number is 32 and the chemical symbol is Ge. The name derives from the Latin *germania* for "Germany". It was discovered and isolated by the German chemist, Clemens-Alexander Winkler (Freiberg, Germany) in 1886 in the mineral argyrodite ($GeS_2.4Ag_2S$). This element had previously been predicted as "eka-silicon" by Mendeleev, along with its properties and its location in the Periodic Table. See also **Germanium**.

Gold [CAS: 7440-57-5], the atomic number is 79 and the chemical symbol is Au. The name derives from the Sanskit jval to shine, the Teutonic word gulth for shining metal and the Anglo-Saxon gold of unknown origin. The chemical symbol Au derives from the Latin *aurum*, for Aurora the Goddess of dawn. Gold was known and highly valued from earliest times. Egyptian inscriptions dating back to 2600 B.C. describe gold and gold is mentioned several times in the Old Testament. See also **Gold**.

Gold is one of the elements which has an alchemical symbol, shown below.

Hafnium [CAS: 7440-58-6], the atomic number is 72 and the chemical symbol is Hf The name derives from the Latin *hafnia* for "Copenhagen". An element named celtium was erroneously claimed to have been discovered in 1911 by the French chemist George Urbain in rare earth samples, until the Danish physicist Nils Bohr, predicted hafnium's properties using his theory of electronic configuration of the elements. Bohr argued that hafnium would not be a rare earth element but would be found in zirconium ore. It was discovered shortly thereafter by the Dutch physicist Dirk Coster and the Hungarian physicist Georg von Hevesy (Copenhagen, Denmark) in 1923, while working at Bohr's institute in Copenhagen, Denmark. See also **Hafnium**.

Hassium [CAS: 54037-57-9], the atomic number is 108 and the chemical symbol is Hs. The name derives from the Latin *Hassias* for the German "state of Hessen", whose former capital was Darmstadt. The element was first synthesized by German physicists Peter Armbruster, and Gottfried Muenzenberg and their co-workers at the GSI (Center for Heavy-Ion Research) Lab at Darmstadt, Germany in 1984 using the nuclear reaction $^{208}\text{Pb}(^{58}\text{Fe}, n)\ ^{265}\text{Hs}$. The longest half-life associated with this unstable element is 11 minute ^{277}Hs. Isolation of an observable quantity of hassium has never been achieved, and may well never be. This is because hassium decays very rapidly through the emission of α-particles.

In 1994, the IUPAC proposed 'hahnium.' Finally in 1997, the name was agreed to hassium. See also **Chemical Elements**.

Helium [CAS: 7440-59-7], the atomic number is 2 and the chemical symbol is He. The name derives from the Greek *helios* for "sun". The element was discovered by spectroscopy during a solar eclipse in the sun's chromosphere by the French astronomer Pierre-Jules-Cesar Janssen in 1868. It was independently discovered and named helium by the English astronomer Joseph Norman Lockyer. It was thought to be only a solar constituent until it was later found to be identical to the helium in the uranium ore cleveite by the Scottish chemist Sir William Ramsay (London, England) in 1895. Ramsay originally called his gas krypton, until it was identified as helium. The Swedish chemists Per Theodore Cleve and Nils Abraham Langet (Uppsala, Sweden) independently found helium in cleveite at about the same time. See also **Helium**.

Holmium [CAS: 7440-60-0], the atomic number is 67 and the chemical symbol is Ho. The name derives from the Greek *holmia* for "Sweden". It was first discovered by the Swiss chemists J. L. Soret, and M. Delafontaine (Geneva, Switzerland) in 1879, who referred to it as element X. It was later independently discovered by the Swedish chemist Per Theodor Cleve (Uppsala, Sweden) in 1879 while working in erbia earth (erbium oxide). It was first isolated in 1911 by Holmberg, who proposed the name holmium either to recognize the discoverer Per Cleve, who was from Stockholm or perhaps to establish his own name in history. See also **Holmium**.

Hydrogen [CAS: 1333-74-0], the atomic number is 1 and the chemical symbol is H. The name derives from the Greek *hydro* for "water" and *genes* for "forming", since it burned in air to form water. It was discovered by the English chemist and physicist Henry Cavendish (London, England) in 1766 when he collected it over mercury and described it as "inflammable air from metals". Cavendish described accurately hydrogen's properties but thought erroneously that the gas originated from the metal rather than from the acid. Hydrogen was named by Lavoisier in 1783. See also **Hydrogen**.

Indium [CAS: 7440-74-6], the atomic number is 49 and the chemical symbol is In. The name derives from indigo for the "indigo-blue" line in the element's spark spectrum. It was discovered in 1863 by the German physicist Ferdinand Reich and the German metallurgist Hieronymus Theodor Richter (Freiberg, Germany), while examining zinc blende. They isolated indium in 1867. See also **Indium**.

Iodine [CAS: 7553-56-2], the atomic number is 53 and the chemical symbol is I. The name derives from the Greek *iodes* for "violet colored" because of its violet vapors. It was discovered in sea weed ash (kelp) by the French chemist Bernard Courtois (Dijon, France) in 1811. It was named iodine by the English chemist Humphry Davy in December 1813 and subsequently was named iode by the French chemist Louis-Joseph Gay-Lussac, when he proved it was an element in 1814. Despite the priority rights dispute between Davy and Gay-Lussac, both acknowledged Courtois as the discoverer of the element. See also **Iodine**.

Iridium [CAS: 7439-88-5], the atomic number is 77 and the chemical symbol is Ir. The name derives from the Latin *Iris*, the greek goddess of rainbows because of the "variety of colors in the element's salt solutions". Iridium and osmium were both discovered in a crude platinum ore in 1803 by the English chemist Smithson Tennant (London, England). Iridium was discovered independently by the French chemist H. V. Collet-Descotils also in 1803. Descotils actually published one month before Tennant but Tennant is given credit for the discovery, perhaps because he alone also found osmium in the ore. See also **Iridium**.

Iron [CAS: 7439-89-6], the atomic number is 26 and the chemical symbol is Fe. The name derives from the AngloSaxon "iron" of unknown origin. The chemical symbol Fe is derived from the Latin *ferrum* for "firmness". It is of interest to note that ^{56}Fe has a larger mass defect than any other nuclide. It is, therefore, the ultimate end product of stellar nuclear

fusion. The element has been known from prehistoric times. Genesis says that Tubal-Cain, seven generations from Adam, was "an instructor of every artificer in brass and iron." Smelted iron artifacts have been identified from around 3000 B.C. A remarkable iron pillar, dating to about A.D. 400, remains standing today in Delhi, India. This solid pillar is wrought iron and about 7.5 m high by 40 cm in diameter. Corrosion to the pillar has been minimal despite its exposure to the weather since its erection. See also **Iron**.

Krypton [CAS: 7439-90-9], the atomic number is 36 and the chemical symbol is Kr. The name derives from the Greek *kryptos* for "concealed or hidden". It was discovered in 1898 by the Scottish chemist William Ramsay and the English chemist Morris William Travers (London England) in the residue left after liquid air had nearly boiled away. Krypton was left in the residue after boiling away water, oxygen, nitrogen, helium, and argon from the sample of air. Krypton is present in the air at about 1 ppm. Neon was discovered by a similar procedure by the same workers just a few weeks later. A wavelength in the atomic spectrum of ^{86}Kr is the fundamental standard of length. See also **Krypton**.

Lanthanum [CAS: 7439-91-0], the atomic number is 57 and the chemical symbol is La. The name derives from the Greek *lanthanein* for "to be hidden or to escape notice" because it hid in cerium ore and was difficult to separate from that rare earth mineral. It was discovered by the Swedish surgeon and chemist Carl-Gustav Mosander (Stockholm, Sweden) in 1839. In 1842, Mosander separated his lanthanium sample into two oxides; for one of these he retained the name lanthanum and for the other he gave the name didymium (or twin). See also **Lanthanum**.

Lawrencium [CAS: 22537-19-5], the atomic number is 103 and the chemical symbol is Lr. The original chemical symbol was proposed as Lw but it was changed because "W" is an unusual occurrence in many languages and it is a cumbersome spoken word. The name derives from Ernest 0. Lawrence American physicist, winner of the 1939 Nobel Prize for Physics for is invention of the cyclotron. Credit for the first synthesis of this element in 1961 is given jointly to American chemists from the University of California laboratory in Berkeley, California Albert Ghiorso, Torbjorn Sikkeland, Almon Larsh, Robert M. Latimer and the Russian scientific team at the JINR (Joint Institute for Nuclear Reactions) lab in Dubna, Russia under Georgi N. Flerov, after a series of preliminary papers presented over a decade. The longest half-life associated with this unstable element is 3.6 hour ^{262}Lr. See also **Lawrencium**.

Lead [CAS: 7439-92-1], the atomic number is 82 and the chemical symbol is Pb. The name derives from the Angol-Saxon lead, which is of unknown origin. The element was known from prehistoric times. The chemical symbol Pb is derived from the Latin *plumbum* for "lead". See also http://elements.vanderkrogt.net/elem/pb.html.

Lead has been known for ages and is mentioned in Exodus. Alchemists believed lead to be the oldest metal and associated it with the planet Saturn. They spent a lot of time trying to "transmute" lead into gold.

Lead is one of the elements which has an alchemical symbol, shown below (alchemy is an ancient pursuit concerned with, for instance, the transformation of other metals into gold). See also **Lead**.

Lithium [CAS: 7439-93-2], the atomic number is 3 and the chemical symbol is Li. The name derives from the Greek *lithos* for "stone" because lithium was thought to exist only in minerals at that time. It was discovered by the Swedish mineralogist Johan August Arfwedson (Stockholm, Sweden) in 1817 in the mineral petalite LiAl (S1205)2. Arfvedson subsequently discovered lithium in the minerals spodumene and lepidolite. C.G. Gmelin observed in 1818 that lithium salts color flames bright red. Neither Gmelin nor Arfvedson were able to isolate the element itself from lithium salts, for example in attempted reductions by heating the oxide with iron or carbon. The first isolation of elemental lithium was achieved later by W.T. Brande and Sir Humphrey Davy by the electrolysis of lithium oxide. In 1855, German chemists Robert Wilhelm Bunsen and Augustus Matthiessen isolated larger quantities of the metal by electrolysis of lithium chloride. In 1923 the first commercial production of lithium metal was achieved by Metallgesellschaft AG in Germany using the electrolysis of a molten mixture of lithium chloride and potassium chloride, exploiting a suggestion made by Guntz in 1893. See also **Lithium**.

Lutetium [CAS: 7439-94-3], the atomic number is 71 and the chemical symbol is Lu. The name was originally "lutecium" but in 1949, IUPAC's CNIC changed the "c" to "t" since the name derives from "lutetia", the ancient Greek name for the city of "Paris", rather than from its French equivalent "lutece". The discovery is credited to the French chemist George Urbain (Paris, France) in 1907 although it had been separated earlier and independently by the Austrian chemist Carl Auer von Welsbach from an ytterbium sample. Auer von Welsbach named the element cassiopeium for the constellation "Cassiopeia". Although Auer von Welsbach's paper appeared prior to the Urbain paper, Urbain argued that he had sent his paper to the editor earlier. The International Committee on Atomic Weights (where Urbain was one of the four members) adopted Urbain's name and his claim of priority. The German Atomic Weights' Committee accepted Auer von Welsbach's name of cassiopeia for the element for the next forty years. Urbain's name for the element was officially adopted by IUPAC's CNIC in 1949 based on consideration of prevailing usage, finally ending the controversy. See also **Lutetium**.

Magnesium [CAS: 7439-95-4], the atomic number is 12 and the chemical symbol is Mg. The name originally used was magnium and was later changed to magnesium, which is derived from Magnesia, a district in the northeastern region of Greece called *Thessalia* (Thessaly). See also http://plato-dialogues.org/tools/loc/thessali.htm. The Scottish chemist Joseph Black (Edinburgh, Scotland) recognized it as a separate element in 1755. In 1808, the English chemist Humphry Davy obtained the impure metal and in 1831 the French pharmacist and chemist Antoine-Alexandre Brutus Bussy isolated the metal in the pure state. See also **Magnesium**.

Manganese [CAS: 7439-96-5], the atomic number is 25 and the chemical symbol is Mn. The name derives from the Latin *magnes* for "magnet" since pyrolusite (Mn0_2) has magnetic properties. It was discovered by the Swedish pharmacist and chemist Carl-Wilhelm Scheele in 1774. Also in 1774, the Swedish chemist Johan Gottlieb Gahn (Stockholm, Sweden) first isolated the metal. He reduced the dioxide (MnO_2, as the mineral pyrolusite) with charcoal (essentially carbon) by heating and the result was a sample of the metal manganese. See also **Manganese**.

Meitnerium [CAS: 54038-01-6], the atomic number is 109 and the chemical symbol is Mt. The name derives from the Austrian physicist "Lise Meitner", who had discovered the element, protactinium. The first synthesis of the element Meitnerium is credited to West German physicists Peter Armbruster, F. P. Hessberger, S. Hofmann, K. Poppensieker, W. Reisdorf, K. Schneider, K. H. Schmidt, C. C. Sahm, and D. Vermeulen, from the GSI (Center for Heavy-Ion Research) lab at Darmstadt, Germany under Gunther Munzenberg, in 1982 using the nuclear reaction ^{209}Bi(^{58}Fe, n) ^{266}Mt. The longest half-life associated with this unstable element is 0.07 second (2 and 20 milliseconds) ^{268}Mt. Isolation of an observable quantity of meitnerium has never been achieved, and may well never be. This is because meitnerium decays very rapidly through the emission of α-particles. See also **Chemical Elements**.

Mendelevium [CAS: 7440-11-1], the atomic number is 101 and the chemical symbol is Md. The original chemical symbol proposed was My but this was changed in 1955. The element name derives from the Russian chemist "Dimitrii Mendeleev" who developed the Periodic Table of the chemical elements. Credit for the first synthesis of this element is given American chemists Albert Ghiorso, Bernard G. Harvey, Gregory R. Choppin, and Stanley G. Thompson at the University of California lab in Berkeley, California under Glenn T. Seaborg in 1958, who used the nuclear reaction ^{253}Es(^{4}He, 2n) ^{255}Md and the nuclear reaction ^{253}Es (^{4}He, n) ^{256}Md. The longest half-life associated with this unstable element is 51 day ^{258}Md. See also **Mendelevium**.

Mercury [CAS: 7439-97-6], the atomic number is 80 and the chemical symbol is Hg. The name derives from the Roman god "Mercury", the nimble messenger of the gods, since the ancients used that name for the element, which was known from prehistoric times. The name mercury originated in 6th-century alchemy, in which the symbol of the planet was used to represent the metal; the chemical symbol Hg derives from the Latin *hydrargyrum*, "liquid silver or quick silver." Although its toxicity was recognized at an early date, its main application was for medical purposes.

Mercury is one of the elements which has an alchemical symbol, shown below (alchemy is an ancient pursuit concerned with, for instance, the transformation of other metals into gold). See also **Mercury**.

Molybdenum [CAS: 7439-98-7], the atomic number is 42 and the chemical symbol is Mo. The original name that was proposed was molydaenum but this was changed because of the prevailing usage of "e" rather than "ae" in English, American and French. Since the ending of the name was spelt "num" and not "nium" in most languages, this ending was not changed. The name derives from the Greek *molybdos* for "lead". The ancients used the term lead for any black mineral which leaves a mark on paper. It was discovered by the Swedish pharmacist and chemist Carl Wilhelm Scheele in 1778. It was first isolated by the Swedish chemist Peter-Jacob Hjelm (Uppsala, Sweden) in 1781. See also **Molybdenum**.

Neodymium [CAS: 7440-00-8], the atomic number is 60 and the chemical symbol is Nd. The name was originally neodidymium and was later shortened to neodymium, which is derived from the Greek *neos* for "new" and *didymos* for "twin". It was discovered by the Swedish surgeon and chemist Carl Gustav Mosander in 1841, who called it didymium (or twin) because of its similarity to lanthanium which he had previously discovered two years earlier. In 1885, the Austrian chemist Carl Auer von Welsbach separated didymium into two elements. One of which he called neodymium (or new twin). See also **Neodymium**.

Neon [CAS: 7440-01-9], the atomic number is 10 and the chemical symbol is Ne. The name derives from the Greek *neon* for "new". It was discovered from its bright red spectral lines by the Scottish chemist William Ramsay and the English chemist Morris William Travers (London, England) in 1898 from a liquefied air sample. A little later they discovered xenon using similar methods. See also **Neon**.

Neptunium [CAS: 7439-99-8], the atomic number is 93 and the chemical symbol is Np. The name derives from the planet "Neptune" (the Roman god of the sea), since it is the next outer-most planet beyond the planet Uranus in the solar system and this element is the next one beyond uranium in the periodic table. It was first synthesized by Edwin M. McMillan and Philip H. Abelson (Berkeley, CA.) in 1940 via the nuclear reaction $^{238}\mathrm{U(n, }\gamma)\,^{239}\mathrm{U} \rightarrow \beta^{-} \rightarrow {}^{239}\mathrm{Np}$. The longest half-life associated with this unstable element is 2.14 million year ^{237}Np. It was the first synthetic transuranium (elements after uranium) element discovered. See also **Neptunium**.

Nickel [CAS: 7440-02-0], the atomic number is 28 and the chemical symbol is Ni. The name derives from the German nickel for "deceptive little spirit", since miners called mineral niccolite (NiAs) by the name Kupfernickel (false copper, Devil's copper or St. Nicholas copper) because it resembled copper ores in appearance but no copper was found in the ore. It was discovered by the Swedish metallurgist Baron Axel-Fredrik Cronstedt (Stockholm, Sweden) in 1751. See also **Nickel**.

Niobium [CAS: 7440-03-1], the atomic number is 41 and the chemical symbol is Nb. The name derives from the Greek mythological character "Niobe", who was the daughter of Tantalus (see the element tantalum), since the elements niobium and tantalum were originally thought to be identical elements. Niobium was discovered in a black mineral from America called columbite by the British chemist and manufacturer Charles Hatchett (London, England) in 1801 and he called the element columbium, since the mineral was discovered in America. See also **Columbite**. A year later in 1802, the element tantalum was discovered. In 1809, the English chemist William Hyde Wollaston claimed that the elements columbium and tantalum were identical. Forty years later, the German chemist and pharmacist, Heinrich Rose, determined from their acids that columbium and tantalum were two different elements in 1846 and gave the name niobium to columbium because it was so difficult to distinguish it from tantalum. Rose claimed that his niobium had a larger atomic weight than tantalum. Finally, in 1866, the Swiss chemist Jean-Charles Galissard de Marignac separated these elements. For more than a century, the name columbium continued to be used in America and niobium in Europe until IUPAC's CNIC adopted the name niobium in 1949 based on consideration of prevailing usage. Niobium was first isolated by the chemist C. W. Blomstrand in 1846. See also **Niobium**.

Nitrogen [CAS: 7727-37-9], the atomic number is 7 and the chemical symbol is N. The name derives from the Latin *nitrum* and Greek *nitron* for "native soda" and *genes* for "forming" because of nitrogen's presence in potassium nitrate (KNO), so called salpeter or nitre or native soda. It was known during the 18th century that air contains at least two gases, one of which supports combustion and life, and the other of which does not. Nitrogen was discovered by the Scottish physician and chemist Daniel Rutherford (Edinburgh, Scotland) in 1772, who called it noxious air, but Scheele, Cavendish, Priestley, and others at about the same time studied "burnt" or "dephlogisticated" air, as air without oxygen was then called. See also **Nitrogen**.

Nobelium [CAS: 10028-14-5], the atomic number is 102 and the chemical symbol is No. The name derives from "Alfred Nobel", the discoverer of dynamite and founder of the Nobel prizes. It was first synthesized in 1966 by the Russian scientists from the JINR (Joint Institute for Nuclear Research) lab in Dubna, Russia under Georgi Flerov. Earlier claims to have synthesized "Nobelium" beginning in 1957 were shown to be erroneous but the original name was retained because of its widespread use throughout the scientific literature. In 1958 a group at Berkeley, California, USA reported that they were unable to reproduce this work, findings agreed by a Russian group at Dubna. However an authenticated discovery of nobelium was made in 1958 by A. Ghiorso, T. Sikkeland, G. T. Seaborg and J. R. Walton at Berkeley, California. Since then a number of isotopes with mass numbers in the range 250–259 have been made. The longest half-life associated with this unstable element is 58 minute ^{259}No. See also **Nobelium**.

Osmium [CAS: 7440-04-2], the atomic number is 76 and the chemical symbol is Os. The name derives from the Greek *osme* for "smell" because of the sharp odor of the volatile oxide. Both osmium and iridium were discovered simultaneously in a crude platinum ore by the English chemist Smithson Tennant (London, England) in 1803. See also **Osmium**.

Oxygen [CAS: 7782-44-7], the atomic number is 8 and the chemical symbol is O. The name derives from the Greek *oxys* for "acid" and *genes* for "forming", since the French chemist Antoine-Laurent Lavoisier originally thought that oxygen was an acid producer because by burning phosphorus and sulfur and dissolving them in water, he was able to produce acids. Oxygen was discovered independently by the Swedish pharmacist and chemist Carl-Wilhelm Scheele in 1771 and the English clergyman and chemist Joseph Priestly (Leeds, England) in 1774. Scheele's "Chemical Treatise on Air and Fire" was delayed in publication until 1777, so Priestly is credited with the discovery, since he published first. See also **Oxygen**.

Palladium [CAS: 7440-05-3], the atomic number is 46 and the chemical symbol is Pd. The name derives from the second largest asteroid of the solar system Pallas (named after the goddess of wisdom and arts — Pallas Athene). The element was discovered by the English chemist and physicist William Hyde Wollaston (London, England) in 1803, one year after the discovery of Pallas by the German astronomer H. W. M. Olbers in 1802. The discovery was originally published anonymously by Wollaston to obtain priority, while not disclosing any details about his preparation. See also **Palladium**.

Phosphorus [CAS: 7723-14-0], the atomic number is 15 and the chemical symbol is P. The name derives from the Greek *phosphoros* for "bringing light", since white phosphorus oxidizes spontaneously in air and glows in the dark. This was also the ancient name for the planet Venus, when it appears before sunrise. It was discovered by the German merchant Hennig Brand (Hamburg, Germany) in 1669. See also **Phosphorus**.

Platinum [CAS: 7440-06-4], the atomic number is 78 and the chemical symbol is Pt. The name derives from the Spanish platina for "silver". In 1735, the Spanish mathematician Don Antonio de Ulloa found platinum in Peru, South America. In 1741, the English metallurgist Charles Wood found platinum from Columbia, South America. In 1750, the English physician William Brownrigg prepared purified platinum metal. See also **Platinum**.

Platinum is one of the elements which has an alchemical symbol, shown below.

Plutonium [CAS: 7440-07-5], the atomic number is 94 and the chemical symbol is Pu. The name derives from the planet Pluto, (the Roman god of the underworld). Pluto was selected because it is the next planet in the solar system beyond the planet Neptune and the element plutonium is the next element in the period table beyond neptunium. Plutonium was first

synthesized in 1940 by American chemists Glenn T. Seaborg, Edwin M. McMillan, Joseph W. Kennedy and Arthur C. Wahl at Berkeley, California, in the nuclear reaction $^{238}U(^{2}H, 2n)\ ^{238}Np \rightarrow \beta^{-} \rightarrow\ ^{238}Pu$. The longest half-life associated with this unstable element is 80 million year ^{244}Pu. See also **Plutonium**.

Polonium [CAS: 7440-08-6], the atomic number is 84 and the chemical symbol is Po. This radioactive metal was also known as radium-F. The name derives from "Poland", the native country of Marie Sklodowska Curie. It was discovered by Marie Curie (Paris, France) in 1898, from its radioactivity. It was independently found by the German chemist Willy Marckwald in 1902 and called radiotellurium. The longest half-life associated with this unstable element is 102 year 209Po. See also **Polonium**.

Potassium [CAS: 7440-09-7], the atomic number is 19 and the chemical symbol is K. The name derives from the English "potash or pot ashes" since it is found in caustic potash (KOH). The chemical symbol K derives from the Latin *kalium* via the Arabic *qali* for alkali.

Until the 18th century no distinction was made between potassium and sodium. This was because early chemists did not recognize that "vegetable alkali" (K_2CO_3, potassium carbonate, coming from deposits in the earth) and "mineral alkali" (Na_2CO_3, sodium carbonate, derived from wood ashes) are distinct from each other. Eventually a distinction was made.

Well before potassium was recognized as an element, potassium carbonate was mixed with animal fat to make soap. The carbonate was made by extracting wood ash with water before concentration by boiling — hence the name "potash" for potassium salts.

Potassium was first isolated by Humphry Davy (London, England) in 1807 from electrolysis of potash (KOH). Potassium was the first metal isolated by electrolysis. Davy isolated sodium by a similar procedure later in 1807. See also **Potassium**.

Praseodymium [CAS: 7440-10-0], the atomic number is 59 and the chemical symbol is Pr. The name was originally praseodidymium and was later shortened to praseodymium, which is derived from the Greek *prasios* for "green" and *didymos* for "twin" because of the pale green salts it focus. It was discovered by the Austrian chemist Carl Auer von Welsbach (Vienna, Austria) in 1885, who separated it and the element neodymium from a didymium sample. Didymium had previously been thought to be a separate element. See also **Praseodymium**.

Promethium [CAS: 7440-12-2], the atomic number is 61 and the chemical symbol is Pm. The name promethium was preferred to prometheum because most metallic elements have names ending in "ium" and "eum" would have caused problems. The name derives from "Prometheus" who stole fire from heaven and gave it to the human race, since it was found by the harnessing of nuclear energy which also provides a dangerous threat of punishment. In 1926, there had been a claim of discovery of element 61 at the University of Illinois in the USA and the element was named illinium. Subsequently another claim was made that element 61 had actually been discovered in Italy in 1924 but the manuscript had been secretly stored in a sealed envelope with Academia dei Lincei and the element had been named Florentium. Both elements were supposedly found in natural minerals. It was later shown that this element does not exist in nature and both of these claims were discarded. In 1941, neodymium and praseodymium were irradiated with neutrons, deuterons and alpha particles at Ohio State University in the USA and new activities were produced. Some of these activities are now associated with element 61. However, no chemical proof of element 61 was available because rare earth elements could not be separated from each other at that time. Promethium was first synthesized in fission products from the thermal neutron fission of ^{235}U at the Clinton (later Oak Ridge National Laboratory) lab by the American chemists, J. A. Marinsky, L. E. Glendenin and Charles D. Coryell in 1947, using chemical separation by ion exchange chromotography. The fission products, ^{147}Pm and ^{149}Pm were also identified in the slow neutron activation of neodymium. The longest half-life associated with this unstable element is 17.7 year ^{145}Pm. See also **Promethium**.

Protactinium [CAS: 7440-13-3], the atomic number is 91 and the chemical symbol is Pa. The name was originally prototactinium but in 1949 it was shortened to protactinium by IUPAC's CNIC. The name derives from the Greek *protos* for "first" and actinium, since it was found to be the parent of actinium. An isotope of protactinium, ^{234}Pa, was first identified by the German chemists Kasimir Fajans and O. H. Gohring in 1913. They named the element "Brevium" because of its short halflife. The longer half-lived isotope, ^{231}Pa, was identified by the German chemist Otto Hahn (Berlin, Germany) and the Austrian physicist Lise Meitner in 1917, while Hahn was away in military service. It was first isolated by the German chemist Aristid V. Grosse in 1927. Protactinium was accepted as the name for the element because it was preferred to use the name of the longer-lived isotope. The longest half-life associated with this unstable element is 32.5 thousand year ^{231}Pa. See also **Protactinium**.

Radium [CAS: 7440-14-4], the atomic number is 88 and the chemical symbol is Ra. The name derives from the Latin *radius* for "beam or ray" because of its tremendous ray-emitting power. It was discovered by the French physicist Pierre Curie and the Polish-born, French chemist Marie Sklodowska Curie (Paris, France) in 1898. It was independently discovered by the British chemists Frederick Soddy and John A. Cranston. It was first isolated in 1911 by Marie Curie and the French chemist AndreLouis Debierne. The longest half-life associated with this unstable element is 1599 year ^{226}Ra. See also **Radium**.

Radon [CAS: 10043-92-2], the atomic number is 86 and the chemical symbol is Rn. The name indicates its origin from radium. It had first been called radium emanation or just emanation (with chemical symbol Em) because it was a decay product of radium. Ramsay next suggested the name "niton" (with chemical symbol Nt), which is Latin for shining. It was finally changed to radon in 1923. Radon was discovered in 1900 by the German chemist Friedrich Ernst Dorn and it was first isolated in 1910 by the Scottish chemist William Ramsay and the English chemist Robert Whytlaw-Gray. The longest half-life associated with this unstable element is 3.8 day ^{222}Rn. See also **Radon**.

Rhenium [CAS: 7440-15-5], the atomic number is 75 and the chemical symbol is Re. The name derives from the Latin *rhenus* for "the Rhine River in Germany". It was discovered by x-ray spectroscopy in 1925 by the German chemists, Walter Noddack, Ida Tacke and Otto Berg (Berlin, Germany). See also **Rhenium**.

Rhodium [CAS: 7440-16-6], the atomic number is 45 and the chemical symbol is Rh. The name derives from the Greek *rhodon* for rose because of the "rose color of dilute solutions of its salts". It was discovered by the English chemist and physicist William Hyde Wollaston (London, England) in 1803 in a crude platinum ore from South America rather soon after his discovery of another element, palladium. He dissolved the ore in aqua regia (a mixture of hydrochloric and nitric acids), neutralised the acid with sodium hydroxide (NaOH), and precipitated the platinum by treatment with ammonium chloride, NH_4Cl, as ammonium chloroplatinate. Palladium was then removed as palladium cyanide by treatment with mercuric cyanide. The remaining material was a red material containing rhodium chloride salts from which rhodium metal was obtained by reduction with hydrogen gas. See also **Rhodium**.

Roentgenium [CAS: 54386-24-2], the atomic number is 111 and the chemical symbol is Rg. On November 1, 2004 the IUPAC Council officially approved element 111 to be named roentgenium in honor of the famous scientist Wilhelm Conrad Roentgen who discovered X-rays in 1895. This element was first synthesized in a December 8, 1994 experiment by a multi-national team of scientists S. Hofmann, V. Ninov, F. P. Hessberger, P. Armbruster, H. Folger, G Münzenberg, H. J. Schott, A. G. Popeko, A. V. Yeremin, A. N. Andreyev, S. Saro, R. Janik, and M. Lein working at the GSI (Heavy Ion Research Center) in Darmstadt, Germany. The scientific teams were from GSI, Darmstadt, Germany, JINR, Dubna, Russia, the Comenius University in Bratislava, Slovakia and the University of Jyvaskyla, Finland. They used the nuclear reaction $^{209}Bi(^{64}Ni, n)\ ^{272}111$. The longest half-life associated with this unstable element is 0.015 second $^{272}111$. Chemically, roentgenium should be in the same group as the elements copper, silver, and gold (Group 11). See also **Chemical Elements**.

Rubidium [CAS: 7440-17-7], the atomic number is 37 and the chemical symbol is Rb. The name derives from the Latin *rubidus* for deepest red because of the two "deep red lines" in its spectra. It was discovered in the mineral lepidolite (a form of mica) by the German chemist Robert Wilhelm Bunsen (University of Heidelberg, Germany) and the German physicist Gustav-Robert Kirchoff in 1861. Bunsen isolated rubidium in 1863. See also **Rubidium**.

Ruthenium [CAS: 7440-18-8], the atomic number is 44 and the chemical symbol is Ru. The name derives from the Latin *ruthenia* for the "old name of Russia". It was discovered in a crude platinum ore by the Russian chemist Gottfried Wilhelm Osann in 1828. Osann thought that he had found three new metals in the sample, pluranium, ruthenium and polinium. He later withdrew his claim of discovery. In 1844 the Russian

chemist Karl Karlovich Klaus was able to show that Osann's mistake Gustav-Robert was due to the impurity of the sample but Klaus was able to isolate the ruthenium metal and he retained Osann's original name of ruthenium. See also **Ruthenium**.

Rutherfordium [CAS: 53850-36-5], the atomic number is 104 and the chemical symbol is RE. The name derives from the English physicist "Ernest Rutherford" who won the Nobel prize for developing the theory of radioactive transformations. Credit for the first synthesis of this element is jointly shared by American scientists at the University of California lab in Berkeley, California under Albert Ghiorso and by Russian scientists at the JINR (Joint Institute for Nuclear Reactions) lab in Dubna, Russia under Georgi N. Flerov. The longest half-life associated with this unstable element is 10 minute ^{263}Rf. See also **Chemical Elements**.

Samarium [CAS: 7440-19-9], the atomic number is 62 and the chemical symbol is Sm. The name derives from the mineral Samarskite, in which it was found and which had been named for "Colonel von Samarski", a Russian mine official. It was originally discovered in 1878 by the Swiss chemist Marc Delafontaine, who called it decipium. It was also discovered by the French chemist PaulEmile Lecoq de Boisbaudran (Paris, France) in 1879. In 1881, Delafontaine determined that his decipium could be resolved into two elements, one of which was identical to Boisbaudran's samarium. In 1901, the French chemist Eugene-Anatole Demarcay showed that this samarium earth also contained europium. See also **Samarium**.

Scandium [CAS: 7440-20-2], the atomic number is 21 and the chemical symbol is Sc. The name derives from the Latin *scandia* for "Scandinavia", where the mineral were found. It was discovered by the Swedish chemist Lars-Fredrik Nilson (Uppsala, Sweden) in 1879 from an ytterbium sample. In the same year, the Swedish chemist Per Theodore Cleve proved that scandium was Mendeleev's hypothetical element "ekaboron", whose properties and position in the Periodic Table Mendeleev had previously predicted. See also **Scandium**.

Seaborgium [CAS: 54038-81-2], the atomic number is 106 and the chemical symbol is Sg. The name derives from the American chemist "Glenn Theodore Seaborg", who led a team that first synthesized a number of transuranium elements. The element Seaborgium was first synthesized by American scientists from the University of California lab in Berkeley, California under Albert Ghiorso, who used the nuclear reaction ^{249}Cf(^{18}O, 4n) ^{263}Sg. The longest half-life associated with this unstable element is 21 second ^{266}Sg. See also **Chemical Elements**.

Selenium [CAS: 7782-49-2], the atomic number is 34 and the chemical symbol is Se. The name derives from the Greek *Selene*, who was the Greek goddess of the moon because the element is chemically found with tellurium (Tellus — the Roman goddess of the earth). It was discovered by the Swedish chemist Jons Jacob Berzelius (Stockholm, Sweden) in 1817, while trying to isolate tellurium in an impure sample. See also **Selenium**.

Silicon [CAS: 7440-21-3], the atomic number is 14 and the chemical symbol is Si. The name was originally silicium because it was thought to be a metal. When this was shown to be incorrect, the name was changed to silicon, which derives from the Latin *silex* and *silicis* for "flint". Amorphous silicon was discovered by the Swedish chemist Jons Jacob Berzelius (Stockholm, Sweden) in 1824. Crystalline silicon was first prepared by the French chemist Henri Sainte-Claire Deville in 1854. See also **Silicon**.

Silver [CAS: 7440-22-4], the atomic number is 47 and the chemical symbol is Ag. The name derives from the Anglo-Saxon word *seofor* and *siolfur*, which is of unknown origin. The chemical symbol, Ag, derives from the Latin *argentum* and Sanskrit *argunas* for "bright". Silver has been known since ancient times. It is mentioned in Genesis. Slag dumps in Asia Minor and on islands in the Aegean Sea indicate that man learned to separate silver from lead as early as 3000 B.C. See also **Silver**.

Silver is one of the elements which has an alchemical symbol, shown below.

Sodium [CAS: 7440-23-5], the atomic number is 11 and the chemical symbol is Na. The name derives from the English soda and Latin *sodanum* for "headache remedy". The chemical symbol Na derives from the Latin *natrium* for "natron (soda in english)". It was discovered in 1807 by the English chemist Humphry Davy (London, England) from electrolyosis of caustic soda (NaOH). Sodium collected at the cathode. Davy isolated potassium by a similar procedure, also in 1807. Shortly after, Thenard and Gay-Lussac isolated sodium by reducing sodium hydroxide with iron metal at high temperatures. See also **Sodium**.

Sodium is one of the elements which has an alchemical symbol, shown below.

Strontium [CAS: 7440-24-6], the atomic number is 38 and the chemical symbol is Sr. The name derives from Strontian, "a town in Scotland". The mineral strontianite is found in mines in Strontian. The element was discovered by the Scottish chemist and physician Thomas Charles Hope in 1792 observing the brilliant red flame color of strontium. It was first isolated by the English chemist Humphry Davy in 1808. See also **Strontium**.

Sulfur [CAS: 7704-34-9], the atomic number is 16 and the chemical symbol is S. The American name sulfur was preferred to the English name sulphur because many languages have a spelling using an "f" and the origin of the name is obscure. The name derives from the Latin *sulfurium* or *sulphurium* and the Sanskrit *sulveri*. Sulfur was known as *brenne stone* for "combustible stone" from which brim-stone is derived. Assyrian texts dated around 700-600 BC refer to it as the "product of the riverside", where deposits could be found. In the 9th century BC, Homer mentioned "pest-averting sulphur". In 424 BC, the tribe of Bootier destroyed a city's walls using a burning mixture of coal, sulphur, and tar. Around the 12th century, the Chinese, probably, discovered gun powder (a mixture of potassium nitrate, KNO_3, carbon, and sulphur). In 1809, the French chemists, Louis-Joseph Gay-Lussac and Louis-Jacques Thenard proved the elemental nature of sulfur. See also **Sulfur**.

Sulfur is one of the elements which has an alchemical symbol, shown below.

Tantalum [CAS: 17440-25-7], the atomic number is 73 and the chemical symbol is Ta. The name derives from the Greek "Tantalos", for the mythological character who was banished to Hades, the region of lost souls where he was placed up to his chin in water, which receded whenever he tried to drink it and under branches of fruit, which drew back whenever he tried to pick their fruit. This name was selected because of the insolubility of tantalum in acids, thus when placed in the midst of acids it is incapable of taking any of them up. It was discovered by the Swedish chemist and mineralogist Anders-Gustav Ekeberg in 1802 (see **Niobium**).

Technetium [CAS: 17133-76-7], the atomic number is 43 and the chemical symbol is Tc. The name derives from the Greek technetos for "artificial". The claims of discovery of this element are extensive. It was first thought to be found in platinum ores in 1828 and was named polinium but it was actually impure iridium. In 1846 an element ilmenium was claimed to be found in minerals and after further work, the author claimed another element neptunium (not to be confused with element 93). Ilmenium was determined to be impure niobium. In 1847, pelopium was claimed as a new element but it was also found to be impure niobium. In 1877, a new element, davyum (in honor of Humphry Davy) was claimed in platinum ore but it was determined to be a mixture of iridium, rhodium and iron. In 1896, anew element lucium was claimed to be found but it was determined to be yttrium. In 1909, the element nipponium was claimed to be isolated from various minerals but the claim was never substantiated and it is now argued to be element 75 (rhenium) and not element 43 (technetium). Finally, in 1925, the element masurium was claimed to be found in platinum ores by Ida Noddack-Tacke, Walter Noddack and Otto Berg. They were not able to isolate weighable amounts of the element, so their claim was also never verified. Technetium was first synthesized in 1937 by Italian physicists Carlo Perrier and Emilio Segre from the Royal University of Palermo in a molybdenum sample, which was bombarded with deuterons (2H) to produce ^{95m}Tc and ^{97m}Tc, using the reactions ^{94}Mo(d,n)^{95m}Tc and ^{96}Mo(d,n)^{97m}Tc. The longest half-life associated with this unstable element is 6.6 million year ^{98}Tc.

Tellurium [CAS: 13494-80-9], the atomic number is 52 and the chemical symbol is Te. The name derives from the Latin Tellus, who was the "Roman goddess of the earth". It was discovered by the Roumanian mine director Franz Joseph MUller von Reichenstein in 1782 and overlooked for sixteen years until it was first isolated by German chemist Martin-Heinrich Klaproth in 1798. The Hungarian chemist Paul Kitaibel independently discovered tellurium in 1789, prior to Klaproth's work but after von Reichenstein.

Terbium [CAS: 7440-27-9], the atomic number is 65 and the chemical symbol is Tb. The name derives from the "village of Ytterby" in Sweden, where the mineral ytterbite (the source of terbium) was first found. It was discovered by the Swedish surgeon and chemist Carl-Gustav Mosander in 1843 in an yttrium salt, which he resolved into three elements. He called one yttrium, a rose colored salt he called terbium and a deep yellow peroxide he called erbium. The chemist Berlin detected only two earths in yttrium, i.e., yttrium and the rose colored oxide he called erbium. In 1862, the Swiss chemist Marc Delafontaine reexamined yttrium and found the yellow peroxide. Since the name erbium had now been assigned to the rose colored oxide, he initially called the element mosandrum (after Mosander) but he later reintroduced the name terbium for the yellow peroxide. Thus the original names given to erbium and terbium samples are now switched. Since Bunsen spectroscopically examined Mosander's erbium (now terbium) sample and declared that it was a mixture, the question of who actually discovered terbium, Mosander or Delafontaine remains unresolved to this day.

Thallium [CAS: 7440-28-0], the atomic number is 81 and the chemical symbol is TI. The name derives from the Greek thallos for "green shoot or twig" because of the bright green line in its spectrum. It was discovered by the English physicist and chemist William Crookes in 1861. The metal was first isolated by the French chemist Claude-Auguste Lamy in 1862.

Thorium [CAS: 7440-29-1], the atomic number is 90 and the chemical symbol is Th. The name derives from Thor, the "Scandanavian god of thunder". It was discovered in the mineral thorite (ThSiO_4) by the Swedish chemist Jons Jacob Berzelius in 1828. It was first isolated by the chemists D. Lely Jr. and L. Hamburger in 1914.

Thulium [CAS: 7440-30-4], the atomic number is 69 and the chemical symbol is Tin. The name derives from Thule, the earliest name for the northern most part of the civilized world — "Scandanavia (Norway, Sweden and Iceland)". It was discovered in 1879 by the Swedish chemist Per Theodor Cleve in a sample of erbium mineral. It was first isolated by the American chemist Charles James in 1911.

Tin [CAS: 7440-31-5], the atomic number is 50 and the chemcial symbol is Sn. The name derives from the AngloSaxon tin of unknown origin. The chemical symbol, Sn, is derived from the Latin stannum for alloys containing lead. The element was known in prehistoric times.

Titanium [CAS: 7440-32-6], the atomic number is 22 and the chemical symbol is Ti. The name derives from the Latin titans, who were the mythological "first sons of the earth". It was originally discovered by the English clergyman William Gregor in the mineral ilmenite ($FeTi0_3$) in 1791. He called this iron titanite menachanite for the Menachan parish where it was found and the element menachin. It was rediscovered in 1795 by the German chemist Martin Heinrich Klaproth, who called it titanium because it had no characteristic properties to use as a name. Titanium metal was first isolated by the Swedish chemists Sven Otto Pettersson and Lars Fredrik Nilson.

Tungsten [CAS: 7440-33-7], the atomic number is 74 and the chemical symbol is W. The name derives from the Swedish tung sten for "heavy stone". The chemical symbol, W, is derived from the German wolfram, which was found with tin and interferred with the smelting of tin. It was said to eat up tin like a wolf eats up sheep. In 1949, IUPAC's CNIC officially adopted wolfram as the scientific name for the element and reserved tungsten for the commercial name, similar to the use of iron and steel. By 1951, the chemical community erroneously thought that the name tungsten had been eliminated. A world-wide protest resulted in the CNIC reverting back to the name tungsten pending a further review, which has never occurred. The element was discovered by the Swedish phaiinacist and chemist Carl-Wilhelm Scheele in 1781. Tungsten metal was first isolated by the Spanish chemists Don Fausto d'Elhuyar and his brother Don Juan Jose d'Elhuyar in 1783.

Ununbium [CAS: 54084-26-3], pronounced as oon-oon-BI-em. The atomic number is 112 and the temporary chemical symbol is Uuh. This element is named according to the systematic IUPAC nomenclature (see above). This element was first synthesized in a February 1996 experiment by a multi-national team of scientists working at the GSI (Heavy Ion Research Center) in Darmstadt, Germany. The scientific teams were from GSI, Darmstatdt, the Joint Institute for Nuclear Research (JINR), Dubna, Russia, the Comenius University in Bratislava, Slovakia and the University of Jyvaskyla, Finland. The teams used the nuclear reaction $^{208}Pb(^{70}Zn, n)\ ^{277}112$. The longest half-life associated with this unstable element is 11 minute $^{285}112$.

Ununhexium [CAS: 54100-71-9], pronounced as oon-oon-HEX-i-em. The atomic number is 116 and the temporary chemical symbol is Uuh. This element is named according to the systematic IUPAC nomenclature (see above). This element was first synthesized in a July 2000 experiment at the Joint Institute for Nuclear Research (JINR), Dubna, Russia by a group of Russian scientists from JINR and a group of American scientists from the Lawrence Livermore Laboratory (LNL) in Livermore, California, USA. The group used the nuclear reaction $^{248}Cm\ (^{48}Ca, 4n)\ ^{292}116$. The longest half-life associated with this unstable element is 0.03 second $^{292}116$.

Ununpentium [CAS: 54085-64-2], pronounced as oon-oon-PENT-i-em. This element is named according to the systematic IUPAC nomenclature (see above). The atomic number is 115 and the temporary chemical symbol is Uup. Experiments resulting in the formation of element 115 were reported in February 2004 following experiments carried out between 14 July — 10 August 2003 involving scientists at Dubna (Joint Institute for Nuclear Research at the U400 cyclotron with the Dubna gas-filled recoil separator, DGFRS) in Russia in a collaboration also involving scientists from the Glenn T. Seaborg Institute and the Chemical Biology and Nuclear Science Division at the Lawrence Livermore National Laboratory, USA. Only four nuclei were identified and the claim has not yet been ratified, but the results are now published in a reputable peer-reviewed journal. See also Oganessian , Y.T. et al. "Experiments on the Synthesis of Element 115 in the reaction $^{243}Am\ (^{48}Ca, xn)\ ^{291-x}115$," *Physical Review C*. 69, 021601(R) (February 2004).

Ununquadium [CAS: 54085-16-4], pronounced as oon-oon-QUAD-i-em. This element is named according to the systematic IUPAC nomenclature (see above). The atomic number is 114 and the temporary chemical symbol is Uuq. This element was reported informally in January 1999 following a November-December 1998 experiment by a multi-national team of scientists working at the Joint Institute for Nuclear Research (JINR), Dubna, Russia. The scientific teams were from JINR and the Lawrence Livermore Laboratory in Livermore, California, USA. The teams used the nuclear reaction $^{244}Pu(^{48}Ca, 3n)\ ^{289}114$. The longest halflife associated with this unstable element is 21 second $^{289}114$.

Ununtrium [CAS: 54084-70-7], pronounced as oon-oon-TRI-em. The atomic number is 113 and the temporary chemical symbol is Uut. This element is named according to the systematic IUPAC nomenclature (see above). Scientists from the Glenn T. Seaborg Institute and the Chemical Biology and Nuclear Science Division at the Lawrence Livermore National Laboratory, in collaboration with researchers from the Joint Institute for Nuclear Research in Russia (JINR), have discovered the two newest super heavy elements, element 113 and element 115.

In experiments conducted at the JINR U400 cyclotron with the Dubna gas-filled separator between July 14 and Aug. 10, 2003, the team of scientists observed atomic decay patterns, or chains, that confirm the existence of element 115 and element 113. In these decay chains, element 113 is produced via the alpha decay of element 115. The results have been accepted for publication in the Feb. 1, 2004 issue of *Physical Review C*.

On September 28, 2004, a team of Japanese scientists declared that they succeeded in synthesizing the element 113. See also Morita et al: "Experiment on the Synthesis of Element 113 in the Reaction: $^{209}Bi + ^{70}Zn \rightarrow ^{278}113 + n$," *J. Phys. Soc. Jpn.* (ext) Vol. 73, No.10, page 2593.

If confirmed, the new element, will be the first manmade element created by Japanese, according to Kosuke Morita and his team at Japan's physical and chemical research institute. The team would have the right to name the superheavy element in the periodic table, and japonium is a candidate name, Morita said.

Uranium [CAS: 7440-61-1] the atomic number is 92 and the chemical symbol is U. The name derives from the planet Uranus, which in Roman mythology was "Father Heaven". The German chemist MartinHeinrich Klaproth discovered the element in 1789, following the German/English astronomer William Hershel's discovery of the planet in 1781. The metal was first isolated by the French chemist Eugene-Melchior Peligot in 1841.

Vanadium [CAS: 7440-62-2], the atomic number is 23 and the chemical symbol is V. The name derives from the "Scandanavian goddess of love

and beauty", Freyja Vanadis, because of its many beautiful multicolored compounds. It was discovered by the Swedish physician and chemist Nils-Gabriel Sefstrom in 1830. It had originally been discovered by the Spanish mineralogist Andres Manuel del Rio y Fernandez in 1801, who named it erythronium, after the plant of that name whose flowers have many beautiful colors. Del Rio later decided that it was really chromium in his lead sample, however his lead sample was later shown to have vanadium in it. Vanadium metal was first isolated by the English chemist Henry Enfield Roscoe in 1869.

Xenon [CAS: 7440-63-3], the atomic number is 54 and the chemical symbol is Xe. The name derives from the Greek xenon for "the stranger". It was discovered by the Scottish chemist William Ramsay and the English chemist Morris William Travers in 1898 in a liquified air sample.

Ytterbium [CAS: 7440-64-4], the atomic number is 70 and the chemical symbol is Yb. The name derives from the "Swedish village of Ytterby", where the mineral ytterbite (the source of ytterbium) was originally found. It was discovered by the Swiss chemist Jean-Charles Galissard de Marignac in 1878 in erbium nitrate from gadolinite (ytterbite renamed). In 1907, Carl Auer von Welsbach determined that ytterbium was actually two elements, which he named aldebaranium and cassiopeium. At the same time and independently, George Urbain obtained two elements from ytterbium, which he named neoyterbium and lutecium. Urbain's name of neoyyterbium was accepted over Auer von Welsbach' name of aldebaranium. The name was later shortened back to ytterbium. (See the discussion of the Urbain and Auer von Welsbach priority dispute under lutetium).

Yttrium [CAS: 7440-65-5], the atomic number is 39 and the chemical symbol is Y. The name of this element originally given by Gadolin was ytterbium and it was later shortened to yttrium by Anders Gustav Eckberg. The name derives from the "Swedish village of Ytterby", where the mineral gadolinite was found. In 1794, the Finnish chemist Johan Gadolin discovered yttrium in the mineral ytterbite, which was later renamed gadolinite for Gadolin. Later another element was given the name ytterbium that Gadolin had proposed. The Swedish surgeon and chemist Carl-Gustav Mosander separated the element in 1843.

Zinc [CAS: 7440-66-6], the atomic number is 30 and the chemical symbol is Zn. The name derives from the German zink of unknown origin. It was first used in prehistoric times, where its compounds were used for healing wounds and sore eyes and for making brass. It was recognized as a metal as early as 1374.

Zirconium [CAS: 7440-67-7], the atomic number is 40 and the chemical symbol is Zr. The name derives from the Arabic zargun for "gold-like". It was discovered in zirconia by the German chemist MartinHeinrich Klaproth in 1789. Zirconium was first isolated by the Swedish chemist Jons Jacob Berzelius in 1824 in an impure state and finally by the chemists D. Lely Jr. and L. Hamburger in a pure state in 1914.

CHEMICAL ENERGY. Energy produced or absorbed in the process of a chemical reaction. In such a reaction, energy losses or gains usually involve only the outermost electrons of the atoms or ions of the system undergoing change; here a chemical bond of some type is established or broken without disrupting the original atomic or ionic identities of the constituents. Chemical changes, according to the nature of the materials entering into the change, may be induced by heat (thermochemical), light (photochemical), and electric (electrochemical) energies.

CHEMICAL EQUATION. By means of chemical formulas, the changes occurring during a chemical reaction can be expressed as an equation. Thus the reaction of 1 mole of sulfur with 1 mole of oxygen to produce 1 mole of sulfur dioxide is written as

$$S + O_2 \longrightarrow SO_2$$

The arrow is preferred to the equality sign, which does not emphasize the direction of the reaction. In addition to the identity of the reactants and products, the equation shows the number of atoms entering into the reaction, either in the atomic state or as constituents of molecules. It also shows the number of moles of each reactant and product, so that by use of the table of atomic weights, the relative masses can be computed.

Since the principle of conservation of masses applies to chemical reactions, coefficients must often be used in writing chemical reactions so that the number of atoms of products is equal to the number of atoms of reactants. An example is the reaction of *two* moles of hydrogen with *one* mole of oxygen to form *two* moles of water

$$2\ H_2 + O_2 \longrightarrow 2\ H_2O$$

In writing such equations, a convenient procedure is to write first an expression containing only the formulas, and then to add the smallest coefficients that will give the same number of atoms of products as of reactants. This operation is called balancing the equation.

Equilibrium reactions, such as that of acetic acid and ethyl alcohol to form ethyl acetate and water, which is cited in the entry on **Chemical Reaction Rate**, are indicated by use of the double arrow:

$$CH_3COOH + C_2H_5OH \rightleftharpoons HOH + CH_3COOC_2H_5$$

Reactions that result in the precipitation of a solid or the evolution of a gas are sometimes denoted by vertical arrows:

$$AgNO_3 + NaCl \longrightarrow AgCl \downarrow + NaNO_3$$

$$Na_2CO_3 + 2\ HCl \longrightarrow CO_2 \uparrow + H_2O + 2\ NaCl$$

This information about the state of the products may also be denoted by writing after their formulas the expressions (s), (l), or (g).

In some cases, as in reactions in electrochemical cells or other reactions involving oxidation-reduction, the half reactions of the ions are useful. Consider the Daniell cell, which consists of a zinc electrode in a zinc sulfate solution, and a copper electrode in a copper solution, the two solutions being separated by a porous partition. The half reactions are

$$Zn \longrightarrow Zn^{2+} + 2e^-$$

$$Cu^{2+} + 2e^- \longrightarrow Cu$$

so that the overall reaction is

$$CuSO_4 + Zn(s) \longrightarrow ZnSO_4 + Cu(s)$$

The more difficult oxidation-reduction equations can often be written more easily by use of the Stock system of oxidation numbers, which are positive or negative valences or charges. Consider the reaction of potassium dichromate, $K_2Cr_2O_7$, with potassium sulfite, K_2SO_3, in acid solution to form chromium(III) sulfate, $Cr_2[SO_4]_3$, and potassium sulfate, K_2SO_4. The unbalanced expression for the ionic reaction is

$$Cr_2O_7^{2-} + SO_3^{2-} \longrightarrow 2\ Cr^{3+} + SO_4^{2-}$$

Since the oxidation number of the combined oxygen atom is 2- throughout, that of the chromium atom in $Cr_2O_7^{2-}$ is 6+, that of the Cr^{3+} ion is obviously 3+, that of the sulfur atom in SO_3^{2-} is 4+, and that of the sulfur atom in SO_4^{2-} is 6+. The total loss in oxidation number by the two chromium atoms is therefore $(2 \times 6) - (2 \times 3) = 6+$. Since this loss must be offset by a gain made by the sulfur atoms, and since one sulfur atom gains 2+, the reaction must require 3 sulfur atoms. Therefore, the next partially balanced equation is written as

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-}$$

Counting the charges in this expression shows that there are 8 negative charges on the left-hand side and a net total of 0 charges on the right-hand side. Therefore, since the reaction occurs in acid solution, requiring that hydrogen ions be present, $8H^+$ are added to the right-hand side to balance the expression electronically, giving

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} + 8\ H^+ \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-}$$

Now it is balanced in number of atoms by counting the hydrogen ions (8 on the left-hand side), and the oxygen atoms (an excess of 4 on the left-hand side). Therefore 4 H_2O is added to the right-hand side:

$$Cr_2O_7^{2-} + 3\ SO_3^{2-} + 8\ H^+ \longrightarrow 2\ Cr^{3+} + 3\ SO_4^{2-} + 4\ H_2O$$

If the molecular equation is wanted, it can be written by grouping the ions, and adding those that did not enter into the ionic equations, i.e., the potassium ions of the salts and the anions of the acid:

$$K_2Cr_2O_7 + 3\ K_2SO_3 + 4\ H_2SO_4 \longrightarrow Cr_2(SO_4)_3 + 4\ H_2O + 4\ K_2SO_4$$

CHEMICAL EQUILIBRIUM. The fundamental law of chemical equilibrium was enunciated by Le Châtelier (1884), and may be stated as follows: If any stress or force is brought to bear upon a system in equilibrium, the equilibrium is displaced in a direction which tends to diminish the intensity of the stress or force. This is equivalent to the principle of least action. Its great value to the chemist is that it enables him to predict the effect upon systems in equilibrium of changes in temperature, pressure, and concentration.

The chemical system hydrogen-nitrogen-ammonia furnishes a notable example of the application of the principle:

$$\underbrace{\underbrace{\text{nitrogen}}_{1\text{ vol.}} + \underbrace{\text{hydrogen}}_{3\text{ vol.}}}_{4\text{ vol.}} \rightleftharpoons \underbrace{\text{ammonia}}_{2\text{ vol.}} + \underbrace{\text{heat}}_{\substack{12{,}000\text{ carlories}\\ \text{per mole ammonia}}}$$

At the temperature 700 °C and pressure 1 atmosphere, the equilibrium percentage of ammonia is 0.03 in the above system, and at 100 atmospheres 2.5. Increase of pressure shifts the equilibrium toward the side of the smaller total volume, at a constant temperature. Decrease of pressure shifts the equilibrium toward the side of the larger total volume, at a constant temperature. Systems of the same initial and final volumes are unaffected, as to equilibrium amounts of materials, by change of pressure.

At the pressure 100 atmospheres, and temperature 700 °C, the equilibrium percentage of ammonia is 2.5 in the above system, at 600 °C it is 5, at 500 °C it is 10. Increase of temperature shifts the equilibrium in the direction which absorbs heat, at a constant pressure. Decrease of temperature shifts the equilibrium in the direction which evolves heat (van't Hoff's principle, 1884).

At constant pressure and temperature, the equilibrium is shifted away from the side subjected to an increase in concentration of any constituent, or toward the side subjected to a decrease in concentration of any constituent. (See also **Chemical Reaction Rate**.) For the qualitative effect of temperature change, one may visualize the heat of an equilibrium reaction as material, and an increase of temperature (heat intensity) as operating to increase the concentration of "heat material," thus shifting the equilibrium away from the side of its increased concentration, and conversely. It is possible, knowing the heat of reaction, Q, on the assumption that the heat of reaction is constant between two given (absolute) temperatures, T_1 and T_2, to calculate the equilibrium constant K_2 (at T_2) when the equilibrium constant K_1 (at T_1) and the gas constant, R (equals 2 calories per mole) are known, by the application of van't Hoff's equation:

$$\log_{10} K_2 - \log_{10} K_1 = \frac{Q}{2.3 \times R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

In this way the quantitative effect of temperature change on the state of equilibrium may be calculated.

In reactions of the ammonia synthesis type, to which sulfur trioxide from sulfur dioxide plus oxygen also belongs, the rate of reaction decreases with lowering of the temperature as the conversion is increased. There is, in such types of reactions, a limit to the practicable lowering of the temperature. The finding of a positive catalyzer for a given reaction of this sort permits the operation to gain the advantage of equilibrium conversion at the lower temperature as well as the increased rate of reaction at that temperature due to the presence of the catalyzer. (See also **Chemical Reaction Rate**.) The time yield of product is, therefore, very important, and, with a catalyzer, the space-time yield.

Systems in equilibrium are divided into two great divisions, according to whether they are (A) homogeneous, that is, chemically and physically uniform throughout, or (B) heterogeneous, that is, not uniform throughout but consisting of two or more phases. Each phase is a homogeneous, physically distinct, and mechanically separable portion of a system. For example, ice, water, water vapor are three different phases (solid, liquid, gas) of the substance water. There can be only one gas phase of a system, and only one liquid phase where a *single* homogeneous solution is present. But the number of liquid and of solid phases in general is limited by the number of components (not constituents) of a system. The number of components is the least number of constituents *independently* variable and requisite to compose each and every phase. For example, the system consisting of saturated solution in water, H_2O, of sodium sulfate, Na_2SO_4, plus solid sodium sulfate decahydrate, $Na_2SO_4 \cdot 10H_2O$, plus water vapor consists of three phases, (a) gas, (b) solution, (c) solid sodium decahydrate. The *least* number of constituents independently variable in amount *and* requisite to compose each and every phase is two, namely, Na_2SO_4 and H_2O. These, therefore, are the two components of this system. Since zero and negative as well as positive amounts of compounds are permitted in expressing the composition of each phase of any system, the three phases of this system are composed of the following components:

gas phase, zero	Na_2SO_4 plus H_2O
liquid phase,	Na_2SO_4 plus H_2O
solid phase,	Na_2SO_4 plus H_2O

The number of components in the ice-water–water-vapor system is one, namely, H_2O.

To systems in which equilibrium depends solely upon the variables, (1) composition of each and every phase, (2) temperature, and (3) pressure, the phase rule (Willard Gibbs, 1874) applies: The number of variables, that is (1) the number of components, C, plus (2) temperature plus (3) pressure, above, equals the number of phases, P, plus the number of degrees of freedom, F. The number of degrees of freedom of a system is the least number of the above variables which must be arbitrarily fixed in order to define the condition of the system:

$$C + 2 = P + F$$

The phase rule applies to true equilibrium systems, where the equilibrium can be reached from either side, and, furthermore, takes no account of the time involved to attain equilibrium. The phase rule is a qualitative statement, whereas the law of mass action (concentration effect) is quantitatively applicable to those equilibrium systems where the reaction which occurs may be considered to take place in a homogeneous system, e.g., gas phase, or solution phase. (See also **Chemical Reaction Rate**.).

In a one-component system, $P + F = 3$, and physical changes only occur. When only one phase is present, for example, liquid water (no vapor, no solid), the system is bivariant. That is, two variables — temperature and pressure — may be independently changed over a range. When a second phase, either vapor or solid, appears through a sufficient change of temperature or pressure or both, or when two phases are originally present, the system is univariant. That is, one variable — either temperature or pressure — may be independently changed over a range. When the third phase appears or when three phases are originally present, the system is invariant. That is, a change of either temperature or pressure destroys the equilibrium, and the disappearance of one of the phases occurs. A system of one component in three phases is invariant and the conditions are represented by a point known as the triple point. The triple point for water is 0.007 °C, 4.6 millimeters mercury pressure. When the total pressure is one atmosphere (760 millimeters) the equilibrium temperature of water-ice is 0.000 °C, and when the water vapor pressure is one atmosphere the equilibrium temperature of water–water vapor is 100.000 °C.

If, in dealing with any system, the gas phase or pressure may be neglected, on account of constancy or slightness of effect, the phase rule is simplified for practical purposes to $C + 1 = P + F$, and, if both may be neglected, to $C = P + F$.

Many two- and three-component systems have been studied and recorded in detail. The iron-carbon system is one that has attracted much attention and been of great value in iron metallurgy.

In 1977, Professor Ilya Prigogine of the Free University of Brussels, Belgium, was awarded the Nobel Prize in chemistry for his central role in the advances made in irreversible thermodynamics over the last three decades. Prigogine and his associates investigated the properties of systems far from equilibrium where a variety of phenomena exist that are not possible near or at equilibrium. These include chemical systems with multiple stationary states, chemical hysteresis, nucleation processes which give rise to transitions between multiple stationary states, oscillatory systems, the formation of stable and oscillatory macroscopic spatial structures, chemical waves, and the critical behavior of fluctuations. As pointed out by I. Procaccia and J. Ross (*Science*, **198**, 716–717, 1977), the central question concerns the conditions of instability of the thermodynamic branch. The theory of stability of ordinary

differential equations is well established. The problem that confronted Prigogine and his collaborators was to develop a thermodynamic theory of stability that spans the whole range of equilibrium and nonequilibrium phenomena.

CHEMICAL FORMULA. The formulas of chemistry constitute a shorthand notation used to represent the composition by weight, the molecular properties, the characteristic chemical reactions or at times even the ordering of the atoms in space of the elements which go to make up the chemical compound. Chemical formulas are classified into empirical, molecular, structural, or configurational, the order given being that of increasing content of information. The meaning of empirical and the molecular formulas is explained in the entry on **Chemical Composition**, which also describes methods for determining the formulas for some simple compounds. See also **Atomic Mass**. Their determination for compounds in general, especially if they are present in mixtures, requires considerable experimental work. The first step consists of the isolation of a pure chemical compound. Chemical purification can be obtained by methods such as crystallization, distillation, adsorption, and sublimation. Some of the criteria of purity a substance must satisfy are constancy and sharpness of melting point and boiling point on repeated purification. As an example, let us assume that we have succeeded in purifying a solid compound which we shall call tartaric acid and whose formula we wish to determine.

The second step consists in a qualitative and quantitative analysis of the compound. In the case of tartaric acid, qualitative analysis tells us that the compound contains carbon, oxygen and hydrogen, while quantitative analysis shows that the proportions are 48 parts by weight of carbon, 96 of oxygen, and 6 of hydrogen. To obtain the empirical formula, one divides each proportion by the atomic weight of the particular element, obtaining in this way a set of numbers that can be represented by a ratio of small integers. The simplest ratio of integers is commonly used to indicate as subscripts on the right of the chemical symbol of the element to represent the empirical formula. In the case of tartaric acid, the atomic weights are approximately 12 for carbon, 16 for oxygen, and 1 for hydrogen. Dividing the percentages as determined by analysis by the atomic weights, we get:

$$\text{carbon } \frac{48}{12} = 4.00$$

$$\text{oxygen } \frac{96}{16} = 6.00$$

$$\text{hydrogen } \frac{6}{1} = 6.00$$

The set of numbers is 4,6,6 and can be presented, in this case, by the ratio of integers 2:3:3. The empirical formula is therefore $C_2O_3H_3$. Empirical formula is thus only a convenient method for representing the percentage composition by weight of the different elements in the compound. The third step is the determination of the molecular weight of the compound in question. This allows us to assign to the compound a molecular formula. The molecular weight can be determined in a variety of methods, such as by the determination of the weight of 22.242 liters of the vapor of the substance at 1 atmosphere pressure and 0 °C, temperature. Other methods are based on the differences in the boiling point or freezing point of solutions of known concentration and those of the pure solvent. To determine the molecular formula from the knowledge of the empirical formula and the molecular weight, the following procedure must be followed: Multiply the atomic weight of each element by its subscript, as indicated in the empirical formula, and add the result. On comparison of such a sum with the molecular weight it will be found that the molecular weight is equal to the sum times an integer. To obtain the molecular formula, multiply each subscript in the empirical formula by this integer and obtain a new set of subscripts. We found the empirical formula of tartaric acid was $C_2O_3H_3$. The sum mentioned above is

$$12 \times 2 + 16 \times 3 + 1 \times 3 = 75$$

The molecular weight determined experimentally is 150. The integer multiple is 2, and the molecular formula becomes $C_4O_6H_6$.

The molecular weight of the compound can be obtained from the molecular formula by summing the products obtained by multiplication of the atomic weights of the elements times their subscripts in the molecular formula. The latter contains all the information that the empirical formula contains but in addition specifies the number of atoms in the molecule and also the molecular weight of the substance.

Important as the molecular formula is, it does not describe fully the properties, or even in some cases the identity, of chemical compounds. For example, there are two compounds that have the molecular formula C_2H_6O. They are different in all their properties, both chemical and physical. This difference is due to a difference in the manner in which the atoms are connected in the molecules of the two substances. These differences can be shown only by the use of structural formulas, such as those shown in Fig. 1, in which the valence bonds between the atom are shown. These structural formulas are determined circumstantially, that is, by the chemical reactions into which the compounds enter. (However, their arrangements have been confirmed in many cases by a direct instrumental means such as spectrometric methods, x-ray studies, etc.) These reactions differ markedly for ethyl alcohol and methyl ether. Such compounds which have the same molecular formula but differ due to the arrangements or positions of their atoms are called isomers, and the type just cited, in which the difference is in the grouping of the atoms, are called *functional isomers*. These, and many other types of isomers, are treated in the entry on **Isomerism**.

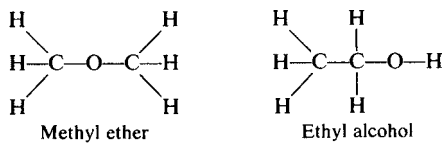

Fig. 1. Examples of structural formulas.

The structural formula is also a shorthand notation for the important chemical reactions of the compound. It can be considered as being built up of a group of organic radicals, i.e., groups of atoms that retain their individuality in the course of certain reactions. Each radical has reactions which are characteristic of its presence in the molecule.

For instance, the carboxyl radical $-C(=O)-OH$ will react with alkali such as sodium hydroxide to form salts $-C(=O)-ONa$ with phosphorus pentachloride to form acid chlorides $-C(=O)-Cl$ with alcohols to form esters; with reducing agents under certain conditions to form successively the aldehyde radical $-C(=O)-H$ and the alcohol radical. Any pound that undergoes such reactions is said to contain a carboxyl group. The number of such carboxyl groups in a molecule can be determined by studying the above reactions quantitatively. On the other hand, if the compound will react: with sodium to give off hydrogen; with phosphorus trichloride to give a halogen substitution product which can be reduced to hydrocarbon; with an oxidizing agent to give an aldehyde or ketone, with organic acids to form esters; and with alcohols to form ethers; then the molecule is said to contain a hydroxyl group $-OH$. Analogously, there are similar characteristic reactions for a variety of radicals. It often happens that the presence of one type of a radical near another type mutually influences their reactivity, but one can consider to the first approximation that the radicals act independently of each other. The structural formula is considered completely established if one can synthesize the compound by simple clear-cut reactions involving no rearrangements on the basis of the proposed formula.

Just as it was stated above that two compounds may have the same molecular formula and yet have quite different structural formulas and properties, so there are also many instances in chemistry of compounds which have the same planar structural formula and yet differ in properties. In such cases their differences in structure can be shown only by three-dimensional formulas or their projections which portray differences in the arrangement in space of the atoms or radicals that make up the molecules of the two compounds.

Thus, in cases where four different atoms or groups are attached to the same atom, it is possible to have two arrangements in space that cannot be made to coincide geometrically. This situation can be demonstrated by

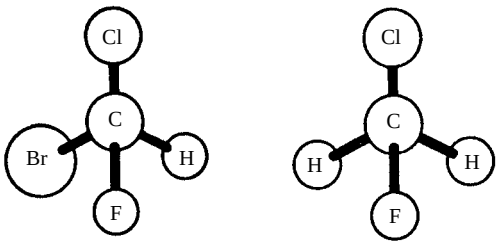

Fig. 2. Formulas to indicate spatial geometry of compounds.

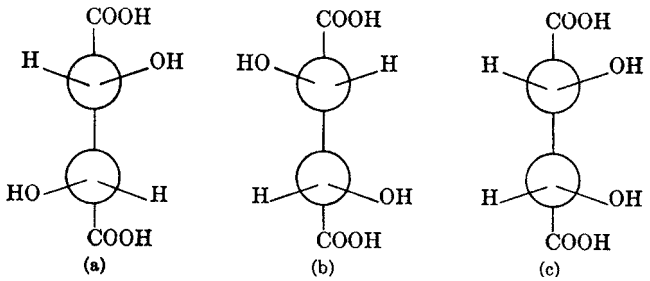

Fig. 3. Formulas to demonstrate stereisomerism.

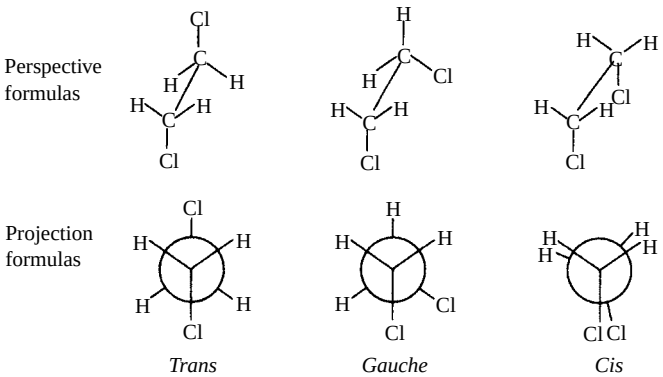

Fig. 4. Perspective and projection type formulas.

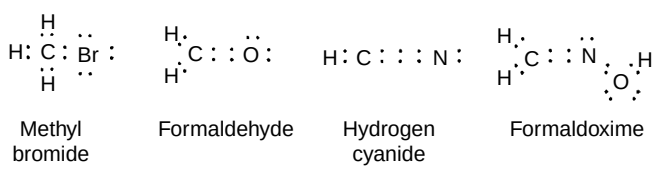

Fig. 5. Formulas to demonstrate bonding.

use of a special type of formula, shown in Fig. 2 for the two forms of the compound fluorochlorobromomethane. This existence of two forms due to a difference in orientation in space is called *stereoisomerism*, and is discussed in the entry on **Isomerism**. It also follows that for compounds containing more than one atom bonded to four unlike groups, the number of different forms increases rapidly, as is shown by the three possible forms of tartaric acid, HOOC−CH-OH−CHOH−COOH, as portrayed by the three formulas shown in Fig. 3.

Still other types of formulas showing the spatial positions of atoms and groups are perspective and projection formulas, as shown in Fig. 4 for the compound 1,2-dichloroethane. These differences are due to differences in conformation, that is, to the various configurations of a molecule, which differ in space by the rotation of two atoms about a single bond.

Another type of formula often written for compounds is the electronic formula, showing the distribution of the valence electrons among the atoms of the molecule, as shown in Fig. 5 and explained under valence and molecule.

CHEMICAL POTENTIALS. Chemical potentials are defined in terms of the entropy by the relationship

$$\mu_i = -T\left(\frac{\partial S}{\partial n_i}\right)_{U,V} \tag{1}$$

Apart from the factor T (the absolute temperature) the chemical potential is equal to the change of the entropy due to the introduction of the mole number **i** into the system, at constant total energy U and volume V. The parentheses in the above equation contain the partial derivative representing this rate of change.

Other independent variables are often much more convenient. One has also

$$\begin{aligned}\mu_i &= \left(\frac{\partial U}{\partial n_i}\right)_{S,V} = \left(\frac{\partial G}{\partial n_i}\right)_{S,p} \\ &= \left(\frac{\partial A}{\partial n_i}\right)_{T,V} = \left(\frac{\partial G}{\partial n_i}\right)_{T,p}\end{aligned} \tag{2}$$

The last member of Equation (2) shows that μ_i is the partial molar quantity associated with the Gibbs free energy, G. Euler's theorem gives then

$$G = \sum_i n_i \mu_i \tag{3}$$

The relation to chemical affinity is also very direct

$$A = -\sum_i v_i \mu_i \tag{4}$$

Note that the roman capital A represents chemical affinity, while the italic capital A symbolizes the Helmholtz free energy (also called work function). It follows that the condition for chemical equilibrium is

$$\sum_i v_i \mu_i = 0 \tag{5}$$

where the v_i are stoichiometric coefficients. This formula expresses the law of mass action. Similarly the condition for two phases α and β to be in equilibrium with respect to species i is

$$\mu_i^\alpha - \mu_i^\beta \tag{6}$$

The chemical potential has then the same value in the two phases. See also **Thermodynamics**.

CHEMICAL REACTION RATE. The chemical composition of a substance is subject to various changes under various conditions, depending upon (1) the nature of the specific substance, (2) the nature of other substances present, and (3) the environment in which it exists (the physical and chemical ambient conditions). Similarly, chemical reaction rates are affected.

The majority of reactions take place between two substances — occasionally one substance only, and sometimes three or more different substances. There are many cases when simple contact of the substances is sufficient to bring about the chemical change, e.g., the rusting of iron in oxygen. In many other cases, the change is not spontaneous, but must be induced, frequently by raising the temperature, as in the burning of fuels. The conditions that are considered important and fundamental are (1) temperature, (2) pressure, (3) medium, if any, (4) catalyzer, if any (5) electric direct current, (6) light. In a given reaction, the change in composition of the substance or substances involved is inherently connected with a change in energy. Thermal, electrical or light energy of a certain potential or intensity and in definite amounts, is requisite to initiate and carry on the reaction, and thermal, electrical or light energy of definite amount is liberated or consumed in the reaction. Every reaction, properly speaking, has both a matter and an energy aspect. While the energy aspect is frequently neglected directly, the conditions must always be in accord with the energy demand, even if apparently not considered. Chemical changes require consideration of three topics, namely, (1) natural rate of chemical reactions, (2) acceleration of the natural rate in the presence of a catalyzer, and (3) the endpoint of chemical reactions. See also **Electrochemistry**; **Photochemistry and Photolysis**; and **Thermochemistry**.

Contemporary Investigations of Reactions and Reaction Rates. The near term and continuing into the early 2000s will witness outstanding progress in the development of a better understanding of chemical reactions and the time frames within which they occur. In this excellent paper

(1985), the late Frederick Kaufman (University of Pittsburgh) stated, "The experimental science of measuring the rates of elementary chemical reactions has advanced to a point where hundreds of such rates either have been determined or are within reach. In a sense, these data give us a global view of chemical reactivity for gas-phase reactions. What this information lacks in detailed, state-to-state insight it more than makes up for in chemical diversity. It is essential that this research be pursued for its own sake rather than just for the sake of providing input data for atmospheric and combustion chemistry (traditional areas of interest), however important these applications are. The existing data bases of elementary-reaction rate constants have not yet been systematically examined for what they tell us about chemical reactivity. In the light of present advances in the techniques for the generation and detection of reactive species, the number of accessible reactions and the range of temperatures and pressures being studied are rapidly increasing and the accuracy of rate measurements is rapidly improving. Strong interaction between theorists and experimentalists has developed but needs to be expanded. What is needed more than anything else is the full realization by the academic community that elementary reaction kinetics is an intellectually exciting field that gives insight into why, how, and how fast chemical reactions take place."

Modern experimental techniques for measuring rate parameters of elementary reactions have transformed the field of gas-phase reaction kinetics from one of indirect inference to one of direct determination. Two general kinds of experimental methods may be cited: (1) In the flash- or laser-photolysis (FP) method, reactive species are produced in a short (10^{-6} to 10^{-8} second) light flash, and their decay resulting from a reaction is monitored in real time by spectroscopic means. (2) In the flow reactor (flowing afterglow) discharge-flow (DF) method, the reactive species are produced continuously in steadily flowing carrier gas (helium or argon) and mixed with other reactants. The rate is determined either by changing the distance over which the reactants are in contact (reaction time) or by changing the concentration of one reactant at constant reaction time. Detailed diagrams of the apparatus used for these experimental methods are beyond the scope of this encyclopedia. They are carefully depicted in the Kaufman (1985) paper listed under additional reading.

As reported by Leone (1985), available laser sources for selective excitation and detection makes it possible to infer many things concerning the dynamics of reactions, such as the particular motions that molecules are likely to undergo during a reaction. The technique makes it possible to interrogate or probe the specific forms of excitation that best lead to chemical reaction, such as vibrational, rotational, or translational motion, or electronic and photo-excitation.

Under ideal circumstances, reactions under investigation are carried out under what is called "single-collision" conditions. These typically require low pressures, so that a product molecule born in a particular state is not modified by subsequent collisions before the time of interrogation has expired. Very short laser pulses usually are used, thus making the time between excitation and interrogation less than 10^{-8} second. However, at this speed, higher pressures can be used so that collisions occurring between formation of a product and its detection and identification can be minimized or essentially eliminated.

One of the fastest reactions reported to date resulted from research at Pennsylvania State University in 1986. It was reported that the time required for the rhodium helide ion ($RhHe^{2+}$) to dissociate into Rh and He was approximately 10^{-13} second, i.e., eight ten-trillionths of a second. Because this kind of interval cannot be resolved by present electronic timer technology, the investigators modified their apparatus to stretch out the reaction time by orders of magnitude. One part of the solution was to use a 4.2 meter evacuated flight tube that lead into an ion detector. Time was determined on the basis of the slight difference in kinetic energy (velocity) of the rhodium ions detected at the end of the flight tube.

Natural Rate of Chemical Reactions. Various factors operate to affect the rate of chemical reactions. By natural rate is understood the rate of a reaction in the absence of a catalyzer. Excluding electrochemical and photochemical reactions, and giving attention to thermochemical reactions only, there are four factors or conditions to be considered, namely, (1) concentration of constituents, (2) temperature, and (3) pressure — important where a gas is involved, (4) nature of the medium, if any.

The general mathematical definition of the rate of a chemical reaction v is

$$v = \frac{d\xi}{dt} \tag{1}$$

where ξ (Greek letter xi) is the extent of reaction, t is time, and the derivative thus represents the rate of change of the extent of reaction.

1. Relation between concentration of reactants and rate of reaction. The rate of a given reaction, at constant temperature and pressure under stated conditions of concentration of the reacting substances, is quantitatively expressible by a velocity constant, which is the fraction of the substances transformed in a unit of time. Many reactions occur instantaneously — true for most reactions in solution in inorganic chemistry — and many others are complicated in subsidiary reactions, so that the velocity constant is measurable in comparatively few cases. The principle, however, holds as stated, whether or not the desired value can be ascertained experimentally.

A simple reaction that was studied by Wilhelmy, and since then by various investigators, is the transformation (hydrolysis) of sucrose $C_{12}H_{22}O_{11}$ in water solution into glucose ($C_6H_{12}O_6$, a polyhydroxy aldehyde) plus fructose ($C_6H_{12}O_6$, a polyhydroxy ketone), which proceeds at a measurable, steady rate in the presence of acid (hydrogen ion). The rate of reaction at any instant is found to be proportional to the amount of sucrose present at that instant.

When a dilute water solution of an ester, such as methyl acetate, is similarly hydrolyzed in the presence of hydrogen ion, the reaction is of the same type. And this statement also applies to the decay of radioactive elements. One of the important radioactive constants is the half-life, that is, the time required for the decay of one-half of the element present at a given instant.

The preceding cases are instances of *first order reactions*, that is, reactions in which the rate depends only upon the concentration of a single molecular or atomic species. They are also *monomolecular reactions*, that is, reactions in which the initial reactant is only of one species, that is, sucrose, or an ester, or a radioactive element. Note that first order reactions are not necessarily monomolecular; thus $H_2 + D_2 \rightleftharpoons 2HD$, is a first order reaction, even though it is called bimolecular because a hydrogen-1 molecule reacts with a hydrogen-2 (deuterium) molecule to form hydrogen deuteride molecules.

We can now introduce a general treatment of the concept of the order of a chemical reaction. A chemical reaction is said to be of the nth order if its rate is directly proportional to the product of n concentrations. Therefore the decomposition of A, if described by the equation

$$\frac{dC_A}{dt} = -\mathrm{k}C_A \tag{2}$$

is a *first order reaction*. Similarly if it is described by the equation

$$\frac{dC_A}{dt} = -\mathrm{k}C_AC_B \text{ or } \frac{dC_A}{dt} = -\mathrm{k}C_A^2 \tag{3}$$

it is a *second order reaction*.

The coefficient k, which appears in (2) or (3), is called the *rate constant*. Generally the temperature variation of a rate constant may be expressed by

$$\mathrm{k} = Pe^{-Q/kT} \tag{4}$$

where k is the rate constant and k is the Boltzmann constant. This equation is called the *Arrhenius equation*.

We now introduce a general treatment of rate of reaction, which is often called the *absolute reaction rate theory*, because its purpose is to calculate the rate in terms of molecular quantities only.

Consider the reaction

$$\mathrm{A} + \mathrm{BC} \longrightarrow; \mathrm{AB} + \mathrm{C} \tag{5}$$

To simplify the discussion, assume that A, B, and C always remain in a straight line. The course of the reaction may then be followed by noting the values of the two interatomic distances r_{AB} and r_{BC}. At the beginning of the reaction r_{AB} is large and r_{BC} is small while at the end of the reaction r_{AB} is small and r_{BC} is large.

Let us introduce the potential energy surface. The representative point of the system moves on this surface along the so-called *reaction coordinate*. The potential energy along the reaction coordinate is represented schematically in Fig. 1. The maximum of the curve corresponds to a situation where three atoms are very close to one another. Moreover this point is a *maximum* along the reaction coordinate but a *minimum* for the direction normal to the reaction coordinate. Indeed the most probable path is the

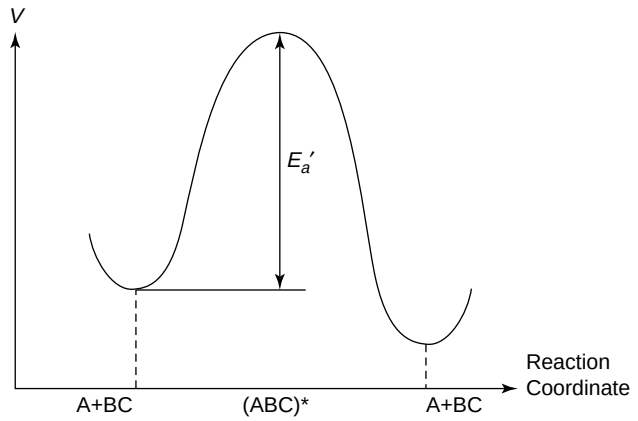

Fig. 1. Potential energy along the reaction coordinate.

path involving the minimum potential energy in going from the initial to the final state.

Therefore the point considered corresponds to a *saddle point* of the energy surface. It is called the *activated complex*.

One may now assume that the reaction rate is the product of the following three factors: (1) the average number of activated complexes; (2) the characteristic frequency of the activated complex (that is, the inverse of its lifetime); and (3) the *transmission coefficient*, K, which is the probability that a chemical reaction takes place after the system has reached the activated state.

Moreover, the number of activated complexes is calculated by the equilibrium assumption.

Using this description of the reaction process one derives the following expression for the reaction constant

$$\mathrm{k} = \mathrm{K}\frac{\phi(T)}{\phi_A(T)\phi_{BC}(T)}\frac{kT}{h}\exp\left(-\frac{E^x}{kT}\right) \tag{6}$$

Here the ϕ terms are the partition function $f(T, V)$, the volume factor being removed

$$f = V\phi \tag{7}$$

ϕ_t corresponds to the activated complex, the degree of freedom associated with the reaction coordinate being removed; k is Boltzmann's constant, h is Planck's constant, E^x is the energy associated with activated complex, or *activation energy* of the reaction.

This expression may also be written in the thermodynamic form

$$\begin{aligned}\mathrm{k} &= \mathrm{K}\frac{kT}{h}\exp\left(-\frac{\Delta G^{\ddagger}}{kT}\right)\\ &= K\frac{kT}{h}\exp[-(\Delta H^{\ddagger} - T\Delta \mathrm{S}^{\ddagger})/kT]\end{aligned} \tag{8}$$

where $\Delta G^{\ddagger}$ is a suitable free energy of activation and $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ the corresponding enthalpy and entropy of activation.

When a reaction involves two different phases, that is, when the system is not homogeneous but heterogeneous, as in reactions between a solid phase, such as zinc or calcium carbonate, and a liquid phase, such as hydrochloric acid solution, the rate of reaction involves consideration of (1) the area of the surface of contact of the solid with the solution, and (2) the rate of diffusion from the surface of the solid, as well as (3) the concentration of hydrogen ion of the acid solution.

When the rate of a chemical process is dependent upon (1) two or more *consecutive* reactions, the observed rate is limited by the rate of the slowest reaction in the series, or (2) two or more *concurrent* reactions, the products are in the same ratio at any instant only when the reactions themselves are of the same rate.

2. Relation between temperature of reactants and rate of reaction. The rate of chemical reaction is increased by an increase in temperature, as is evident from the fact that temperature occurs in the numerators in the foregoing equations.

3. Relation between pressure of reactants, if gaseous, and rate of reaction. Since pressure changes amount to concentration changes in such systems, the behavior is as described above under concentration.

4. Relation between nature of the medium and rate of reaction. Very slight changes in the nature of the medium greatly affect the rate of a chemical reaction, but attempts to relate any physical property of a solvent with the effect observed on the rate of a given reaction appear to have proved unsuccessful.

One should mention here that in reactions involving ions, the effects of electrolytes can be put into two principal categories: (a) primary salt effect and (b) secondary salt effects.

Primary salt effects refer to the effects of electrolyte concentration on the activity coefficients. Secondary salt effects are those concerned with the actual changes in concentration of the reacting species resulting from the addition of electrolytes.

BrØnsted has shown that the variation in specific rate with ionic strength depends on the magnitude and sign of the ionic charges. Thus three main types of primary salt effect in reactions of two species can be distinguished. If the products of the signs of the charges are positive, the velocity of the reaction increases with increasing ionic strength:

$$\mathrm{Co[(NH_3)_5Br]^{2+} + Hg^{2+}} (+2 \times +2 = +4)$$

or

$$\mathrm{S_2O_8^{2-} + I^-} \qquad (-2 \times -1 = +2)$$

or

$$\mathrm{BrCH_2COO^- + S_2O_3^{2-}} \quad (-1 \times -2 = +2)$$

If the products of the charges are negative the velocity of the reaction decreases with increasing ionic strength:

$$\mathrm{Co[(NH_3)_5Br]^{2+} + OH^-} (+2 \times -1 = -2)$$

or

$$\mathrm{H_2O_2 + H^+ + Br^-} (+1 \times -1 = -1)$$

In the third category where the product of the ionic charges is zero, the ionic concentration has no or very little effect on the velocity of the reaction, particularly in dilute solution, as in the case of

$$\mathrm{[Cr(NH_2CONH_2)_6]^{3+} + 6\ H_2O \longrightarrow [Cr(H_2O)_6]^{3+} + 6\ NH_2CONH_2} \qquad (+3 \times 0 = 0)$$

BrØnsted showed the inadequacy of both the classical and the activity theories of rate of certain reactions. He proposed a new theory postulating that when ions or molecules react, they first form an unstable critical complex, which then decomposes to give the reaction products. The reaction that determines the velocity of a chemical change consists in the formation of that unstable critical complex.

Summarizing, the rates of chemical reactions are subject to highly specific influences in each case, as has been abundantly demonstrated by experimental investigations, and recognized in numerous legal battles in chemical patent suits.

Acceleration of the Natural Rate of Chemical Reactions in the presence of a positive or negative catalyzer. When, in the presence of a given substance, the natural rate of a chemical reaction is changed, either increased or decreased, the given substance is called a catalyzer. Examples are numerous. (1) When a gas-lighter of the type known as platinum black, the active part of which consists of very finely divided platinum, is held in a stream of hydrogen or city gas, the gas is ignited in air. Platinum is a catalyzer for this reaction, and causes ignition to take place at a temperature much lower than by subjecting to fire. (2) The changing of sulfur dioxide into sulfur trioxide is accomplished by passing a mixture of sulfur dioxide and air (one-fifth oxygen) over asbestos coated with finely divided platinum. The temperature required is much lower by the use of platinum catalyzer than without its use. (3) Solutions of sulfites are subject to oxidation to sulfates by oxygen upon allowing to stand in air. The addition of sugar or glycerol retards the speed of this reaction. These substances act in this case as negative catalyzers. (4) The combination of nitrogen and hydrogen gases under high pressure to form ammonia gas is accomplished at a lower temperature in the presence of a catalyzer than in its absence, thus increasing the yield of ammonia (see also **Equilibrium**). One of the catalyzers is composed of iron, intimately mixed with 1% aluminum oxide and 1% potassium oxide. Iron is a catalyzer for this reaction, but is more active as such in the presence of aluminum oxide and potassium oxide, which are spoken of as promoters, a sort of catalyzer of a catalyzer. (5) The hydrogenation of liquid fatty oils and of oleic acid is conducted in the presence of finely divided nickel as a catalyzer. (6) Enzymes are very specific catalyzers, "the most selective and delicate of all known catalysts

(Hilditch)," at ordinary temperatures, say 25 to 30 °C. Dextroglucose is converted into ethyl alcohol in the presence of the enzyme (zymase) of yeast, and ethyl alcohol into acetic acid (vinegar) in the presence of the enzyme of *Mycoderma aceti*. (7) Nitric acid reacts slowly with copper metal, but the rate of reaction is accelerated more and more as nitrogen tetroxide (catalyzer) is formed in the solution. This is an example of autocatalysis, wherein the reaction brings about the formation of its own catalyzer. (8) Arsenic-containing substances are extreme negative catalyzers, called inhibitors or poisons, of platinum catalyzer.

When the catalyzer is a solid substance, the greatest difficulty in use is to maintain a clean surface. The presence of a positive catalyzer enables a reaction to proceed more rapidly at a lower temperature than corresponds to the natural rate of the reaction. This increases the amount of substances converted in a given time, decreases the demands as to temperature resistance of materials of construction of the apparatus, and frequently makes possible a state of equilibrium more favorable to the yield of desired material.

The End-point of Chemical Reactions. If a chemically reactive system is isolated from the rest of the universe at a constant temperature and pressure, a definite end-point is often attained short of the complete transmutation of reactants into resultants. In order to be certain that this end-point (short of complete transmutation) is what is known as the equilibrium point, the equilibrium must be approached from both directions, e.g., $A + B \rightarrow C + D$ and $C + D \rightarrow A + B$. If the equilibrium constant (see treatment below) is the same when approached from both directions, then the reaction is one of true chemical equilibrium. Such equilibrium reactions are also referred to as balanced or reversible reactions. In such reactions the extent of the chemical change is proportional to the concentrations of all the reactants — reactants and resultants being interchangeable, depending upon the direction of the reaction. (Generalization of Guldberg and Waage, 1864, called Law of Mass Action, or more correctly Law of Concentration Effect. Reaction studied by Guldberg and Waage (1867): Barium sulfate plus potassium carbonate plus barium carbonate plus potassium sulfate.)

A classical case, frequently cited, is that investigated by Berthelot in 1963. When 1 mole (60 grams) of acetic acid CH_3COOH and 1 mole (46 grams) of ethyl alcohol C_2H_5OH, both of which substances are soluble in water, are mixed, a reaction takes place which results in the formation of water and ethyl acetate ester, which is likewise in the ratio of 1 mole (18 grams) of water, and 1 mole (88 grams) of ethyl acetate $CH_3COOC_2H_5$. On the other hand, when 1 mole of water and 1 mole of ethyl acetate ester are mixed, a reaction takes place which results in the formation of acetic acid and ethyl alcohol in the ratio of 1 mole of acetic acid and 1 mole of ethyl alcohol. Three important observations have resulted from the detailed study of this reaction, namely: (1) the reaction between acetic acid and ethyl alcohol as reactants proceeds at such a rate that the fraction $\frac{0.005}{5}$ of the amount present at any instant reacts, at 6 to 9 °C, in 1 day to form equivalent amounts of water and ethyl acetate ester; (2) the reaction between water and ethyl ester as reactants proceeds at such a rate that the fraction 0.00144 of the amount present at any instant reacts, at 6 to 9 °C, in 1 day to form equivalent amounts of acetic acid and ethyl alcohol; and (3) the end-point of each reaction is the same, that is, the reaction is one of true chemical equilibrium, and the resulting equilibrium mixture contains, in each case, 0.33 mole acetic acid plus 0.33 mole ethyl alcohol plus 0.67 mole water plus 0.67 mole ethyl acetate ester. This system attains practical equilibrium, at 6 to 9 °C in about 1 year, at 100 °C in about 8 days, and at 200 °C in about 24 hours.

The equilibrium constant is calculated numerically as follows:

Equation:	$CH_3COOH + C_2H_5OH \rightleftharpoons HOH + CH_3COOC_2H_5$			
Reaction weights:	60	46	18	88
Molar ratio at equilibrium:	0.33	0.33	0.67	0.67
Weights at equilibrium:	0.33×60	0.33×46	0.67×18	0.67×88

$$\left.\begin{array}{r}\text{Equilibrium}\\ \text{constant at } 9\,^\circ\text{C}\end{array}\right\} = \frac{\text{conc.HOH} \times \text{conc. } CH_3COOC_2H_5}{\text{conc. } CH_3COOH \times \text{conc. } C_2H_5OH} = \frac{0.67 \times 0.67}{0.33 \times 0.33}$$

Knowing the equilibrium constant at any stated temperature enables one to calculate the equilibrium end-point at that temperature for any ratio of reactants. Thus, when 1 mole (60) grams of acetic acid and 10 moles (460) grams of ethyl alcohol at 9 °C are taken:

$$\text{Equilibrium constant at } 9\,^\circ\text{C} = 4 = \frac{X \times X}{(1 - X) \times (10 - X)}$$

where X is the number of moles of water and also the number of moles of ethyl acetate ester formed (1 mole of each is formed by reaction of 1 mole acetic acid plus 1 mole ethyl alcohol). Solution of this equation shows $X = 0.97$. Therefore, by taking the above ratio of acetic acid (1 mole) to ethyl alcohol (10 moles) 0.97 (or 97%) of the acetic acid, the excess reactant being ethyl alcohol (9 moles), is converted at equilibrium into water plus ethyl acetate ester. In practice, the reaction is conducted by the use of a catalyzer, e.g., sulfuric acid concentrated, zinc chloride.

In cases where one of two resultants can be separated from the reactants and the other resultant, by precipitation as a solid, by condensation as a liquid, or by volatilization as a gas or vapor, the yield of the desired substance from a given amount of reactants can sometimes be materially increased. In the case of heterogeneous systems, whenever a solid participant is present, the *concentration* of said solid is considered constant. The precipitation and solution of solids are in this category, as well as the reactions between a gas and a solid, e.g., the system ferroferric oxide plus hydrogen gas plus iron plus water vapor.

The effect of change of temperature on a system in chemical equilibrium is that the equilibrium point is shifted (1) toward the side *away* from that which evolves heat when the temperature is *raised*, and (2) toward the side which evolves heat when the temperature is lowered. It is *as if* the amount of heat were a *material* reactant and its concentration (temperature or intensity of heat) increased, in respect to the *direction* of the shift of the equilibrium point. The amount of the shift at constant pressure can be calculated in cases where one possesses the proper data.

The effect of change of pressure on a system in chemical equilibrium is that the equilibrium point is shifted (1) towards the side possessing the smaller aggregate volume when the pressure is increased, and (2) towards the side possessing the larger aggregate volume when the pressure is decreased. The amount of the shift at constant temperature can be calculated by means of the equilibrium constant (above), recalling that increase of pressure is equivalent to increase of concentration of gases (temperature constant). When the volume of resultants equals the volume of reactants, no effect is produced on the equilibrium point by change of pressure. See also **Chemical Equilibrium**.

In some chemical reactions, the use of concentrations does not give calculated results that agree with those observed, because of the departure from ideality of real gases and solutions. In such reactions, concentrations are replaced by apparent effective concentrations, or activities, as explained in that entry.

CHEMICALS (Number of). With over 100 chemical elements from which chemical compounds can be built, the large numbers of atoms which may be present in various compounds, and the many ways in which the atoms can be linked (straight chains, branching chains, rings, half-rings, etc.), the number of "possible" chemical compounds is a very high number indeed, and, of course, is much larger than the millions of "known" compounds, which can be described fully in terms of constituents and structure. Keeping track of so many compounds — in the interest of fundamental research and, in more recent years, the identification of chemical compounds in terms of both beneficial and adverse effects on biological systems, health, and the environment — commenced many years ago. Thousands of compounds are described in numerous handbooks, various societies have compiled lists and tabulations, as for example the Chemical Abstracts Service (CAS) of the American Chemical Society, and special encyclopedias which describe inorganic and organic compounds. Possibly the most outstanding example is the "Handbuch der Organische Chemie," first undertaken in Germany in 1918. The first 27 volumes of this book were published between 1928 and 1938. Supplements have been released periodically since that time. Part II, consisting of 29 volumes, was published between 1941 and 1957; Part III, 14 volumes, was published between 1958 and 1973. Part IV was commenced in 1972 and continues. Publisher is Springer-Verlag, Berlin. The "Dictionary of Organic Compounds," 5th Edition (J. Buckingham, Executive Editor), published by Chapman and Hall Ltd, London, describes some 150,000 compounds. The book is published in seven volumes, which comprise a total of approximately 7900 printed pages. The "Main Work" was published in October 1982, with supplements scheduled for publication periodically. The First Supplement was released in 1938.

The CAS registry listings run into the millions of compounds, a very high percentage of which contain carbon. The majority are synthesized for specific research use. It is estimated that about three-fourths of the compounds listed are mentioned only once or very few times in the literature. Large numbers of listed materials are coordination compounds, the structure of which has not been fully defined. The registry also lists alloys, polymers, and mixtures with definite names. The registry embraces only papers published since 1965.

The ACS also offers the "Beilstein Online Database." This is claimed to be the most complete and systematic collection of evaluated data on organic compounds. The database is reviewed in a ten-chapter, "The Beilstein Online Database: Implementation, Content, and Retrieval," available from American Chemical Society, Washington, DC. See also **Chemical Elements**; and **Chemical Elements History of the Origin**.

CHEMISORPTION. The binding of a liquid or gas on the surface or in the interior of a solid by chemical bonds or forces.

CHEMORECEPTOR. Sense organ sensitive to chemical substances in the surroundings. See also **Sensory Organs**.

CHEMOSPHERE. The vaguely defined region of the upper atmosphere in which photochemical reactions take place. It is generally considered to include the stratosphere (or the top thereof) and the mesosphere, and sometimes the lower part of the thermosphere. This entire region is the seat of a number of important photochemical reactions involving atomic oxygen O, molecular oxygen O_2, ozone O_3, hydroxyl OH, nitrogen N_2, sodium Na, and other constituents to a lesser degree.

CHEMOSYNTHESIS. Most life on Earth is dependent upon photosynthesis, the process by which plants make energy from sunlight. However, at hydrothermal vents in the deep ocean a unique ecosystem has evolved in the absence of sunlight, and its source of energy is completely different: chemosynthesis. Chemosynthesis is the biological conversion of 1-carbon molecules (usually carbon dioxide or methane) and nutrients into organic matter using the oxidation of inorganic molecules (e.g. hydrogen gas, hydrogen sulfide) or methane as a source of energy, rather than sunlight, as in photosynthesis. Large populations of animals can be supported by chemosynthetic primary production at hydrothermal vents, methane clathrate cold seeps, and whale falls. So the animals that live around hydrothermal vents make their living from the chemicals coming out of the seafloor in the vent fluids! Because they are a local food source, hydrothermal vents typically have high biomass, in stark contrast to the very sparse distribution of animals outside of vent areas where animals are dependent on food dropping down from above. See also **Cold Seeps**; **Hydrothermal Vents**; and **Whale Fall**.

Chemosynthetic microbes provide the foundation for biological colonization of vents. Chemosynthetic microbes live on or below the seafloor, and even within the bodies of other vent animals as symbionts. Where microbial mat covers the seafloor around vents, grazers such as snails, limpets, and scaleworms eat the mat, and predators come to eat the grazers. Tubeworms flourish in small clumps, waving in the warm fluids. A typical picture of an active hydrothermal vent is therefore one with shimmering warm hydrothermal fluids, tubeworms and many other vent species, all densely clustered around the vent, with white microbial mat material covering the surrounding area. See also **Ocean**.

Many microorganisms in dark regions of the oceans use chemosynthesis to produce biomass from 1-carbon molecules. Two categories can be distinguished. In the rare sites at which hydrogen molecules (H_2) are available, the energy available from the reaction between CO_2 and H_2 (leading to production of methane, CH_4) can be large enough to drive the production of biomass. Alternatively, in most oceanic environments, energy for chemosynthesis derives from reactions between O_2 and substances such as hydrogen sulfide or ammonia. In this second case, the chemosynthetic microorganisms are dependent on photosynthesis which occurs elsewhere and which produces the O_2 that they require. Many chemosynthetic microorganisms are consumed by other organisms in the ocean, and symbiotic associations between chemosynthesizers and respiring heterotrophs are quite common.

CHEMOTHERAPEUTICS, ANTICANCER. Cancer is second only to cardiovascular disease as the principal cause of human mortality. As the median age of populations has risen, total deaths from cancer have increased. Treatment of cancer includes surgery, radiation, and chemotherapy, the last encompassing the use of both cytotoxic agents and relatively nontoxic hormonal agents for the control of tumor growth.

Drugs used in cancer chemotherapy or clinical trials are classified according to primary underlying mechanisms of action. However, many drugs operate through multiple mechanisms. Mechanisms include those of antimetabolites, DNA alkylating and/or cross-linking agents, DNA binding/cleaving agents, DNA topoisomerase interactive compounds, agents that act on tubulin structure, and hormones (Fig. 1). In addition to those drugs already approved by the FDA, a number of investigational drugs are undergoing clinical evaluation and many others are in the pipeline.

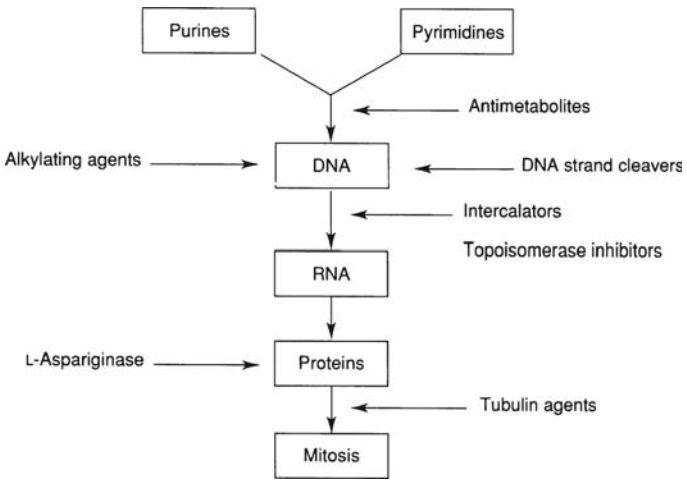

Fig. 1. Schematic of nucleic acid and protein synthesis and the steps leading to mitosis showing the common mechanisms of action and various classes of chemotherapeutic agents.

Antimetabolites, which represent one of the earliest groups of anticancer agents some examples are

5-azacitidine (Mylosar) [CAS: 320-67-2]: Acute myelogenous leukemia
Cytarabine USP (Cytosar) [CAS: 147-94-4]: Acute granulocytic leukemia (adults); acute lymphocytic leukemia (children); Hodgkin's disease
Floxuridine USP (FUDR) [CAS: 50-91-9]: Palliative treatment of gastrointestinal adenocarcinoma with liver metastases
Fluorouracil USP (Fluorouracil) [CAS: 51-21-8]: Palliative treatment of carcinoma of colon, rectum, breast, stomach, and pancreas
Mercaptopurine USP (Purinethol) [CAS: 6112-76-1]: Acute leukemia (more effective in children than in adults); chronic granulocytic leukemia
Thioguanine USP (Tabloid) [CAS: 154-42-7]: Acute leukemia; chronic granulocytic leukemia
Methotrexate USP (Methotrexate) [CAS: 59-05-2]: Acute lymphocytic leukemia; meningeal leukemia; choriocarcinoma; many others
Hydroxyurea USP (Hydrea) [CAS: 127-07-1]: Chronic granulocytic leukemia; melanoma; cancer of ovary, head, neck

DNA Alkylating/Cross-Linking Agents

This category includes compounds of diverse chemical classes (Table 1).

DNA Binding/Cleaving Agents

DNA binding and/or cleaving agents that have anticancer activity are listed in Table 2.

TABLE 1. DNA ALKYLATING/CROSS-LINKING AGENTS

Drug (trade name)	Disease
Carmustine USP (BiCNU) [CAS: 154-93-8]	Hodgkin's disease; non-Hodgkin's lymphomas; meningeal leukemia; brain tumor; multiple myeloma
Lomustine USP (CeeNU) [CAS: 13010-47-4]	Malignant brain tumors; Hodgkin's disease
Tauromustine [CAS: 85977-49-7]	Investigational drug responses observed in malignant melanoma
Streptozocin USP (Zanosar) [CAS: 18883-66-4]	Metastatic islet cell carcinoma of the pancreas
Busulfan USP (Myleran) [CAS: 55-98-1]	Chronic granulocytic leukemia; other myeloproliferative disorders
Cyclophosphamide USP (Cytoxan) [CAS:50-18-0]	Acute and chronic lymphocytic leukemia; lung cancer; rhabdomyosarcoma; neuroblastoma; ovarian and mammary carcinoma; multiple myeloma; lymphosarcoma; Burkitt's lymphoma; Hodgkin's disease; retinoblastoma; mycosis fungoides
Ifosphamide USP (Ifex) [CAS: 3778-73-2]	Germ cell testicular cancer; used in combination with mesna
Mesna USP (Mesnex) [CAS: 19767-45-4]	Prophylactic prevention of hemorrhagic cystitis
Mechlorethamine hydrochloride USP (Mustargen) [CAS: 55-86-7]	Hodgkin's disease; non-Hodgkin's lymphomas; lymphosarcoma; cancer of breast, ovary, lung; neoplastic effusion
Chlorambucil USP [CAS: 305-03-3]	Chronic lymphocytic leukemia; cancer of ovary, breast, testis; Hodgkin's disease; non-Hodgkin's lymphomas
Melphalan USP (Alkeran) [CAS: 148-82-3]	Multiple myeloma; plasmacytic myeloma; cancer of breast and ovary
Thiotepa USP (Thiotepa) [CAS: 52-24-4]	Cancer of breast, ovary, lung, bladder; Hodgkin.s disease; non-Hodgkin.s lymphomas; neoplastic effusion
Mitomycin C USP (Mutamycin) [CAS: 50-07-7]	Chronic myelogenous leukemia; reticulum cell sarcoma; Hodgkin.s disease; non-Hodgkin.s lymphomas; cancer of stomach, pancreas, lung; epithelial tumors
BMY-25067 [CAS: 95056-36-3]	Investigational drug
KW2149 [CAS: 118359-59-4]	Investigational drug
Cisplatin USP (Platinol) [CAS: 15663-27-1]	Metastatic testicular tumors; metastatic ovarian tumors; advanced bladder cancer
Carboplatin USP (Paraplatin) [CAS: 41575-94-4]	Recurrent ovarian carcinoma
Dacarbazine USP (DTIC) [CAS: 4342-03-4]	Malignant melanoma; Hodgkin's disease; soft tissue sarcomas

TABLE 2. DNA INTERACTIVE AGENTS

Drug (trade name)	Disease
Daunorubicin hydrochloride USP (Cerubidine) [CAS: 20830-81-3]	Acute lymphocytic and granulocytic leukemia; lymphomas
Doxorubicin USP (Adriamycin) [CAS: 23214-92-8]	Soft-tissue and osteogenic sarcomas; Hodgkin's disease; non-Hodgkin's lymphomas; acute leukemia; cancer of thyroid, breast, lung, genitourinary (GU) tract; Wilm's tumor; neuroblastoma
Idarubicin hydrochloride (Idamycin) [CAS: 57852-57-0]	Acute myeloid leukemia in adults
Mitoxanthrone hydrochloride USP (Novantrone) [CAS: 70476-82-3]	Acute nonlymphocytic leukemia, including myelogenous promyelocytic, monocytic, and erythroid acute leukemias
Bleomycin sulfate USP (Blenoxane) [CAS: 11056-06-7]	Squamous cell carcinoma of head, neck, esophagus, skin, GU tract; testicular tumor; Hodgkin's lymphomas
Dactinomycin USP (Cosmegen) [CAS: 50-76-0]	Wilm's tumor; Ewing's tumor; choriocarcinoma; testicular carcinoma; rhabdomyosarcoma; neuroblastoma; melanoma; soft-tissue and osteogenic sarcomas
Plicamycin USP (Mithracin) [CAS: 18378-89-7]	Testicular tumors; hypercalcemia and hypercalciuria associated with advanced malignancies
Procarbazine hydrochloride USP [CAS: 366-70-1]	Hodgkin's disease; non-Hodgkin's lymphomas; lung cancer

TABLE 3. TOPOISOMERASE INTERACTIVE DRUG

Drug (trade name)	Disease
Etoposide USP (Vepesid) [CAS: 33419-42-0]	Refractory testicular tumors; small cell lung cancer
Etoposide phosphate [CAS: 11709-64-2]	Investigational drug; prodrug of etoposide
Teniposide [CAS: 29767-20-2]	Refractory acute lymphocytic leukemia in children
CPT-11 [CAS: 100286-90-6]	Investigational drug; topoisomerase I inhibitor
Topotecan hydrochloride [CAS: 119413-54-6]	Investigational drug; topoisomerase I inhibitor
Elsamitrucin tartrate [CAS: 123303-9 S-7]	Investigational drug
Amsacrine (Amsidyl) [CAS: 51264-14-3]	Investigational drug

TABLE 4. TUBULIN ACTIVE DRUGS

Drug (trade name)	Disease
Vinblastin sulfate USP (Velban) [CAS: 143-67-9]	Hodgkin's disease; lymphosarcoma; reticulum cell sarcoma; neuroblastoma; choriocarcinoma; carcinoma of breast, lung, oral cavity, testis, bladder; acute and chronic leukemia; histiocytosis; mycosis fungoides
Vincristin sulfate USP (Oncovin) [CAS: 2068-78-2]	Acute leukemia in children; lymphocytic leukemia; Hodgkin's disease; non-Hodgkin's lymphomas; Wilm's tumor; neuroblastoma; rhabdomyosarcoma.
Taxol (Paclitaxol) [CAS: 33069-62-4]	Refractory ovarian cancer; refractory breast cancer; melanoma; lung cancer; head and neck cancer
Taxotere (Docetaxol) [CAS: 114977-28-5]	Investigational drug

TABLE 5. HORMONAL THERAPY

Drug (trade name)	Disease
Tamoxifen citrate USP (Nolvadex) [CAS: 54965-24-1]	Breast cancer
Diethylstilbestrol Diphosphate USP (Stilphostrol) [CAS: 522-40-7]	Prostatic carcinoma
Chlorotrianisene USP (TACE) [CAS: 569-57-3]	Androgen dependent carcinoma of the prostate
Estradiol USP (Estrace) [CAS: 50-28-2]	Breast cancer; prostatic carcinoma
Estramustine phosphate sodium USP (Emcyt) [CAS: 52205-73-9]	Prostatic carcinoma
Medroxyprogesterone acetate (USP Depo-provera) [CAS: 71-58-9]	Metastatic endometrial carcinoma; renal carcinoma
Megestrol acetate USP (Megace) [CAS: 595-33-5]	Carcinoma of the breast or endorometrium
Testolactone USP (Teslac) [CAS: 968-93-4]	Breast cancer
Goserelin USP (Zoladex) [CAS: 65807-02-5]	Prostatic carcinoma
Leuprolide acetate USP (Leupron) [CAS: 74381-53-6]	Prostatic carcinoma
Octreotide acetate USP (Sandostatin) [CAS: 79517-01-4]	Mestastatic carcinoid tumors; vasoactive intestinal peptide-secretory tumors
Flutamide (Eulexin) [CAS: 13311-84-7]	Metastatic prostatic carcinoma in combination with LHRH agonist

Topoisomerase Interactive Drugs

Topoisomerases I and II have emerged as interesting targets for the design of new anticancer agents (Table 3).

Tubulin Active Drugs

Tubulin active drugs are listed in Table 4.

Hormones

Although not strictly cytotoxic, hormones have been used to control the environment of hormone-dependent tumors such as those of the prostate, breast, and endometrium, i.e., androgens are used to control the growth of estrogen-dependent breast tumors, whereas estrogens control androgen-dependent tumors of the prostate. Hormones that have anticancer activities are listed in Table 5.

Toxicity

As a result of the life-threatening nature of cancer and the general lack of therapeutically effective drugs for most cancers, doses of chemotherapeutic drugs in Phase I clinical trials are escalated until the emergence of a dose-limiting toxicity. The efficacy of these compounds in one or more tumor types is then established in Phase II/III clinical trials. The commonly observed dose-limiting toxicities include myelosuppression, gastrointestinal upset, and renal, hepatic, and cardiotoxicities.

Toxicity Amelioration

Research efforts to address the problem of toxicity amelioration has progressed in several directions. The three most prominent areas are analogue synthesis, chemoprotection, and drug targeting.

Drug Resistance

The most recognized and studied mechanisms of drug resistance are attributed to multidrug resistance (MDR), gene amplification, DNA repair, topoisomerase II activity, and glutathione and metallothionein levels. Even with advances in understanding the biology and mechanism of drug resistance among different classes of antitumor agents, no real breakthrough appears imminent.

CHEMOTHERAPY. The administration of specific substances to inhibit or destroy microorganisms, parasites, and other causes of disease and disorders, without the chemotherapeutic substances themselves causing serious harm to the tissues of the host. Such substances interact chemically in one fashion or other in target biological systems. The chemotherapeutic agents may be strictly of a chemical nature, such as the sulfonamide drugs, quinine, piperazine, tetrachlorethane, and so on, or they may be derived from and perform in a manner more closely identified with bacterial and viral processes, as in the instances of various antibiotics. In numerous instances of chemotherapy, a thorough understanding of the processes which occur is not at hand, but based upon studies with laboratory animals and further confirmation from testing programs involving human beings, many agents have come into use with varying degrees of success. Scores of examples of chemotherapy are given in this encyclopedia. Consult specific diseases and disorders. See also **Cancer and Oncology**.

CHERGUI. See **Winds and Air Movement**.

CHERT. An impure, flinty hard rock composed chiefly of cryptocrystalline silica. Chert varies in color from gray through brown to black according to the kind and amount of coloring matter. It occurs principally as concretions, nodules or bands in limestones and dolomites, and unlike flint its fracture tends to be splintery instead of conchoidal. A great deal has been written on the occurrence and origin of chert and there is no doubt but that it may be formed in several different ways. Many of the nodular and concretionary cherts have grown around siliceous sponge spicules or radiolaria. Chert may be either sygenetic or epigenetic. The former type is supposed by some authors to be chemically precipitated from river waters on the bottom of the sea as a colloid contemporaneously with the limestones or dolomites. On the other hand certain cherts are obviously secondary although they may have been formed previous to the final lithification of the formations in which they occur. Cherts containing relatively large amounts of iron are called Jasper.

CHESTNUT TREES. Members of the family Fagaceae (beech family), these trees are of the genus Castanea. They are deciduous trees with toothed leaves and are quite tolerant of shade. As indicated by the names of the

TABLE 1. RECORD CHESTNUT TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
American chestnut (1993) *(Castanea dentata)*	235	597	106	32.3	101	30.8	Washington
American chestnut (1993) *(Castanea dentata)*	247	627	86	26.2	111	33.8	Washington

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

following species, chestnut trees are found in the eastern United States, southern Europe, northern Africa, and parts of Asia, including Korea and China.

American sweet chestnut	*Castanea dentata*
Chinese chestnut	*C. mollissima*
Japanese chestnut	*C. crenata*
Spanish or sweet chestnut	*C. sativa*

The American chestnut grows along the Allegheny Mountains and from New Hampshire southward to Georgia. It is a large tree and many years ago was one of America's most valued trees for timber. However, a fungus imported from Asia affected the bark of the tree. The tree was also attacked by a chestnut borer (*Ariopalus fulminans*), as a result of which a large portion of the chestnut tree population died. Some trees in Mendocino County, California were from 70 to 100 feet (21 to 30 meters) in height and were over 500 years old.

The record chestnuts, *C. denata*, as listed in the "National Registry of Big Trees," issued by American Forests, are located in Washington. (See Table 1).

Chestnut wood weighs about 28 pounds per cubic foot (448.5 kilograms per cubic meter), is coarse, durable, and of a pale brown color. When available, the wood is used for posts, cross ties, veneers, and mill products.

The Japanese have successfully propagated the C. crenata, which is valued for its fine nuts. The tree is dwarf and is apparently free from blight attack. Orchards of these trees have been started in several parts of the world. The nut has an excellent taste.

The common horse chestnut, red horse chestnut, Baumann's horse chestnut, and Japanese horse chestnut are members of another tree family, *Hippocastanaceae* (horse chestnut family), and are closely associated with the buckeyes. See also **Buckeye and Horse Chestnut Trees**.

Chestnut Blight. As reported by Anagnostakis (Connecticut Agricultural Experiment Station), chestnut blight is a classic among plant diseases. It is caused by an introduced fungus that has nearly eliminated its host, the American chestnut tree. Since the blight was first detected in the United States in the early 1900s, there has been no evidence of the natural development of genetic resistance to the disease and chemical control methods have not proved useful. The first infected trees were found in the Bronx (New York) Zoo in 1904 and the lethal canker organism was identified as *Endothia parasitica* (Murr). The disease spread in ever-widening circles to encompass all of the natural range of the tree. By 1950, an estimated 9 million acres (~3.6 million hectares) of American chestnut trees were dead or dying. The tree was once the most important hardwood species in the eastern United States. Its beautiful wood was used extensively for furniture and woodwork. The tall, straight, decay-resistant timbers were in great demand for telegraph and fence poles and for railroad ties. The tannin extracted from chestnut bark and wood was the basis of a large leather tanning industry. The nuts were food for wildlife, livestock, and people.

The fungus attacks through wounds caused by broken branches, breaks in the bark, or woodpecker or bark borer holes. Growing out from the point of infection, the mycelium grows in the bark and outer sapwood, until it has completely encircled and effectively "girdled" the tree or branch. The trees may resist by producing callus tissue, but the fungus usually penetrates the callus with ease. For many years, much research was conducted to locate possible biological or chemical controls, but essentially to no avail — until relatively recently.

It was noticed a number of years ago that chestnut trees in Europe and notably in Italy could be seriously infected with the disease, but with comparatively moderate damaging results. Through time-consuming and meticulous investigation, it was found that there are two strains of the damaging organism, identified as the normal virulent strain V and a hypovirulent strain H. The strain found in the damaged and dead American chestnut trees is the virulent V type. Even though diseased trees may put out shoots, they do not live beyond 3 to 5 years. From observations of affected trees in the Genoa, Italy area, it was noted that even though about 85% of shoots were infected by E. *parasitica*, only a few showed the usual symptoms of the blight. Cankers were found to be healing and it was noted that the fungus was restricted to the outer layer of bark on such trees. These trees were infected with the hypovirulent H strain. Based upon much further research, it was concluded: (1) that hypovirulence is a disease or group of diseases of the fungus that reduces its ability to kill susceptible chestnut tree hosts; (2) that it is controlled by genetic determinants in the cytoplasm of the fungus; (3) that determinants are probably on, or associated with, dsRNA; and (4) that all hypovirulent strains contain (as examined) dsRNA. Thus, as Anagnostakis stresses, for the first time since the advent of chestnut blight disease in the United States, there possibly may be a therapeutic treatment of blight cankers. Currently repeated testing of the H strain is underway in the United States. There are three targets — to find or produce stable H strains (1) that survive in nature without killing C. *dentata*; (2) that are present in broad ranges of vegetative compatibility; and (3) that are conducive to natural spread.

CHEZY, ANTOINE (1718–1798). Chezy was a contemporary of d'Alembert. He was a French engineer working in fluid mechanics. The matter of fluid resistance is the most important one in the field of hydraulics. Chezy discovered a simple resistance relationship for streams. In 1769, he developed the first uniform-flow formula.

See also **Chezy Formula**.

J. M. I.

CHEZY FORMULA. This formula is concerned with the friction loss in water conduits. The formula is

$$V = C\sqrt{RS}$$

R is the hydraulic radius of the cross section of flow. It is the cross-sectional area of flow divided by the wetted perimeter. S is the energy loss per foot length of conduit or the drop of the water surface per foot of length of an open channel. Manning's expression for the value of C in the Chezy formula is much used. It is as follows:

$$C = \frac{1.486R^{1/6}}{n}$$

in which n is a coefficient of roughness. The values of n are the same as those used in the older Canquillet-Kutter formula for C. Values of n range from about 0.015 for vitrified sewer pipe, concrete pipe, or plank flumes, to 0.03 or more for canals and natural stream channels.

See also **Hydrokinetics**.

CHICKADEE *(Aves, Passeriformes).* Birds of several species found in various parts of North America, all quietly colored in grays with some black markings and in some species a little white and brown. The common widely distributed species is also called the black-capped titmouse, *Penthestes atricapillus*.

CHICKENPOX *(Varicella).* A common communicable disease caused by the same virus which causes shingles (Herpes zoster) and which behaves in many ways like its close cousin the herpes simplex virus. Chickenpox and zoster are due to the same virus infecting the non-immune and the immune host. It produces a primary infection, chickenpox, in the non-immune host and, after the acute, often trivial primary infection, the virus becomes latent in the nerve cells. Sooner or later when cell-mediated immunity and neutralizing antibodies fail to keep the virus in check, it is reactivated in the "immune" host and reappears as zoster, or shingles. There are epidemics of chickenpox, but not of zoster.

Most women of childbearing age have had chickenpox and congenital chickenpox is rare. Intrauterine chickenpox, which occurs before the 20th week of pregnancy, may, apart from skin lesions, lead to cerebral atrophy, optic atrophy, and choroidoretinitis. Chickenpox caught at the end of pregnancy may be followed by severe chickenpox in the newborn — because the infant is not protected by antibodies passed across the placenta.

The disease is contracted by direct contact and the incubation period is from 14 to 16 days. Characteristically there are minimal prodromal symptoms in children, the first manifestation being the rash, which may be so slight as to be missed. In older children, the rash usually itches and the physician confirms the diagnosis. In adults, prodromal symptoms are much more common and may be severe. Headache, general aches and pains, backache, and extreme malaise have been reported. There may be a transient pink rash before the major onset and the vesicles erupt on the face or trunk, with the greatest density between the shoulders. The limbs are usually spared. The vesicles appear in crops over 3 to 4 days and scabs form and fall at the end of 10 days.

Although usually a disease of childhood, chickenpox in many countries is appearing more frequently in elderly groups. Secondary infections, such as pneumonitis, encephalitis and hemorrhagic chickenpox have been seen. Recurrence of the disease in otherwise healthy individuals is extremely rare. No treatment is indicated in the average case except local use of calamine to ease itch. Complications must, of course, receive appropriate treatment.

CHICK, HARRIETTE (1875–1977). Harriette Chick was a British nutritionist who did pioneer work on rickets and B vitamins. Born in London, the daughter of a lace merchant, Chick studied science at University College London and received an award for graduate study of bacteriology in Vienna and Munich. In 1905 she joined the staff of London's Lister Institute. During World War I the Institute's senior male staff was attached to military hospitals overseas and Harriette Chick became probably the first woman to direct a significant program of nutritional research. She and her colleagues devised a biological assay for the antiscorbutic potency of citrus products and showed that naval "lime juice" had lost most of its activity during processing. She also demonstrated the value of dried yeast and dried eggs for countering the problem of beriberi among army units in the Middle East. See also **Aykroyd, Wallace Ruddell (1899–1979)**; **Eijkman, Christiaan (1858–1930)**; and **Nutritional Science (The History)**.

After the war, with food shortages in Central Europe, Chick led a large investigation of rickets in the children's hospital in Vienna, demonstrating unequivocally, with the aid of X-rays, that the disease could be cured either with ultraviolet irradiation or by giving cod liver oil, and that it was not caused by overcrowding or lack of hygiene. See also **Vitamin D**.

From then on she worked mainly on the problem of pellagra, involving both protein quality and the B vitamins. In World War II her work contributed to the improvement of milling procedures to maintain the nutritional value of bread. She was elected to serve as President of the British Nutrition Society from 1956 to 1959, and remained interested in the progress of nutritional research until her death at the age of 102.

K. J. CARPENTER, University of California, Berkeley, CA

CHIGGER *(Arachnida, Acarina).* This pest is of several species. It is also sometimes referred to as the jigger or the red bug.[1] It attacks humans, domestic and farm animals, poultry, some birds that nest on the ground, frogs, toads, some snakes and turtles, and lagomorphs and rodents such as rabbits and squirrels. Because of its size, about 1/50 inch (0.5 millimeter) or less in diameter, this creature is barely visible to the naked eye. It is annoying to all of its hosts, inflicting bites that cause intense itching and small, reddish welts on the skin. The chigger is distributed throughout the United States and much of the world. In warm areas, such as Florida and southern Texas, chiggers may be present throughout the year. In most other areas of the United States, chiggers are most abundant from May to September, to the first frost. Chiggers raised experimentally complete their life cycle — from egg to egg — in about 50 days. The damaging stage is the larva, which feeds on humans and animals. The larva transforms to a nymph and the nymph to an adult, neither of which is a parasite.

The chigger larva is hairy and has three pairs of legs. Its mouth parts include two pairs of grasping palps, which are provided with forked claws. An enlarged view of the chigger larva is rather awesome, considering its real size.

A chigger attached in a pore or at the base of a hair may be so enveloped in swollen skin that it appears to be burrowing into the skin. This fact sometimes leads persons to believe, in error, that a chigger embeds itself in the skin, or that welts contain chiggers. Any welts, swelling, itching, or fever from a chigger attack will be developed within 24 hours. Chiggers attacking in large numbers can cause serious injury to poultry and sometimes can cause the death of young chickens.

CHIKUNGUNYA. The word "chikungunya" is Swahili for "that which bends up," in reference to the stooped posture of patients afflicted with the severe joint pain associated with this disease. The disease was first recognized in epidemic form in East Africa in 1952–1953. The etiologic agent, chikungunya virus, is arthropod-borne and has been placed in the family Togaviridae, genus Alphavirus [Calisher, et. al.]. Human infections are acquired by the bite of infected *Aedes aegypti* mosquitoes, and epidemics are sustained by human-mosquito-human transmission. The epidemic cycle is thus similar to those of dengue and urban yellow fever.

Since 1954, the virus has been implicated as the cause of epidemics in Asian countries including the Philippines, Thailand, Cambodia, Vietnam, India, Burma, and Sri Lanka. Epidemics of chikungunya were documented in the Philippines in 1954, 1956, and 1968 [Campos and Macasaet refs]. Serosurveys suggest that virus activity occurred in the central and southern part of the archipelago [Tesh, et. al.]. Chikungunya virus has been isolated from humans and mosquitoes in eastern, southern, western, and central Africa and in southeastern Asia, where it has been responsible for illnesses in hundreds to thousands of individuals.

[1] Not to be confused with the chigoe flea. See **Flea**.

After causing outbreaks in India, Sri Lanka, Burma, and Thailand, it all but disappeared in India, Sri Lanka, Burma, and Bangkok. However, localized outbreaks and sporadic cases continued in Burma, Thailand, and the Philippines in the 1980s. In addition, the virus spread into Indonesia for the first time from 1982 to 1985, with outbreaks in South Sumatra, Java, and West Kalimantan (1982); southern, eastern, and central Kalimantan (1983); southern Sulawesi (1993); eastern Timor and eastern Nusatengarra (1984); Mollucas Islands (1985); North Sulawesi (1985); and Irian Jaya (1985 to 1986). Outbreaks occurred in Thailand in 1995 and Port Klang in Malaysia in 1998 to 1999 affecting 27 people. The latter was the first outbreak to be recorded in Malaysia, although in the 1960s, antibody to Chikungunya virus was relatively common in the people of Malay Peninsula and Sarawak. In February 2005, an outbreak was recorded on the French island of Réunion in the Indian Ocean. As of January 2006, about 40,000 cases have been officially recorded, which makes it a major public-health issue. In neighboring Mauritius, 5,000 islanders have been hit in 2005.

After an incubation period of 3–12 days there is a sudden onset of flu-like symptoms including a severe headache, chills, fever ($>40\,^{\circ}$C, $104\,^{\circ}$F), joint pain, nausea and vomiting. The joints of the extermities in particular become swollen and painful to the touch. A rash may sometimes occur. Hemorrhage is rare and all but a few patients recover within 3–5 days. Some can suffer for joint pain for months. Children may display neurological symptoms. In contrast to dengue, chikungunya is characterized by a briefer febrile episode, by persistent arthralgia in some cases, and by the absence of fatalities. However, similarities between clinical appearances of the two diseases probably account for misclassification and some underreporting of chikungunya fever in areas with endemic dengue; therefore, laboratory confirmation of reported cases is important. The IgM-capture ELISA used for diagnosis of these patients is especially useful in this regard [Calisher, et. al.].

There is no specific treatment for Chik virus. Anti-inflamtory drugs may releave arthralgia. Chloroquine phosphate has been used for refractory chronic arthralgias. Prevention depends on mosquito control and decreasing mosquito exposure.

CHILBLAIN. Inflammation, accompanied by swelling, painfulness, itching, and redness of the hands or feet due to exposure to cold in persons predisposed to the condition. The causes of such predisposition are unknown.

CHILL. A paroxysm of shaking or shivering, accompanied by a sense of cold and pallor of the skin. During a severe chill the temperature becomes elevated. A chill may indicate the onset of a disease, often a severe infection, notably lobar pneumonia and malaria.

Nervous chill is shaking or shivering due to excitement, fear, or anger, and is not accompanied by any rise in temperature.

See also **Fever**.

CHILLED-MIRROR HYGROMETER. A device for measuring dewpoint temperature by chilling a mirror until water vapor condenses on it.

The onset of condensation is measured by bouncing a light beam off the mirror and recording when the reflection changes from specular to diffuse. The mirror can be cooled and heated by a variety of methods, one of which is thermoelectrically. Electronic circuits continuously monitor the light reflection and adjust the mirror temperature to maintain it at the dewpoint, even while humidity is varying. These devices often have high absolute accuracy and precision, but somewhat slow response.

CHILL HOUR. A unit of measure for fulfillment of plant dormancy requirements prior to the start of springtime growth, especially tree fruits. Determined by totaling the number of hours during a cold season when air temperature is below a specified value. The reference temperature (base temperature) for chill hour accumulation is species dependent; for example, for peach dormancy to be fulfilled, the number of hours that the air temperature is below $7\,^{\circ}$C ($45\,^{\circ}$F) is accumulated. A minimum number of chill hours dependent upon species and variety must be exceeded before normal springtime growth can begin.

CHILL UNIT. An index calculated from air temperature to estimate fulfillment of plant dormancy requirements and the ability to start springtime growth, especially tree fruits. Chill units are calculated in hourly time steps and summed over a time period. Cold temperatures add to chill units as the index ranges from 0 at temperatures less than $1\,^{\circ}$C ($34\,^{\circ}$F), to 1 near $7\,^{\circ}$C ($47\,^{\circ}$F), and 0 at $14\,^{\circ}$C ($57\,^{\circ}$F). Temperatures above $14\,^{\circ}$C ($57\,^{\circ}$F) reduce chill unit accumulation as the index falls to -1 at $21\,^{\circ}$C ($70\,^{\circ}$F). A minimum total number of chill units dependent upon species and variety must be exceeded before normal springtime growth can begin. Chill hour calculations frequently require hourly data from late evening to early morning.

CHILOPODA. The centipedes, usually considered as a class of arthropods related to but distinct from the millipedes and a few rare forms, but sometimes ranked as a class in the subphylum *Myriapoda*, containing all of these forms.

These animals are elongate and slender with numerous segments, most of them bearing a single pair of appendages. They have one pair of antennae and the first pair of legs is modified to form a pair of poison claws with which they catch their prey. They are terrestrial, breathing by air tubes (tracheae) which open separately on the various segments. The body is flattened and the segments are composed of dorsal and ventral plates connected by softer lateral walls, which bear the legs. Centipedes have poison glands opening through the poison claws but there is no evidence to show that they are ever dangerous to humans.

CHIMAEROIDS *(Chondrichthyes)*. Otherwise termed elephant fishes, ghost sharks, or ratfishes, the chimaeroids are of the subclass *Holocephali* and are cartilage fishes. They would appear to lie midway between sharks and bony fishes, but authorities believe they had shark-like ancestors. There are three major families: (1) short-nosed chimaeras or ratfishes (*Chimaeridae*); (2) long-nosed chimaeras (*Rhinochimaeridae*); and (3) plow-nosed or elephant chimaeras (*Callorhinchidae*). The *Chimaera montrosa* is the most common ratfish of European species, occurring from Norway to the Mediterranean. The *Hydrolagus colliei* (American Pacific ratfish) frequents waters from Alaska to Lower California and seldom attains a length of 3 feet (0.9 meters). They sometimes are a nuisance to fishermen because they can fill up the trawl nets. The term ratfish comes from the long rodent-like tail.

As indicated by the name, the long-nosed rhinochimaerids have a long slender nose something like a stiletto. They prefer deep waters between 2,000 and 8,500 feet (610 and 2590 meters) and thus are difficult to obtain and specimens are quite rare. The plow-nosed chimaeras are also well-named because of their appearance. The plow or hoe shape of the nose differs drastically from the features seen in any other fishes. Only a few species have been reported. The plow-noses frequent the coastal waters of South America, South Africa, New Zealand, Tasmania, and Australia. They may attain a length of about $3\frac{1}{2}$ feet (1 meter) and a weight of 20 pounds (9 kilograms). They have a minor commercial value in the South Pacific.

CHIMNEY CLOUD. See **Clouds and Cloud Formation**.

CHIMNEY ROCK. A column of rock, shaped somewhat like a chimney, which rises above its surroundings, or is isolated on the face of a steep slope. The term also is used to describe a small, weathered outlier, shaped like a sharp pinnacle. A stack formed by wave erosion also may be referred to as a chimney rock. *Pulpit rock* is synonymous.

CHIMPANZEE. See **Anthropoids**.

CHINA CLAY. A commercial term, more or less identical with kaolin, as applied to the relatively pure clay concentrated by washing from a thoroughly kaolinized granite. England is the chief exporter of china clay. France has unique clays from which are made the famous Sèvres and Limoges potteries.

China-clay rock is a kaolinized granite made up chiefly of quartz and kaolin, with sometimes the presence of muscovite and tourmaline. The rock crumbles easily in the fingers. *China stone* is (1) a partially kaolinized granite, which contains quartz, kaolin, and sometimes mica and fluorite, is harder than china-clay rock and is used as a glaze in the production of china; or (2) a fine-grained, compact mudstone or limestone found in England and Wales.

CHINA COSTAL CURRENT. See **Ocean Currents**.

CHINCH BUG *(Insecta, Hemiptera)*. One of the major and most damaging of food crop pests, the chinch bug, in some years, causes many millions of dollars in damage to corn (maize) crops in the United States. The insect damages numerous crops of the grass family, including corn, small grains, and wild grasses. The insect occurs throughout the United States and southern Canada, as well as in Mexico and Central America. It is most destructive in the regions of the Mississippi, Missouri, and Ohio River valleys. Illinois, for example, has had numerous serious infestations.

The common form of chinch bug (*Blissus leucopterus*), as shown in Fig. 1, has black-and-white wings. These are strongly developed and quite useful. The hairy chinch bug (*Blissus leucopterus hirtus*, Montandon) is found more commonly in the northeastern United States. This species does not have the strong characteristic of the common form insofar as migrating from one major food source to another is concerned. The hairy chinch bug prefers continuing vegetation as provided by lawns and grass pastures to going from one plant to another, as required in a grain field.

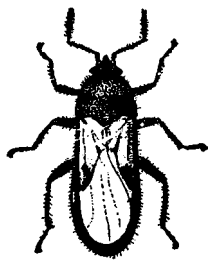

Fig. 1. Chinch bug. Actual length is about 0.25 inch (6 millimeters).

The life cycle of the common chinch bug is aptly depicted in the chart of Fig. 2.

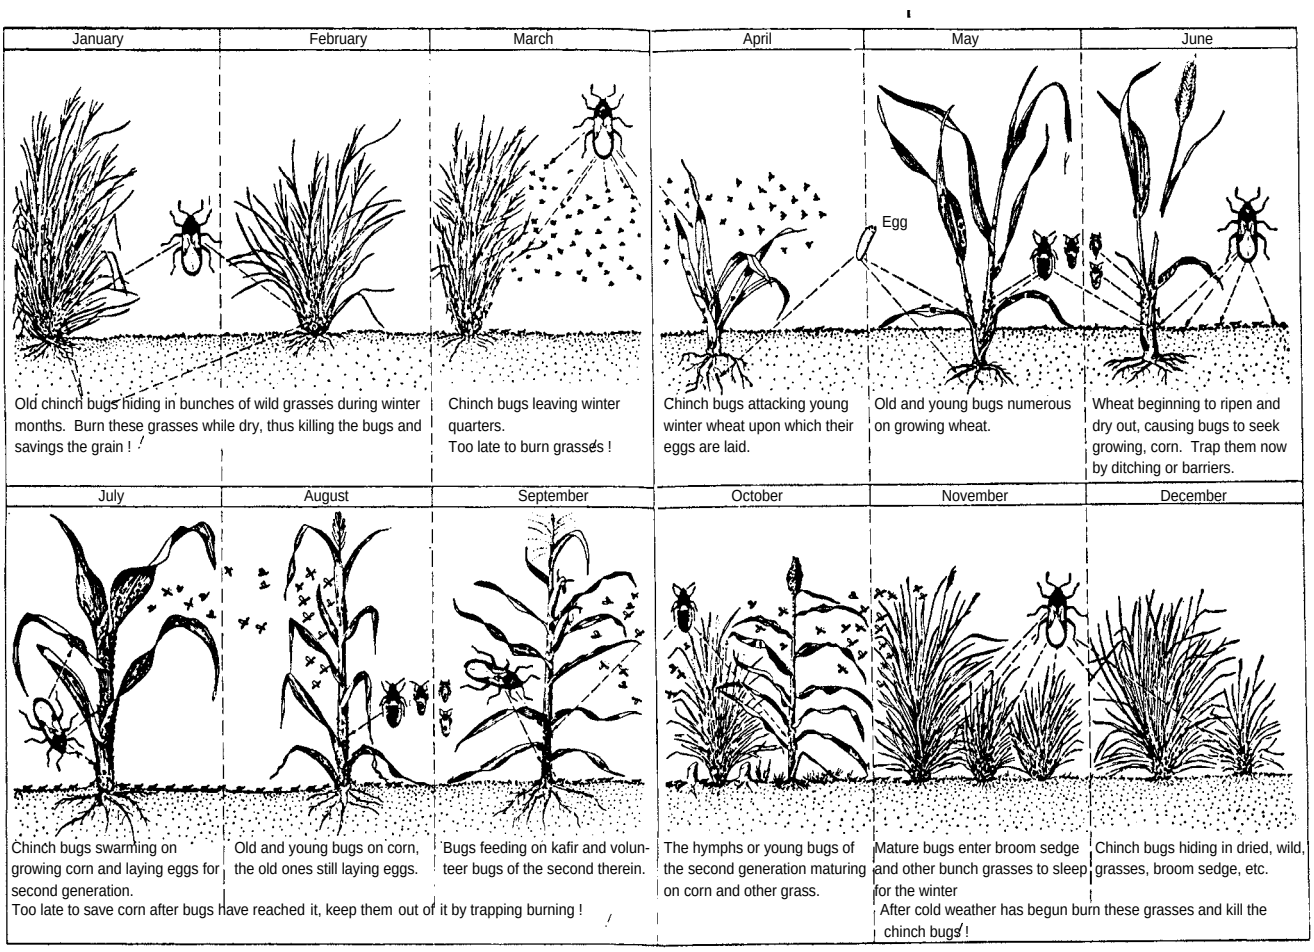

Fig. 2. Seasonal life cycle of common chinch bug. From December to February, the bugs hibernate at edges of wooded areas, notably in clusters of grass under fallen leaves and other natural debris. In late winter and early spring (February-March), the bugs fly to young grain fields (barley, oats, wheat, etc.), a migrating process that may continue until about mid-May. In early and mid-summer (June and July), the bugs crawl *en masse* from ripening grain (such as wheat) to tender, young corn (maize) plants. It is during this migration that ditches, traps, and chemical barriers can be effective. Upon achieving adulthood (about August 1st), the bugs move throughout the corn (maize) crop, feeding and laying eggs for a second generation. The August eggs develop into adults during late September through early November and these immediately seek hibernating locations for wintering over until the following spring.

If outbreaks of the chinch bug can be determined sufficiently early in the season, it is well to consider raising more nongrass crops during the period. The latter not only are not attacked by the chinch bug, but the areas so planted are thus subtracted from the available area for chinch bug breeding and growing. Care should be taken to avoid planting corn (maize) next to a field that is or has been planted with small grain. For example, fields of winter and spring wheat, barley, and oats are an ideal habitat for the multiplication of the chinch bug population. These matters should be taken into serious consideration in planting a year-to-year crop rotation program. Concurrent planting of soybean or cowpea with corn (maize) can produce a beneficial effect, resulting from the shade of these other plants on the base of the corn plant. The chinch bug prefers sunny locations and the absence of sunlight tends to slow down their population expansion. In the western area of the United States (west of the Mississippi River), the chinch bug usually winters in bunch grasses. Burning over such areas is sometimes done, although it is estimated that this may destroy only about one-fourth of the insects in the infested area. It is definitely a measure to be considered, provided that it can be accomplished safely.

Chinch bugs can be trapped by constructing a barrier line that the insect must cross to reach a corn (maize) field from a small grain planting. The bugs are repelled by the odor of creosote. Thus by creating a barrier line an inch or so wide on the surface of the soil, soaked with creosote, the bugs will be turned back. To establish such a line with a persistent repelling effect, several applications of the chemical may be necessary. A further method is that of digging holes on the inside of the barrier, along the border. Thousands of bugs can be trapped in these holes. Small amounts of chemical insecticide can be placed in the holes to kill the bugs as they fall in. Where the soil is gravelly, tarred felt paper strips several inches wide that have been saturated with creosote also can be used. Barriers of toxic dust also are used. These bands of chemicals, however, are easily destroyed by wind and rain.

CHINOOK. Wind is defined as the movement of air. Although we commonly define wind as a gentle breeze or a harsh gust of cold air, there is a wind phenomenon that can increase the temperature instead of lowering it. It is called a Chinook wind. Chinooks are most commonly associated with the Rocky Mountain range in North American but can also be found in the Swiss Alps and the Andes. They can increase temperatures high enough to melt the snow in their path as they travel down the mountainside. The Chinook wind falls under the classification of katabatic wind, which means that it moves downhill.

The name "Chinook" was taken from the Chinook Indians that lived along the Rocky Mountains until the early 1800s when the tribe became extinct due to disease. Although the tribe died off, their legends and tales live on. One such legend is that of the Chinook wind, which in its literal translation means "snow-eater."

It is possible for a Chinook to take place anytime during the year, but its effects are much more dramatic during the winter months. Chinook winds cause dramatic increases in the temperature on the eastern side of the Rockies and can send temperatures into the fifties and sixties. A temperature change of this magnitude can take anywhere from an hour to a day. The heat produced is a reaction formed from the change of gas to liquid in the atmosphere. These warm gusts of air then cause the evaporation of any snow on the ground, hence the name snow-eater. There is no definite length of time that a Chinook will last. On average, it can last hours or days.

Chinooks are the end result of the warm moist air of the Pacific Ocean moving up and down the Rocky Mountains. A westerly wind collects the warm moist air in the Pacific Ocean and carries it to the coast where it meets the western side of the Rockies. As the air makes its way up the mountain, the air becomes cooler, and the precipitation is squeezed out of it. Through this process warm, dry air is produced as it makes its way down the eastern side of the mountain. This process is repeated over and over again on each mountain that is in the way of the wind and each time produces warmer, dryer air. The air that makes its way down the last mountain is extremely dry and warm. This wind is called the Chinook wind. These warm gusts of air can reach speeds up to 100 mph.

The results from Chinook winds are both positive and negative. Chinook winds cause evaporation of the snow covering the ground, so the length of the grazing season is extended. A longer grazing season decreases the need to stock up on feed for animals. A negative result is the decreased amount of precipitation due to the quick evaporation of snow. Less precipitation causes hardships in planting.

See also **Winds and Air Movement**.

ARTHUR M. HOLST, Philadelphia Water Department, Philadelphia, PA

CHINOOK ARCH. See **Clouds and Cloud Formation**.

CHIRALITY. In chemistry, chiral is a term used to describe asymmetric molecules that are mirror-images of each other, i.e., they are related to each other optically as right and left hands. Such molecules are also called enantiomers and are characterized by optical activity.

CHIRP. An all-encompassing term for the various techniques of pulse expansion–pulse compression applied to pulse radar; a technique to expand narrow pulses to wide pulses for transmission, and compress wide received pulses to the original narrow pulse width and wave shape, to gain improvement in signal-to-noise ratio without degradation to range resolution and range discrimination.

CHI-SQUARE. If a sample of n values is drawn from a normal distribution with variance σ^2, and if the variance is estimated as

$$s^2 = \sum (x - \overline{x})^2/(n-1)$$

then the ratio $(n-1)s^2/\sigma^2$ is known as χ^2, and has the probability function

$$P(\chi^2)d\chi^2 = \frac{1}{\Gamma\left(\frac{1}{2}\nu\right)} e^{-(1/2)\chi^2} \left(\frac{1}{2}\chi^2\right)^{\nu-2/2} d\left(\frac{1}{2}\chi^2\right) 0 \le \chi^2 \le \infty$$

when $\nu = (n-1)$ is the degrees of freedom. This is a special case of the Pearson Type III function; the probability integral is an incomplete gamma function.

If a hypothesis completely specifies the frequencies f_t to be expected in n classes, the goodness of fit of a sample providing frequencies f_o can be tested by calculating

$$\chi^2 = \sum \frac{(f_o - f_t)^2}{f_t}$$

and entering a table of χ^2 with $(n-1)$ degrees of freedom. This quantity closely approximates the above distribution provided that none of the f_t's are too small — say, less than 5. To avoid this it is often necessary to combine two or more classes with small expectations. If the hypothesis specifies a probability distribution in which p parameters have to be estimated from the sample in order to compute the expected frequencies, the degrees of freedom are reduced to $(n-p-1)$.

With discrete variates, χ^2 provides a sensitive test of departure from the Poisson distribution. If we put

$$\chi^2 = (n-1)s^2/\overline{x}$$

where $\overline{x}$ is the sample mean and n the number of observations the standard distribution is closely followed for a true mean ≥ 2.

A similar test can be applied to the binomial distribution. In this form, χ^2 is sometimes referred to as the index of dispersion.

The χ^2 distribution tends to normality for large values of ν. The usual tables do not extend above $\nu = 30$; for larger values, it is ordinarily sufficient to take sqrt $\sqrt{2\chi^2}$ as normally distributed with mean sqrt $\sqrt{2\nu - 1}$ and unit standard deviation.

CHITIN. An essential constituent of the cuticula of arthropods. Also found to a lesser extent in most of the invertebrate groups. It is a material of variable and intricate chemical composition. It is a principal component of the insect exoskeleton and appears in both the rigid and flexible parts, which are usually said to be chitinized or not chitinized; the degree of rigidity has recently been said to depend upon other materials deposited with the chitin. Chitin is inelastic, hence the arthropods shed the exoskeleton at intervals during growth to permit expansion during the formation of a new covering. Chitin is chemically very inactive.

CHLAMYDIA. A genital tract infection caused by *Chlamydia trachomatis* and considered by some authorities as the most prevalent sexually transmitted disease in the world today. Although not fatal, the infection is attributed to increasing the risk of ectopic pregnancies — and infants born to chlamydia-infected mothers have a 5% or greater chance of developing chlamydial pneumonia, which can be a crucial factor for those neonates with additional complications at birth. It is estimated that approximately half of infected women are asymptomatic carriers and are unaware of their susceptibility to pelvic inflammatory disease, ectopic pregnancies, and infertility. Although affected to a somewhat lesser extent than the female, the male patient does not fully escape the consequences of chlamydial infections. Of all cases of nongonococcal urethritis and epididymitis (which can result in sterility), about 60% are caused by chlamydial infections.

CHLORAL. See **Chlorinated Oraganics**.

CHLORARGYRITE. Also known as horn silver, chlorargyrite is silver chloride, AgCl. The mineral crystallizes in the isometric system but is usually massive, appearing like wax or horn, hence the name. It has no cleavage, is highly sectile, yielding bright surfaces; hardness, 2.5; specific gravity, 5.55; luster, resinous to adamantine; color, gray, white to colorless. May be blue, violet-brown after exposure to light; transparent to translucent. Chlorargyrite is largely a secondary mineral, usually associated with other silver minerals as well as with compounds of lead, zinc, and copper. Saxony and the Harz Mountains are European localities. The Broken Hill district of New South Wales is a well-known occurrence, but probably the most important deposits are found in Atacama, Chile. The mineral also is found in Bolivia and Mexico. In the United States, chlorargyrite comes from Colorado, Idaho, Utah, Nevada, Arizona, and New Mexico.

CHLORELLA. A genus of unicellular green algae. Several species of this genus will grow very well in artificial media and have been used for many years in experiments on metabolism in plant cells. These green cells have been especially valuable in studying photosynthesis. Since the organism is unicellular, many of the complications caused by the complex structure of leaves are avoided.

Within the algae there is a complete nutritional spectrum from obligate heterotrophy (requirement for organic compounds) in colorless form, to obligate autotrophy (utilization of carbon dioxide). Close to the middle of the spectrum is the most commonly studied genus, *Chlorella*. Some species of *Chlorella* can make the transition between dark assimilation of glucose and photosynthetic assimilation of carbon dioxide (and vice versa) without any of the lag expected of adaptive enzyme formation. Considerable variability in metabolism of any one alga can be induced by special conditions. In *Chlorella*, photosynthetic metabolism can be switched to almost exclusive carbohydrate synthesis by a preceding period of dark starvation or light-limited growth. Nitrogen deficiency leads to shunt or overflow metabolism, and accumulation of reserve materials, such as starch, various other exotic polysaccharides, and fats. The most common forms of algae found in swimming pools are *Chlorella variegata* and *C. pyrenoidosa*.

CHLORIDE (Biological Aspects). Sodium chloride, potassium chloride, and other chloride salts, when ingested by animals from feedstuffs and humans from various food substances, reduce to a consideration of the cation involved (Na^+, K^+, etc.) and the Cl^- (chloride) ion. Generally, in terms of animal and human nutrition, more research has been conducted and more is known about the role of cations in metabolism than that of the chloride ion. Some physiologists and nutritionists in the past have described chloride as playing a "passive role" in maintaining the body's ionic and fluid balance. With exception of the "chloride shift" in venous blood, the movements of chloride have usually been considered secondary to those of the cations.

Much is known, of course, concerning the effects of excessive sodium chloride and of deficient sodium chloride in human and animal diets, but the physiological and nutritional roles of chloride have not been thoroughly studied and fully explained. C.E. Coppock, Department of Animal Science, Texas A & M University, College Station Texas; and M.J. Fettman, Cornell University College of Veterinary Medicine, undertook a study of chloride (targeted to chloride as a required nutrient for lactating dairy cows) and also carefully reviewed the prior work in this area of other researchers. (Interested readers are referred to the bibliography at end of article, "Chloride as a Required Nutrient for Lactating Dairy Cows," *Feedstuffs* (February 10, 1978).)

Despite important physiological functions and its presence in milk at about 0.11%, chloride is a neglected element in large animal nutrition. The practice of adding sodium chloride to concentrate mixtures and free-choice feeding seems to have precluded the possibility of a practical deficiency problem. When salt was omitted from the diet, researchers found that under the conditions used in their study, sodium was the first limiting element. This was true because sodium is present in most natural ingredients at much lower levels, relative to the cow's requirements, than is chloride.

Those who formulate diets usually ignore sodium levels in the natural ingredients (which are usually low in forages, but may be appreciable in certain concentrate ingredients) because of the traditional value of salt as a condiment. In addition, other sodium salts are often included in concrete mixtures: sodium sulfate as a sulfur replacement, the sodium phosphates as phosphorus supplements, and sodium bicarbonate as a buffer. Even when these supplements are used, salt is still often included because of tradition. Under many conditions, gross overfeed of both sodium and chloride occurs. High dietary levels of sodium and chloride do not increase the levels of these elements in milk. Excess will be excreted in urine and manure. Excess salt intake may result in greater water consumption, waste transport, bedding requirements, and transfer of sodium and chloride to the soil.

Of the seven macro mineral elements required by dairy cattle, five can be considered fertilizer elements (potassium, calcium, phosphorus, magnesium, and sulfur), but sodium and chloride are both toxic to plants at high concentrations and present practical problems in areas with saline soils. High salt intakes have also been shown to increase udder edema in heifers. Because of the importance of chloride in nutrition and metabolism, research is needed to define the chloride requirements of lactating cows and clarify mineral relationships, especially between chloride and potassium plus sodium.

Chloride and Plants. Chloride is one of the most recent elements to be shown essential for plant growth. Evidence shows that tomato plants grown in a low-chloride solution developed wilting of leaflet blade tips, which progressed to chlorosis, bronzing, and necrosis. Growth was proportional to chloride concentration (up to a point) in the culture medium. Chloride additions to the medium prevented the deficiency symptoms and caused their disappearance in deficient plants. Later, the same team showed that often, other species, including barley and alfalfa, displayed severe deficiency symptoms when grown in a low-chloride medium. Although buckwheat, corn (maize), and beans did not exhibit these obvious symptoms, yield effects were apparent.

Despite the presence of 250 parts per million (ppm) in the leaves of chloride-deficient tomato plants compared to a 0.1 ppm for molybdenum, chloride was classified as a micronutrient by plant physiologists. The essentiality of chloride escaped detection for so long because of its wide distribution in nature, the high solubility of most chloride salts, and difficulties of purification. Because chloride is a principal ion of sea water, it is picked up by winds from sea spray and carried far inland. For example, Geneva, New York has been estimated to receive 18 kilograms/hectare of chloride annually; Mount Vernon, Iowa, 73 kilograms/hectare annually. Deposits of more than 45 kilograms/hectare have been reported near coastlines. It was also suggested that leaf structures were capable of capturing airborne chloride. The popularity of potassium chloride as a potassium fertilizer and manure from cows fed excessive levels of chloride relative to their requirement are additional sources of soil chloride.

Chloride differs from other nutrient elements present in native rocks because it is not fixed by colloids; it is repelled by negatively charged clay surfaces, and all chloride compounds formed in soils are highly soluble. In addition to leaching, chloride is lost from soils through crop removal.

Several factors affect chloride uptake by plants: (1) age or advancing maturity shown in avocado, apricot, and grape leaves; (2) chloride concentration in the soil; (3) soil oxygen levels; (4) plant species; and (5) competition from other anions. Research has shown a specific antagonism between nitrate-nitrogen and chloride; increasing chloride levels in the growth medium reduces nitrogen uptake, but this reduction is primarily in the nitrate-nitrogen fraction, with little if any effect on the protein-nitrogen fraction. The reciprocal effect was also observed between chloride and sulfate accumulation. Chloride is essential in the plant for photosynthetic reactions in chloroplasts, which produce oxygen.

Chloride is also treated as a toxic element as well as a part of saline toxicity. Over the toxic range, the reduction in growth is approximately linear. For example, at about 3500 ppm chloride in the cultural medium, alfalfa growth will be depressed to about 60% that of normal. Obviously, in areas with saline soils, there is concern about excessive levels of salt returned to the soil via manure.

Gastrointestinal Absorption of Chloride. Since 1952, when in goats, sheep, and dairy cattle, the observation was made that chloride could be absorbed from ruminal fluid into the blood against a tenfold concentration difference (normal rumen fluid chloride concentrations may range from 10 to 30 mEq/l, while those of the plasma may range from 100 to 110 mEq/l), numerous researchers have attempted to describe accurately and explain the processes by which chloride might move across the reticulorumen epithelium against its apparent chemical gradients. For a number of years, it was assumed by some workers that the observed electrical potential difference across the forestomach epithelium, making the plasma approximately 30 mV positive to the contents of the reticulorumen, could adequately account for the otherwise anomalous movements. If chloride's movement into the blood was truly attributable solely to the combined electrochemical gradient acting upon it, then its distribution across the gastric epithelium should have been describable by the Nernst equation.

In rumen-fistulated experimental animals, it has been observed that for certain distribution ratios of chloride in the ruminal fluids and blood plasma, the calculated equilibrium potential for chloride is relatively the same as that measured directly with KCl−agar bridges and calomel electrodes. However, in many circumstances, the calculated and measured values have been found to be significantly different, an observation that could only be accounted for by the presence of an active transport mechanism responsible for the movement of chloride out of its equilibrium distribution.

The active transport of chloride has also been demonstrated across the wall of the frog stomach, rat ileum, dog ileum, and the human ileum. Experiments have produced a double exchange model in which bicarbonate secretion and chloride absorption are linked by an isoelectric mechanism to hydrogen ion secretion and sodium absorption across the human ileum. In 1972, a group of researchers proposed a similar model of coupled transport across the reticulorumen epithelium, and further concluded that active anion and cation transport in the rumen cannot function efficiently unless both components are intact, i.e., the net transport of the body's major cations from the rumen to the blood, appeared to be dependent in part on the activity of chloride in the system.

Chloride in Cerebrospinal Fluid. A similar story has unfolded concerning the distribution and movement of chloride between the blood and cerebrospinal fluid (CSF). The first indication for the possible existence of an active mechanism responsible for the maintenance of chloride levels in the CSF in the mid-20th Century when, Hiatt demonstrated in dogs the persistence of CSF chloride concentrations at 44% of normal, despite the reduction of chloride levels to 30% of normal in all body fluids during a nitrate-induced diuresis. Over the next 20 years, researchers recorded chloride ion concentration and electrical potential differences across CSF-ECF (extracellular fluid) and CSF-blood barriers ranging from 15 to 20% and from 5 to 30 mV, respectively, in such varied subjects as dogfish, rats, cats, dogs, monkeys, and humans. In all cases, the CSF was both higher in chloride ion concentration and negative in potential with respect to the reference body fluid.

In 1970, researchers studied the distribution and kinetics of chloride in cats following the iso-osmotic replacement of body chloride with isethionate via extracorporeal hemodialysis. They found that when the plasma chloride concentration was reduced by approximately 93%, the cerebral cortex, corpus callosum, and CSF chloride concentrations were reduced by approximately only 26.5, 35, and 21%, respectively. Other body tissues and fluids showed reductions in chloride concentration closer to those of the plasma (skeletal muscle and liver, 73%). The influx of chloride into the CSF at various plasma chloride concentrations was then plotted as a Lineweaver-Burk plot, and was shown to behave as a carrier-mediated process, as described by Michaelis-Menten kinetics. This information, combined with the observations made by Abbot et al. that reduction of the plasma chloride concentration by isethionate replacement did not produce a change in electrical potential "commensurate with or even in the same direction" as that expected by Nernst equation predictions, led workers in the field to ascribe the bulk of chloride movement from the blood into the CSF to an active transport process. It is possible that control of the rate of chloride transport is a factor in the regulation of the secretion of CSF, the medium that bathes, protects, and nourishes the central nervous system.

Chloride in the Humoral Regulation of Sodium and Potassium. Conventional presentations of the regulatory mechanisms involved in body fluid and electrolyte homeostasis usually have considered maintenance of the sodium/potassium ratio in the ECF both the prime means and end toward a functional electrolyte balance. Certainly, the sodium/potassium ratio provides the axis about which the body's humoral mechanism of electrolyte homeostasis revolves, represented mainly by the renin-angiotensin-aldosterone system. Aldosterone increases the activity of sodium retaining processes in the body. These include the active uptake of sodium from the gastrointestinal tract and the reabsorption of sodium from the renal tubes in exchange for potassium or hydrogen ion.

Given chloride's role in ruminal absorption and CSF secretion, perhaps its participation in the aldosterone mechanism of regulating the sodium/potassium "axis" should come as no surprise.

Upon detection of decreased blood pressure, volume, and/or sodium, the juxtaglomerular apparatus in the kidney secretes renin, an enzyme which then cleaves a decapeptide, angiotensin I, from a plasma *a* 2-globulin, angiotensinogen. A converting enzyme present in the plasma, and most abundant in the pulmonic circulation, cleaves a dipeptide from angiotensin I, thus forming angiotensin II. The effect of angiotensin II, potentiated by ACTH and high plasma potassium, is to induce the secretion of aldosterone by cells in the zona glomerulosa (arcuata) of the adrenal gland cortex. Aldosterone than exerts its effects on the sweat glands, salivary glands, intestinal mucosa, and distal convoluted tubules of the kidneys, promoting sodium absorption and retention. Because of its potent vascoconstrictive properties (40 times that of norepinephrine) angiotensin II can effectively reduce both renal blood flow and glomerular filtration rate, leading to an immediate decrease in excretion of water and electrolytes, before aldo-sterone can affect tubular sodium reabsorption.

Research has demonstrated that chloride is not only responsible in part for angiotensin II formation, but also for its deactivation or catabolism by the major angiotensinase of the body. Furthermore, chloride ion's relation to angiotensin II may not be its only route to affecting aldosterene secretion and sodium/potassium balance. Chloride's role in the metabolism of ACTH has led to support for the hypothesis that fluid and electrolyte homeostatic mechanisms may revolve not just around the sodium/potassium ratio, but also around the levels of chloride in the body.

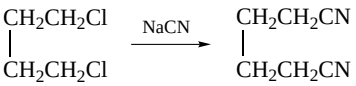
CHLORINATED ORGANICS. Organic compounds containing chlorine are valued as reagents and intermediates in chemical synthesis and for their commercial and industrial importance. Several are produced in high tonnages. The large-volume market for these compounds is in plastics, including vinyl chloride for polyvinyl chloride (PVC), or as a copolymer with vinyl acetate; vinylidene chloride for *Saran*; and chloroprene for neoprene. Other important uses include agricultural chemicals, solvents, plasticizers, and medicines. Uses as intermediates to produce other chemicals also are important and varied. The largest-volume chlorine organic is ethylene dichloride (EDC). About 14 billion pounds (6.2 billion kilograms) per year of EDC are produced, but over half of this is consumed by the producers to make vinyl chloride monomer. Methyl chloride is the intermediate for many chemicals, as are benzyl chloride, phosgene, and chloroform.

The chlorine on certain compounds is used as a facile leaving group for the introduction of another functional group. The displacement of a halogen atom by a cyano group to form a nitrile is one of the most useful reactions of halogen compounds. This opens a route to carboxylic acids having one carbon atom more than the original halide, aside from the importance of the nitriles themselves. Adiponitrile, used in the manufacture of nylon, can be made by treatment of 1,4-dichlorobutane with cyanide:



Long-chain alkyl chlorides can be used for the synthesis of various amines, while benzyl chloride is used for production of quaternary ammonium compounds. Alkyl chlorides are used for the formation of organometallics, including the Grignard reagents as well as for alkylation of aromatics. One of the important reactions of phosgene is with diamines for production of diisocyanates (polyurethanes).

Synthesis of Chlorinated Organics

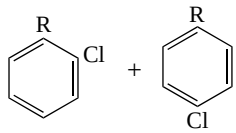
Chlorine derivatives of organic compounds are obtained by substitution, addition, or displacement. Substitution reactions of Cl on hydrocarbons involve radical attack to remove a hydrogen, forming the hydrocarbon radical as an intermediate: $R{-}H + Cl\cdot \rightarrow R\cdot + HCl$. Since a tertiary carbon radical $-\overset{|}{\underset{|}{C}}\cdot$ is most stable, it chlorinates more readily than a secondary carbon $-CH_2$ and that more readily than a methyl group. Due to inductive effects, the presence of chlorine in a molecule reduces the activity of the hydrogens on adjacent carbons more than on the chlorinated carbon. Thus, a second radical (Cl·) will preferentially attack a hydrogen on the same carbon. For example, chlorination of ethyl chloride will produce nearly twice as much 1,1-dichloroethane as 1,2-dichloroethane. Specificity of this sort is decreased at higher temperatures, leading to more random substitution. Hydrogens further away on a longer-chained molecule are essentially unaffected by the first chlorine, therefore little selectivity occurs for subsequent substitutions.

The wide range of organic compounds that can be produced through chlorination is illustrated by the very abridged listing in Table 1.

TABLE 1. PROPERTIES OF SOME CHLORINATED ORGANICS

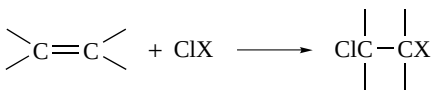
Compound	Specific Gravity	Melting Point, °C	Boiling Point, °C
Acetyl chloride	1.105	−112	51
Acetylene dichloride	1.291	−80	60
Allyl chloride	0.938	−136	45
Benzoyl chloride	1.212	−5	97
Benzyl chloride	1.100	−39	179
Carbon tetrachloride	1.595	−23	77
Chloroacetic acid	1.580	61	190
Chloral	1.505	−57	98
Chloral hydrate	1.619	52	98 (decomposes)
Chlorobenzene (mono)	1.107	−45	213
Chloroform	1.489	−64	61
Chlorophenol (ortho)	1.241	7	175
Cholorophenol (meta)	1.268	32	214
Chlorophenol (para)	1.306	42	217
Dichlorobenzene (ortho)	1.305	−18	179
Dichlorobenzene (meta)	1.288	−25	172
Dichlorobenzene (para)	1.458	53	174
Epichlorohydrin	1.204	—	−94
Ethyl chloride	0.917	−139	13
Ethylene dichloride	1.255	—	−84
Methyl chloride	0.952	−98	−24
Methylene chloride	1.336	−97	−40
Nitrochlorotoluene	—	−38	238
Pentachloroethane	1.671	−22	162
Vinyl chloride	0.908	−160	−12

Chlorine can be substituted onto an aromatic ring in the presence of a catalyst, such as ferric chloride, $FeCl_3$, or aluminum chloride, $AlCl_3$. The simplest case would be chlorination of benzene. Substitution of a second Cl onto the ring preferentially goes to the para position, but the ortho and meta isomers can be formed with the latter least favored. If the chlorination is carried out in the presence of a radical source, such as ultraviolet light, addition occurs instead. See *Chlorinated Aromatics* described later in this entry. When a functional group is present on the aromatic ring, Cl attack will depend upon the type of group present. Phenol and benzoic acid will chlorinate on the ring to give chlorophenol and *p*-chlorobenzoic acid. Alkyl benzenes will chlorinate on the alkyl group if a radical source is present. In the presence of an iron catalyst, the product is a mixture of the ortho- and para-chloroalkyl-benzenes:



With higher aromatics, such as naphthalene, chlorine successively substitutes all of the hydrogens. The first product is α-chloronaphthalene and the final compound is perchloronaphthalene.

Chlorine addition occurs on unsaturated hydrocarbons having double or triple bonds. Addition can occur by use of Cl_2, HCl, or HOCl:



where X=Cl, H, or OH.

With ethylene, the products would be 1,2-dichloroethane, ethyl chloride, or ethylene chlorohydrin. When the unsaturated molecule has three or more carbons, HCl will add, preferentially, with the Cl on the carbon having the fewest hydrogens. For addition of HOCl, the opposite is favored.

Displacement occurs when a functional group is replaced. Chlorine can displace groups, such as hydroxyl, OH, in an acid-catalyzed reaction. For example, methyl chloride can be prepared from the reaction of HCl on methanol. Other alkyl chlorides can be made from their corresponding alcohols. Another type of displacement would be the exchange of one halogen for another, e.g., Cl can be substituted for bromine or iodine in a molecule. An acyl chloride can be formed by the reaction of a strong dehydrating Cl carrier, such as PCl_3, PCl_5, POCl, or $SOCl_2$ with an organic acid or its salt.

Industrially, chlorinations are carried out in five ways: (1) radical substitution of hydrogens (protons); (2) addition across unsaturated (double or triple) bonds, using molecular Cl, HCl, or HOCl; (3) HCl reaction with an alcohol; (4) chlorinolysis, in which the oxidative power of Cl is used at high temperature to cleave hydrocarbons, resulting in formation of smaller chlorinated fragments; and (5) oxychlorination. The latter reaction is similar to producing molecular chlorine, *in situ*, from HCl and air in the presence of a catalyst. An example of this is the production of ethylene dichloride, 1,2-dichloroethane, from ethylene, HCl, and oxygen.

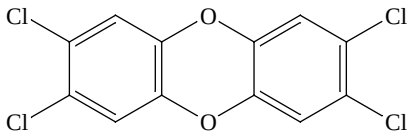
Characteristics of Chlorinated Organics

The presence of Cl in an organic molecule increases the density, viscosity, and chemical reactivity, while decreasing the specific heat, solubility in water, and flammability. Chlorine is normally an excellent leaving group, particularly in base-catalyzed reactions, which makes it important for syntheses. Toxicity is the principal hazard. Threshold Limit Values, established by the American Conference of Governmental Industrial Hygienists, for tetra- and pentachloroethane are 5 ppm (vol.) in the atmosphere. Corresponding values for CCl_4, $CHCl_3$, and perchloroethylene are 10, 50, and 100 ppm, respectively. Chloroacetylenes are highly explosive, especially in contact with caustic, e.g., NaOH.

Safety and Handling. Chlorinated organics are absorbed through the skin and lungs and can seriously damage vital organs, especially the liver. Therefore, they should be handled with rubber gloves and in well-ventilated areas. When these materials are subject to burning, they have the potential of forming hydrochloric acid and phosgene, $COCl_2$, besides carbon monoxide. In highly chlorinated compounds, such as carbon tetrachloride and perchloroethylene, there is some danger of forming phosgene in a fire, or from high heat. Compounds that have sufficient hydrogen to combine with any Cl released, such as methyl chloride, vinyl chloride, and ethyl chloride, will form large amounts of hydrochloric acid.

Although some small amounts of phosgene may be produced, the hydrogen chloride will naturally drive personnel away from such a fire.

Dioxin (2,3,7,8 tetrachlorodibenzo-*p*-dioxin [CAS: 1746-01-61]), shown below,



is the extremely toxic byproduct of manufacture of certain chemicals, notably 2,4,5-T. Unfortunately, the name *dioxin* is used synonymously for other, non-chlorinated compounds, such as 2,6 dimethyl-1,3-dioxin-4-ol acetate [CAS: 828-00-2], which do not deserve the notoriety.

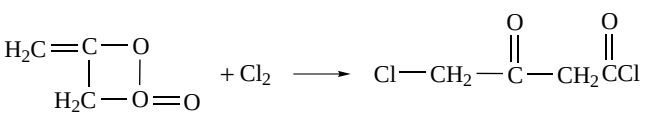
Types or Families of Chlorinated Organics

Chlorinated Paraffins. Cl will displace one, two, three, or more hydrogens from the paraffins. These substitution products are referred to as *mono* ($C_nH_{2n+1}Cl$), *di* ($C_nH_{2n}Cl_2$), *tri* ($C_nH_{2n-1}Cl_3$), and so on. *Monochloro* derivatives include methyl chloride, CH_3Cl, ethyl chloride, C_2H_5Cl, and propyl chloride, C_3H_7Cl. These are also called *alkyl chlorides*. Examples of *dichloro* compounds include methylene dichloride, CH_2Cl_2, and ethylene dichloride, $C_2H_4Cl_2$. Chloroform, $CHCl_3$, and 1,1,1-trichloroethane, $C_2H_3Cl_3$, are *trichloro* derivatives, while carbon tetrachloride, CCl_4, is a *tetrachloro* molecule. When all the hydrogens are substituted by Cl, the term *perchloro* is sometimes used.

Chlorinated Carbonyls. Chlorination of an aldehyde or ketone occurs most readily on a carbon next to the carbonyl function. This is due to proton interaction with the carbonyl and is acid catalyzed. Reaction of Cl with acetone yields chloroacetone. Substitution of a second Cl on chloroacetone occurs with no preference for sites. Thus, equal amounts of 1,1-dichloro- and 1,3-dichloroacetone are produced. (The opposite is true when brominating, since it is possible to form nine parts of 1,3-dibromo- to one of 1,1-dibromoacetone.) Chloral is produced from acetaldehyde. It is also produced by hydrolysis of trichlorodiethyl ether. Acrolein reacts with dry HCl at low temperatures to give β-chloropropionaldehyde.

The chlorinated acetones are strong lachrymators. Tear gas contains chloroacetophenone, which is also a component of the nonlethal disabling spray chemical *Mace*.

Chlorination of diketene yields α-chloroacetoacetyl chloride:



This product is both a vesicant (blistering agent) and a lachrymator.

Chlorinated Fatty Acids. Chlorination of carboxylic acids is much more difficult because the contribution of the carbonyl group toward proton removal is offset by the electron donation effect from the hydroxyl group. This hindrance is obviated by reaction with the acid chloride or anhydride. Chlorination is normally accomplished by use of a catalyst, such as phosphorus trichloride. Monochloroacetic acid is an important industrial chemical. Dichloro- and trichloroacetic acids can be produced by further chlorination, although the latter can be produced conveniently by nitric acid oxidation of chloral. Higher chlorinated fatty acids can be produced by treatment of the hydroxy carboxylic acid or ester with HCl or PCl_5:

$$CH_3CHOHCH_2COOR + PCl_5 \longrightarrow CH_3CHClCH_2COOR$$

Amino fatty acids can be treated with a mixture of nitric oxide and chlorine to produce the corresponding chloroacid. Mono- and dichlorosuccinic acids are examples of chlorinated dicarboxylic acids.

Chlorinated Ethers. Ethylene chlorohydrin reacts with sulfuric acid to form β,β'-dichloroethyl ether. It is a byproduct of ethylene glycol production. The chlorines on this ether are inert, making it a good solvent. Further chlorination at 20–30 °C gives α,β,β'-trichloro diethyl ether which hydrolyzes to chloroacetaldehyde and ethylene chlorohydrin. Ethylene and sulfur monochloride react to give β,β'-dichlorodiethyl sulfide (mustard gas), which is a thioether.

Chlorinated Aromatics. Chlorination of benzene in the presence of a catalyst ($FeCl_3$ or $AlCl_3$) yields chlorobenzene as the first product. Substitution with a second Cl yields ortho, para, or meta dichlorobenzene. Eventually all the hydrogens can be substituted to give hexachlorobenzene, C_6Cl_6. In the presence of ultraviolet light, the chlorination of benzene yields benzene hexachloride, $C_6H_6Cl_6$, a derivative of cyclohexane. Under the same conditions toluene chlorinates on the methyl group to give one, two or three substitutions (benzyl chloride, benzal chloride or benzotrichloride), while in the presence of an iron catalyst, one obtains ortho- and parachlorotoluene.

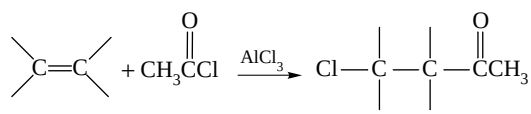
Chlorinated Heterocyclics. Substitution in pyridine is more difficult than in benzene but Cl will enter the β position slowly. Chlorine will not add to furan to give stable addition products but substitution occurs to give 2-chloro- or 3-chlorofuran, 2,5-dichlorofuran, and 2,3,5-trichlorofuran.

Important Specific Chlorinated Organic Compounds

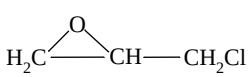
Several thousand chlorine-containing compounds are known and have been synthesized. A select group is included for description here to provide a cross section of the most important of these compounds. The number in brackets following each heading, where appropriate, is the *Chemical Abstracts Service Registration* number.

Acetyl Chloride (CH_3COCl)[CAS: 75–36–5]. Acetyl chloride can be prepared by treatment of acetic acid with various reagents, such as PCl_3, $SOCl_2$ or $COCl_2$. It can be prepared by chlorination of acetic anhydride in several different ways, by reaction of methyl chloride with carbon monoxide in the presence of catalysts, by reaction of ketene ($H_2C{=}C{=}O$) with HCl, or by partial hydrolysis of 1,1,1-trichloroethane. Acetyl chloride hydrolyzes in the presence of water to give acetic acid. It reacts with ammonia and amines to give acetamides:

$CH_3CCl + RNH_2 \rightarrow CH_3CNHR$. Reaction with alcohols gives the corresponding acetate esters. Acetyl chloride will add across unsaturated bonds in the presence of suitable catalysts to give halogenated ketones:

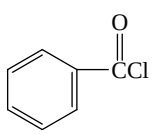


Allyl Chloride (3-chloropropene-1) [CAS: 107-05-1]. Allyl chloride can be synthesized by reaction of allyl alcohol with HCl or by treatment of allyl formate with HCl in the presence of a catalyst ($ZnCl_2$). Commercial production is by chlorination of propylene at high temperatures, about 500 °C, using a large excess of propylene. It is used in the synthesis of glycerol, allyl alcohol and epichlorohydrin. Since the chlorine is situated alpha to a double bond, it is particularly reactive. Thus, hydrolysis to allyl alcohol occurs rapidly in dilute caustic at about 150 °C. Addition of HOCl followed by treatment with an alkali yields epichlorohydrin:



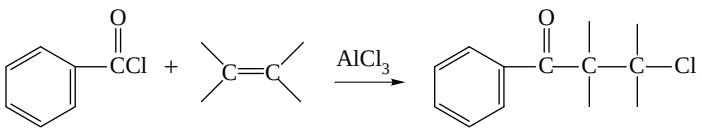
Addition of HBr in the presence of an oxidizing agent yields 1-chloro-3-bromopropane, which is used to prepare cyclopropane. Allyl chloride is one of the most toxic of the chlorinated organics.

Benzoyl Chloride [CAS: 98-88-4].

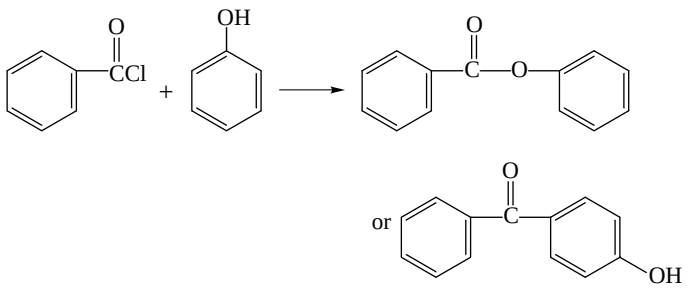


Benzoyl chloride can be prepared from benzoic acid by reaction with PCl_5 or $SOCl_2$, from benzaldehyde by treatment with $POCl_3$ or SO_2Cl_2, from benzotrichloride by partial hydrolysis in the presence of H_2SO_4

or $FeCl_3$, from benzal chloride by treatment with oxygen in a radical source, and from several other miscellaneous reactions. Benzoyl chloride can be reduced to benzaldehyde, oxidized to benzoyl peroxide, chlorinated to chlorobenzoyl chloride and sulfonated to *m*-sulfobenzoic acid. It will undergo various reactions with organic reagents. For example, it will add across an unsaturated (alkene or alkyne) bond in the presence of a catalyst to give the phenylchloroketone:

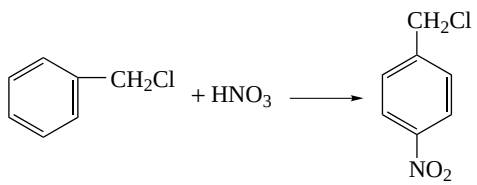


Reaction with benzene yields benzophenone while toulene gives phenyl-*p*-tolyl ketone. Reaction of benzoyl chloride with monohydric alcohols gives the corresponding alkyl ester, but with phenols the product can either be the phenylbenzoate or a phenolic ketone:

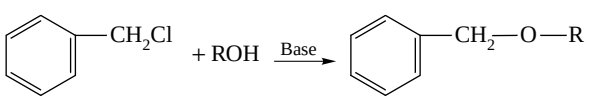


With ammonia and various primary and secondary amines the corresponding amide is formed.

Benzyl Chloride (α-chlorotoluene) [CAS: 100-44-7]. Benzyl chloride can be synthesized by chloromethylation of benzene in the presence of a catalyst ($ZnCl_2$) or by treatment of benzyl alcohol with SO_2Cl_2. Commercially it is produced by chlorination of boiling toluene in the presence of light. Benzyl chloride can be oxidized to benzoic acid or benzaldehyde, or substituted to give the halogenated, sulfonated or nitrated product:



With NH_3 it yields mono-, di- or tribenzyl amine. With alcohols in base the benzylalkyl ether is formed



With phenols either the phenolic or nuclear hydrogens can react to give benzylaryl ether or benzylated phenols. Reaction with NaCN gives benzyl cyanide (phenylacetonitrile); with aliphatic primary amines the product is the N-alkylbenzylamine, and with aromatic primary amines N-benzylaniline is formed. Benzyl chloride is converted to butyl benzyl phthalate plasticizer and other chemicals.

Carbon Tetrachloride (tetrachloromethane) [CAS: 56-23-5]. Carbon tetrachloride can be synthesized by the chlorination of CS_2, acetylene and other higher hydrocarbons but the primary source is the exhaustive chlorination of methane. It can be pyrolyzed to yield hexachloroethane, oxidized to phosgene and carbonylated with CO in the presence of $AlCl_3$ to give trichloroacetylchloride:

$$CCl_4 + CO \xrightarrow{AlCl_3} Cl_3C{-}\overset{\overset{O}{\|}}{C}{-}Cl$$

Some of the more important commercial uses involve fluorine displacement to yield chlorofluoromethane refrigerants, such as trichlorofluoromethane (R-11) and dichlorodifluoromethane (R-12). See also **Carbon Tetrachloride**.

Chloroacetic Acid ($ClCH_2COOH$) [CAS: 79-11-8]. Chloroacetic acid can be synthesized by the radical chlorination of acetic acid, treatment of trichloroethylene with concentrated H_2SO_4, oxidation of 1,2-dichloroethane or chloroacetaldehyde, amine displacement from glycine, or chlorination of ketene. It behaves as a very strong monobasic acid and is used as a strong acid catalyst for diverse reactions. The Cl function can be displaced in base-catalyzed reactions. For example, it condenses with alkoxides to yield alkoxyacetic acids: $ClCH_2COOH + KOR \rightarrow ROCH_2COOH$. Oxidation of chloroacetic acid leads to formation of methylene chloride. Treatment with ammonia yields glycine ($ClCH_2COOH \xrightarrow{NH_3} H_2NCH_2COOH$) while use of amines leads to formation of substituted glycines. Commercially, chloroacetic acid is an intermediate in the production of herbicides (2,4-D, 2,4,5-T and others) and cellulose ethers.

Chloroacetylene ($HC{\equiv}CCl$) [CAS: 593-63-51]. This compound is a gas with a very unpleasant odor. It ignites spontaneously in air and may detonate during handling. It can be synthesized by dehydrochlorination of dichloroethylenes with a strong base. It will react with silver or mercury to give explosive salts. Addition occurs across the unsaturated bond-for example, bromination yields 1-chloro-1,1,2,2-tetrabromoethane.

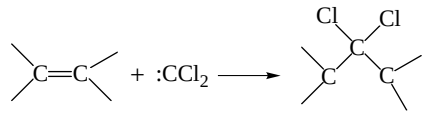
Chloral (trichloroacetaldehyde) [CAS: 75-87-6]. Chloral can be prepared by action of Cl_2 on ethanol, chlorination of acetaldehyde, oxidation of 1,1,2-trichloroethylene in the presence of a catalyst ($FeCl_3$, $AlCl_3$, $TiCl_4$ or $SbCl_3$, and by reaction of CCl_4 with formaldehyde. Chloral can be reduced either at the $-CCl_3$ group or the $-CHO$ group. In the first case the product is acetaldehyde while the second gives $Cl_3C{-}CH_2OH$. Oxidation of chloral gives trichloroacetic acid. Polymerization in the presence of H_2SO_4 leads to metachloral or parachloral, depending on the temperature. It undergoes various condensation reactions with alcohols to yield hemiacetals. With organic acids and other functional groups a multitude of reactions are possible. It is used in medicine as a hypnotic.

Chlorobiphenyls. These compounds can be synthesized by direct chlorination of biphenyl in the presence of iron or other catalysts. Other means of preparation include reaction of diazotized aminobiphenyl with copper chloride. Treatment of chlorobiphenyls at elevated temperatures (300–400 °C) with strong caustic yields hydroxybiphenyls. Various reactions, normal to aromatic systems, will occur — usually on the unsubstituted ring.

Chloroform (trichloromethane) [CAS: 67-66-3]. Although chloroform can be prepared by various means it is almost exclusively produced by the chlorination of methane. It can be oxidized to phosgene, substituted with various halogens, nitrated to chloropicrin (Cl_3CNO_2), hydrolyzed to formic acid ($HC(=O)OH$) and carbonylated to dichloroacetic acid. It will react with unsaturated halohydrocarbons in the presence of $AlCl_3$:

$$ClHC{=}CHCl + CHCl_3 \xrightarrow{AlCl_3} Cl{-}\underset{H}{\overset{Cl}{C}}{-}\underset{H}{\overset{Cl}{C}}{-}\underset{H}{\overset{Cl}{C}}{-}Cl$$

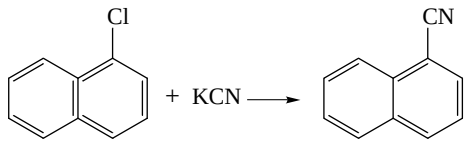
With aromatic aldehyde or ketones base catalyzed additions occur, while it condenses with primary amines to yield isocyanides: $C_2H_5NH_2 + CHCl_3 \xrightarrow{NaOH_3} C_2H_5N{\equiv}C$. A special type of addition can occur when chloroform is reacted with an unsaturated molecule in the presence of potassium alkoxide or sodium hydroxide in a polymer medium. The strong base removes HCl and produces dichlorocarbene ($:CCl_2$) which adds across the double bond:



Commercially, about 60% of chloroform is used in production of fluorocarbon refrigerants and propellants. Cl is replaced by treatment with fluorinated antimony pentachloride. The product, $CHClF_2$ (R-22),

is used for home air-conditioning units. It is also used as a feed for production of tetrafluoroethylene, which polymerizes to Teflon. Total demand for chloroform approximates 600 million pounds (136 million kilograms) per year.

Chloronaphthalenes. These compounds can be prepared by direct chlorination of naphthalene in the liquid or vapor phase. They also can be synthesized from naphthylamines via diazotization reactions or from naphthols by treatment with PCl_5. Chloronaphthalenes can be further substituted in normal aromatic reactions e.g., halogenation, nitration and alkylation. The chloro group can be displaced to yield a naphthol, an amine, or a nitrile:

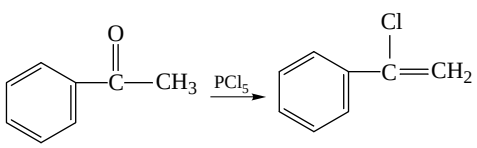


Chlorparaffins. These are produced by the random chlorination of various mixed long-chain paraffins. They are used as secondary plasticizers for polyvinyl chloride, lubricating oil additives, resinous materials for coatings, and in flame-retardants.

A particularly valuable use for chlorparaffins is in preparation of linear, primarily internal olefins as feedstock for long-chain synthetic oxoalcohols. Typically, *n*-paraffins ($C_{11} - C_{14}$) are chlorinated in a fluidized bed at about 300 °C. Conversion is maintained low to limit multiple chlorination. After separation of the monochlorinated alkanes by distillation, dehydrochlorination over nickel acetate at 300 °C yields the desired internal olefins. Unreacted paraffins are recycled.

Chloroprene (2-chlorobutadiene-1,3) [CAS: 126-99-8]. Chloroprene can be synthesized by addition of HCl to vinyl acetylene $H_2C{=}CH{-}C{\equiv}CH + HCl \rightarrow H_2C{=}CH{-}CCl{=}CH_2$, and by dehydrochlorination of dichlorobutenes or 2,2,3-trichlorobutane. It undergoes the normal addition reactions across the double bond and readily polymerizes or copolymerizes with other unsaturated compounds. These polymers resemble natural rubber but are superior in some respects, such as oil resistance (neoprene). Almost all the chloroprene produced is used for the manufacture of these polychloroprene rubbers. Chloroprene is a volatile, toxic, flammable liquid and is especially susceptible to oxidation and polymerization.

Chlorostyrene (chlorovinylbenzene) [CAS: 1331-28-8]. The alpha isomer can be prepared by PCl_5 reaction on acetophenone



by heating of acetophenone dichloride, or by hydrolysis of styrene dichloride in aqueous NaOH.

Dichlorobenzenes [CAS: 95-50-1] [CAS: 106-46-7] [CAS: 541-73-1]. Dichlorobenzenes are primarily produced by the chlorination of benzene in the presence of a catalyst ($FeCl_3$ or $AlCl_3$) although there are other possible synthetic routes. The two commercially important isomers are the ortho- and para-dichlorobenzenes. Further chlorination yields 1,2,4-trichlorobenzene. Dichlorobenzenes participate in normal aromatic substitution and alkylation reactions. In the presence of $CuCl_2$, ammonia will react with the dichlorobenzenes to yield chloroanilines. The ortho-dichlorobenzene is used for pesticides, moth control, as a solvent and for dyestuff manufacture. About half of the para is used as a space odorant.

Epichlorohydrin (γ-chloropropylene oxide) [CAS: 106-89-8]. This compound can be prepared from 1,3-dichloropropanol-2, 2,3-dichloropropanol-1, or allyl chloride. Commercially it is prepared as an intermediate in glycerol synthesis via alkaline hydrolysis of glycerol dichlorohydrin. Both come from allyl chloride. Epichlorohydrin reacts with monohydric alcohols to give ethers by opening the oxide ring. It will react with ethers, aldehydes, ketones, organic acids and amines to give a wide variety of useful syntheses.

Commercially the most important use is production of glycerine. Large volumes are consumed in nonglycerine areas, which largely consist of the various epoxy resins. It has use as a solvent and in the production of epichlorohydrin rubber.

Ethyl Chloride (chloroethane) [CAS: 75-00-3]. This compound can be synthesized by treatment of ethyl alcohol with HCl, cleavage of diethylether with HCl in the presence of a catalyst ($ZnCl_2$), chlorination of ethane or hydrochlorination of ethylene. The latter is the choice of industry. The reaction is carried out at 125 °F and 125 psi in the presence of $AlCl_3$, which is dissolved in ethyl chloride. It will undergo all the reactions of a typical alkyl chloride — halogenation, hydrolysis, amination, alkylation — and will form the magnesium Grignard reagent. The compound is used in production of tetraethyllead (TEL) by reaction with sodium-lead alloy:

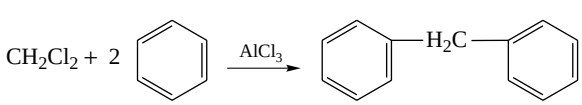
$$4\ PbNa + 4\ C_2H_5Cl \longrightarrow Pb(C_2H_5)_4 + 3\ Pb + 4\ NaCl$$

Ethyl cellulose is produced by treating alkali cellulose (cotton linter digested in dilute caustic) with ethyl chloride. Up to three ethyl ether stages can be made, giving various grades. These are used as synthetic gums and thickeners in the lacquer and plastics industries. Ethyl chloride is also used in the Friedel-Crafts alkylation of benzene and other aromatics. Additional uses include solvent, refrigerant, heat-transfer medium, aerosol propellant and anesthetic. Much is used captively by the producers.

Ethylene Dichloride (1,2-dichloroethane) [CAS: 107-06-2]. Ethylene dichloride (EDC) is produced by reacting ethylene and chlorine in the presence of ferric chloride, using the liquid product as solvent. It is also produced by oxychlorination — ethylene, hydrogen chloride, and air are reacted at about 250 °C with a copper chloride catalyst. This latter is the reaction of choice only when cheap by-product HCl is available. EDC reacts with Cl_2 to give derivatives of ethylene or ethane, depending on conditions and catalysts. It will dehydrochlorinate to give vinyl chloride, which is its principal commercial use. EDC hydrolyzes to ethylene glycol and reacts with aormatic hydrocarbons in the presence of $AlCl_3$ to give polyarylethylene plastics. The largest use is for vinyl chloride; next is its use as a solvent intermediate. Other uses include the manufacture of ethylenediamine and succinic acid, by way of the nitrile. Reaction of EDC with sodium tetrasulfide is used to produce thiokol rubbers.

Methyl Chloride [CAS: 74-87-3]. This compound is produced by direct chlorination of methane. Since methyl chloride adds chlorine faster than methane, the yield of methyl chloride is increased by using a large excess of methane in the feed, i.e., about ten volumes of methane to one volume of chlorine. The reaction is carried out at about 450 °C with very short contact times. Methyl chloride is also commercially produced by reaction of HCl on methanol in the presence of zinc chloride. Methyl chloride is mainly used in the production of silicone resins and rubbers. Silicon is reacted with an excess of methyl chloride at 300 °C in the presence of a copper catalyst. The product includes mono-, di-, and trichloromethyl silanes. Hydrolysis of the chloro groups converts them into the corresponding hydroxymethylsilanes. There are then polymerized to silicones. Nearly equal amounts of methyl chloride are used in making these rubbers and the other principal user, production of tetramethyllead. Production of methyl chloride approximates 440 million pounds per year.

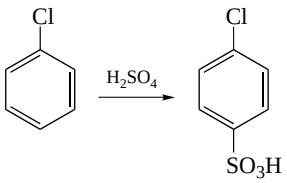
Methylene Chloride (dichloromethane) [CAS: 75-09-2]. As with the other members of the methyl series of chlorinated hydrocarbons, methylene chloride can be produced by direct chlorination of methane. The usual procedure involves a modification of the simple methane process. The product from the first chlorination passes through aqueous zinc chloride, contacting methanol at about 100 °C. Thus, HCl from chlorination is used to displace the alcohol group, producing additional methyl chloride. This is further chlorinated to methylene chloride. Methylene chloride reacts violently in the presence of alkali or alkaline earth metals and will hydrolyze to formaldehyde in the presence of an aqueous base. Alkylation reactions occur at both functions, thus di-substitutions result. For example, reaction with benzene plus $AlCl_3$ yields diphenyl methane:



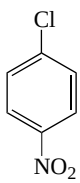
Catalyzed carbonylation (CO) reactions lead to formation of either chloroacetyl chloride or malonyl dichloride.

Methylene chloride is used in refrigeration, aerosol propellants, paint stripping, urethane foam-blowing agents, adhesive, and food extractants. It has low toxicity compared with other chlorinated hydrocarbons and has been shown to be neither mutagenic nor carcinogenic toward humans.

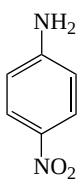
Monochlorobenzene (phenyl chloride) [CAS: 108-90-7]. Benzene is chlorinated at 80 °C in the presence of $FeCl_3$ catalyst. By using low conversions very little dichlorobenzene is produced. The chlorine on this compound is quite inactive, but hydrolysis can be effected by use of a strong caustic at high temperature and pressure, especially in the presence of a catalyst. This has been an important commercial route to phenol. With concentrated aqueous ammonia heated at high temperatures in the presence of a copper catalyst, aniline or diphenylaniline can be synthesized. Reaction with nitric acid yields chloronitrobenzenes-the para isomer predominates. Treatment with hot sulfuric acid leads to formation of *p*-chlorobenzensulfonic acid:



Monochlorobenzene is used commercially as a solvent and to produce phenol and nitrochlorobenzenes.



p-Nitrochlorobenzene [CAS: 100-00-5]. This compound is made by the nitration of chlorobenzene and is largely used to produce *p*-nitrophenol with smaller production of *p*-nitroaniline:



Various agricultural pesticides, rubber chemicals, phenacetin, and *p*-aminophenol consume about 30% of the total. Most of the production is used captively as an intermediate in the production of other chemicals.

Pentachlorophenol [CAS: 87-86-5]. This compound can be produced by the chlorination of phenol in the presence of $AlCl_3$, or by hydrolysis of hexachlorobenzene with NaOH in methanol. Pentachlorophenol is used as a wood preservative for poles, crossarms, and pilings and thus competes with creosote.

Vinyl Chloride [CAS: 75-01-4]. This compound is produced by alkaline dehydrochlorination of ethylene dichloride, or by thermal cracking of EDC, or 1,1-dichloroethane. Vinyl chloride is polymerized in various ways to polyvinyl chloride (PVC). It is also copolymerized with various other monomers to make a variety of useful resins. The copolymers with about 3 to 20% vinyl acetate are the most important. Demand for vinyl chloride is high, approximating 8 billion pounds (3.6 billion kilograms) per year.

CHLORINATION (Process). See **Chlorinated Oraganics**.

CHLORINATION (Water). A principal means for disinfecting municipal water supplies as well as public swimming pools, and some municipal and industrial wastes is by liquid- or gas-phase chlorination. Liquid chlorine is packaged in several types of containers to accommodate a wide range of uses, which may vary from a few hundred pounds during a season (in the case of a swimming pool) to many thousands of tons per year for water supplies. Liquid chlorine is obtainable in pressurized 100- and 150-pound (~45- and 68-kilogram) cylinders, 1-ton (0.9-metric-ton) containers, and for large users, is shipped by railroad tank cars, tank barges, and tank trailers. Large users, of course, must provide local storage means.

Chlorine cylinders are equipped with a single valve. Gas is delivered when the tank is in an upright position; liquid when the cylinder is in an inverted position. However, liquid withdrawal from cylinders is not usually practiced. In the case of ton containers, two valves are provided, permitting easy withdrawal of either gaseous or liquid chlorine. Bulk shipments almost always are unloaded in the liquid phase.

In the case of gaseous withdrawal, the vaporization of the liquid chlorine lowers the temperature surrounding the valve and hence withdrawal rates are limited, ranging up to a maximum of about 1.75 pounds (0.8 kilogram) per hour for a 150-pound (~68-kilogram) cylinder; 15 pounds (6.8 kilograms) per hour for a ton container. Sometimes, cylinders are manifolded to increase the capacity of the system. In the case of liquid withdrawal, the rate ranges up to 400 pounds (181 kilograms) per hour for ton containers; up to 7,000 pounds (3175 kilograms) per hour for a tank car where discharge is from one valve. Usually the liquid is forced out of the container or tank by its own vapor pressure. However, air pressure up to 200 psi (13.6 atmospheres) may be superimposed to increase withdrawal rates.

In municipal water and wastewater treatment installations, the chlorine usually is introduced into the main water system by way of a concentrated water solution of chlorine. Chlorine is metered under a vacuum created by the ejector. The chlorine is dissolved in water in the ejector, and then discharged into the water system as a high-strength solution. Frequently, the chlorine feeding is done automatically in proportion to the flow of water being chlorinated.

In the control of chlorine disinfectant systems, the effective use of the chlorine for its intended purpose is assumed if the treated water considerably downstream from the chlorinator contains a residual of chlorine. Depending upon use, full-contact time may be assumed after ten minutes, or the interval may be extended to several hours. The systems also are usually carefully monitored by bacteriological testing. Normally a dose of 1 to 2 milligrams of chlorine per liter is adequate to destroy all bacteria and leave an effective residual. Residuals of 0.1 to 0.2 milligrams per liter are usually maintained in the effluent streams from water-treatment plants as a factor of safety for consumers.

Surface waters require in most instances more extensive treatment, including chlorination, than do groundwaters. By the time some river water reaches some consuming communities it will have received large inputs of organics. Because of its great oxidizing power, chlorine is highly reactive and can combine in a variety of ways with both inorganic and organic pollutants. Thus, there is concern over the possible formation of carcinogens or otherwise harmful compounds in waters that are heavily chlorinated, particularly waters that have been recycled a number of times along a waterway. Major halogenated compounds found in water supplies suspected of posing health hazards to humans include: (1) chloro-esters, such as *bis*-(2-chloroethyl)ether and *bis*-(2-chloroisopropyl)ether; (2) halobenzenes, such as chlorobenzenes, bromobenzenes, and chloro-bromo benzenes; and (3) haloforms, such as chloroform, bromodichloromethane, dibromochloromethane, and bromoform. More information on this topic can be found in "Chlorine in the Marine Environment," by J.C. Goldman, *Oceanus*, **22**, 2, 36–43 (1979).

CHLORINE. [CAS: 7782-50-5] Chemical element, symbol Cl, at. no. 17, at. wt. 35.435, periodic table group 17 (halogens), mp −101 °C, bp −34.6 °C, density (chlorine gas) 3.209 grams/liter (0 °C and 1 atmosphere pressure). Chlorine gas is approximately 2.5 times heavier than air at standard conditions. Chlorine in the gaseous phase is diatomic (mol. wt. 70.906), pale greenish yellow of marked odor, irritating to the eyes and throat, poisonous. At 10 °C and one atmosphere pressure 9.8 grams of Cl_2 will dissolve in one liter of water; at 30 °C and one atmosphere pressure 5.6 grams will dissolve. Critical pressure is 1118.4 psia (7.7 mPa), critical temperature 144 °C. CAS Registry No. 7782-50-5. Other important physical characteristics of chlorine are given under **Chemical Elements**.

Chlorine was discovered by Scheele in 1774 and confirmed as an element by Davy in 1810. It is a high-tonnage industrial chemical with many uses.

Naturally occurring isotopes 35, 37. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^5$. Ionic radius Cl^{7+} 0.26 Å, Cl^- 1.81 Å. Covalent radius 1.050 Å. First ionization potential 13.01 eV; second, 23.70 eV; third, 39.69 eV; fourth, 53.16 eV; fifth, 67.4 eV. Oxidation potential $ClO_3^- + H_2O \rightarrow ClO_4^- + 2H^+ + 2e^-$, −1.00 V; $HClO_2 + H_2O \rightarrow ClO_3^- + 3H^+ + 2e^-$, −1.23 V; $\frac{1}{2}Cl_2 + 4H_2O \rightarrow ClO_4^- + 8H^+ + 7e^-$, −1.34 V; $Cl^- \rightarrow \frac{1}{2}Cl_2 + e^-$, −1.3583 V; $Cl^- + 3H_2O \rightarrow ClO_3^- + 6H^+ + 6e^-$, −1.45 V; $\frac{1}{2}Cl_2 + 3H_2O \rightarrow ClO_3^- + 6H^+ + 5e^-$, −1.47 V; $Cl^- + H_2O \rightarrow HClO + H^+ + 2e^-$, −1.49 V; $Cl^- + 2H_2O \rightarrow HClO_2 + 3H^+ + 4e^-$, −1.56 V; $\frac{1}{2}Cl_2 + H_2O \rightarrow HClO + H^+ + e^-$, −1.63 V; $\frac{1}{2}Cl_2 + 2H_2O \rightarrow HClO_2 + 3H^+ + 3e^-$, −1.67 V; $ClO_3^- + 20H^- \rightarrow ClO_4^- + H_2O + 2e^-$, −0.17 V; $ClO_2^- + 2OH^- \rightarrow ClO_3^- + H_2O + 2e^-$, −0.35 V; $ClO^- + 2OH^- \rightarrow ClO_2^- + H_2O + 2e^-$, −0.59 V; $Cl^- + 6OH^- \rightarrow ClO_3^- + 3H_2O + 6e^-$, −0.62 V; $Cl^- + 4OH \rightarrow ClO_2^- + 2H_2O + 4e^-$, −0.76 V; $Cl^- + 2OH^- \rightarrow ClO^- + H_2O + 2e^-$, −0.94 V; $ClO_2^- \rightarrow ClO_2 + e^-$, −1.15 V.

Production: Most of the chlorine produced in the world is manufactured by electrolysis of sodium chloride brine. Two processes are in common use: the mercury cell process and the diaphragm cell process. Since 1969 when international concern about the effect of mercury in the environment became widespread, some mercury cell plants have been shut down. Most expansion of chlorine production has been in diaphragm cell plants. Indeed, all mercury cell plants in Japan must now be converted to diaphragm cell plants. However, it should be noted that existing mercury cell plants operate well within strict standards as to mercury discharge both into the air and into waterways. They produce chlorine (and caustic soda) of the most exacting quality suitable for all uses including food preparation. There is no reason to believe that mercury cell technology is obsolescent in this country or, generally speaking, worldwide.

Technology. In production of chlorine by the diaphragm cell process, salt is dissolved in water and stored as a saturated solution. Chemicals are added to adjust the pH and to precipitate impurities from both the water and the salt. Recycled salt solution is added. The precipitated impurities are removed by settling and by filtration. The purified, saturated brine is then fed to the cell, which typically is a rectangular box. It uses vertical anodes (ruthenium dioxide with perhaps other rare metal oxides deposited on an expanded titanium support). The cathode is perforated metal, which supports the asbestos diaphragm. This is vacuum deposited in a separate operation. The diaphragm serves to separate the anolyte (the feed brine) from the catholyte (brine containing caustic soda). Chlorine is evolved at the anode. It is collected under vacuum, washed with water to cool it, dried with concentrated sulfuric acid, and further scrubbed, if necessary. It is then compressed and sent to process as a gas or liquefied and sent to storage for transfer to shipping containers and, ultimately, shipment to consumers.

A cell of this type is called a monopolar cell. In a cell bank, several cells have their negative electrodes and their positive electrodes connected by means of external bus bars. Some companies use a bipolar cell in which the electrodes are internally connected. This results in a configuration like a plate and frame filter press.

The latest development in cell technology is the so-called membrane cell. This uses a cation exchange membrane in place of an asbestos diaphragm. It permits the passage of sodium ions into the catholyte but effectively excludes chloride ions. Thus the concept permits the production of high-purity, high-concentration sodium hydroxide directly. The chlorine side of the cell is identical to existing technology. Research in membrane cells is proceeding at a rapid rate. Some companies are known to be operating this process commercially, but as of 1981 not all problems have been solved.

In the mercury cell process chlorine is liberated from a brine solution at the anodes which are, today, typically metal anodes (Dimensionally Stable Anodes or DSA). Collection and processing of the chlorine is similar to the techniques employed when diaphragm cells are used. However, the cathode is a flowing bed of mercury. When sodium is released by electrolysis it is immediately amalgamated with the mercury. The mercury amalgam is then decomposed in a separate cell to form sodium hydroxide and the mercury is returned for reuse.

Uses: The principal use of chlorine is in the production of organic compounds. Of these the production of PVC (polyvinylchloride) is probably the single largest consumer although chlorinated solvents as a class account for larger tonnage. See also **Chlorinated Organics**.

In many cases chlorine is used as a route to a final product which contains no chlorine. For instance propylene oxide has traditionally been manufactured by the chlorohydrin process. Modern technology permits abandoning this route in favor of direct oxidation, thus eliminating a need for chlorine.

Large quantities of chlorine are used in bleaching. Pulp bleaching for paper manufacture consumes about 13% of all chlorine produced in the United States. Since none of the chlorine used for this purpose winds up in the finished product, it must all be discharged as chlorides or chlorinated organics or be reprocessed. At the present time there is no proven, wholly satisfactory technique for removing chlorine compounds from pulp mill bleach plant wastes. It is doubtful that existing mills will be converted to a bleaching technique that does not require chlorine, but future mills may be designed to minimize the use of chlorine.

Substantial quantities of chlorine go into household bleaches. It is used also in laundry and other commercial bleaches. It is the active element in most swimming pool sanitizers.

Large quantities of chlorine are used for treating municipal and industrial water supplies and this use will probably continue. However, some concern has been felt that traces of organic compounds in all water supplies react with the chlorine to form chlorinated organics, which are suspected of being carcinogenic. Further the usefulness of chlorination of municipal wastes has been questioned in some quarters in the light of the fact that such treatment adds chlorinated organics to the waterways. See also **Chlorination (Water)**.

Safety and Handling: Although chlorine is a hazardous substance, it can be handled safely. All persons who handle chlorine should be thoroughly trained in its properties, in correct use of safety equipment, and in the operation of all other equipment including containers. The Chlorine Institute, 342 Madison Ave., New York, NY 10017, publishes the *Chlorine Manual* (available from the Institute at nominal cost) which provides useful information on these matters. In addition the Chlorine Institute has designed emergency kits capable of capping off certain types of leaks which can occur in chlorine containers.

There have been several recent studies of the physiologic effects of chlorine. These have considered chlorine both as an occupational exposure and as an environmental pollutant (see references). The National Institute of Occupational Safety and Health study recommended an 0.5 ppm concentration of chlorine in air for any 15-minute sampling period as the maximum permissible ceiling value. This contrasts with the generally accepted value of 1 ppm TLV (time weighted average for an eight hour exposure).

Chlorine is primarily a respiratory irritant. When the concentration in the air is sufficient, chlorine irritates the mucous membranes, the respiratory system, and the skin. It causes irritation of the eyes, coughing, and labored breathing. It may cause vomiting. In extreme cases, the difficulty of breathing may increase to the point where death can occur from suffocation. Liquid chlorine in contact with the eyes or skin will cause local irritation or severe burns.

Persons who have been overcome by chlorine should be removed to an uncontaminated area, their contaminated clothing should be removed, and they should be kept warm. Medical help should be provided. If breathing appears to have ceased artificial respiration should begin immediately. If breathing is labored, the administration of oxygen may be helpful.

Chlorine Chemistry: Chlorine exhibits in common with the other halogen elements a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. Thus, chlorine behaves in its normal chemical reactions as an electron acceptor. While there are many compounds in which chlorine has a positive valence, there are no simple

compounds of positively charged chlorine (contrast the I^+ of iodine). The positively charged chlorine forms part of a radical, as in combination with oxygen. The electron affinity of chlorine (4.02 eV) is the greatest of all the halogens, and is greater than that of oxygen.

Chlorine reacts readily with hydrogen to form hydrogen chloride, with metals and many non-metals to give chlorides, with metal oxides to give chlorides or oxychlorides, and with many salts of metals to give chlorides. These include the iodides and bromides, whose halogen is displaced by chlorine.

Four isolatable oxides of chlorine are known, Cl_2O, ClO_2, Cl_2O_6($\rightleftharpoons 2ClO_3$), and Cl_2O_7. Chlorine(I) oxide, Cl_2O, obtained by passing Cl_2 over mercury(II) oxide and sand, is a gas, bp 2 °C, somewhat soluble in H_2O to form hypochlorous acid. The Cl−O−Cl bond angle is 111° and the Cl−O distance 1.71 A. Cl_2O is an active oxidizing agent. Chlorine(II) oxide, ClO, is produced by reaction of Cl_2O with atomic chlorine, or as an intermediate product in the decomposition of the Cl_2O. The ClO then decomposes into chlorine and oxygen. In view of this instability the properties of the compound are not established. Chlorine(IV) oxide, ClO_2, is produced by treatment of sodium chlorate, $NaClO_3$, with mixed HCl, oxalic acid or other mild reducing agent, and H_2SO_4 (and H_2O). Cl(IV) oxide is a greenish yellow gas, having an odd electron in its molecule and is consequently paramagnetic. Electron diffraction studies indicate its structure to be

with the odd electron in an antibonding orbital. The O−Cl−O bond angle is 116.5° and C−O distance 1.49 Å. It is readily hydrolyzed, but is stable when dry. The mechanism of its hydrolysis is complex, yielding all four of the oxychloric acids, and it is widely used as a heavy-duty oxidizing agent. It reacts with metal hydroxides to give the mixture of chlorate and chlorite, with metal peroxides to give chlorite and oxygen and with metals to give chlorite alone. ClO_2 is photosensitive, decomposing when illuminated at about 8 °C, to give some Cl_2O_6, bp 3.5 °C. Chlorine hexoxide, Cl_2O_6, has a molecular weight corresponding to the formula ClO_3-ClO_3. Its vapor pressure in the liquid state is 0.31 mm at 0 °C against values of 23.7 for Cl_2O_7, 490 for ClO_2 and 699 mm for Cl_2O. This is consistent with a bi-trigonal-pyramidal structure in which the two pyramids have three oxygen atoms at their base corners, and are joined by the two chlorine atoms at the apices. In contrast, the additional oxygen atom of Cl_2O_7 would separate the two chlorine atoms, preventing close packed structure. Chlorine heptoxide, Cl_2O_7, the anhydride of perchloric acid, is obtained by heating the latter with phosphorus pentoxide, and consists of two chlorine atoms, each bonded to three oxygen atoms, and jointly bonded to the seventh. All of the oxides of chlorine are thermodynamically unstable with respect to decomposition into the elements.

Hypochlorous acid, HClO, is formed by hydrolysis of chlorine(I) oxide. It is present in aqueous solutions of chlorine because of the equilibrium

$$Cl_2 + 2\ H_2O \rightleftharpoons HClO + H_3O^+ + Cl^-$$

and can be freed by the addition of any substance that combines with the Cl^-, such as mercury(II) oxide, or with the H^+, such as calcium carbonate or other weak bases which do not react with HClO. HClO is a weak acid ($K = 3 \times 10^{-8}$ at 25 °C). It reacts with hydrochloric acid to give chlorine and H_2O. On warming or irradiation it undergoes this reaction as well as two other decompositions, i.e., to oxygen, H^+ and Cl^-, and to ClO_3^- and H^+. The presence of oxygen favors the last reaction. HClO and its salts are strong oxidizing agents, oxidizing iodine and bromine to iodates and bromates. Covalent hypochlorites are known, such as the alkyl esters, ROCl. In common with other esters of oxidizing acids, these are unstable if R is a primary or secondary alkyl group. However, *t*-butyl hypochlorite is quite stable. Reduction of chlorine dioxide, ClO_2, with hydrogen peroxide, yields oxygen and chlorous acid, $HClO_2$, which exists only in solution. It is stronger than hypochlorous acid ($K = 1.01 \times 10^{-2}$ at 23 °C). It is also a strong oxidizing agent and its sodium salt is widely used for this purpose, generally as a source of ClO_2.

Chloric acid, $HClO_3$, is readily prepared by passing chlorine into hot caustic solutions, since these conditions favor the formation of chlorate. Chloric acid is a more active oxidizing agent than HClO, reacting explosively with organic matter. Its alkali salts undergo on heating two modes of decomposition, one (catalyzed, e.g., by manganese dioxide) into the chloride and oxygen, and the other (uncatalyzed) into the chloride and perchlorate.

Perchloric acid, $HClO_4$, is obtained in anhydrous form from perchlorates by H_2SO_4 distillation, or from ammonium perchlorate by aqua regia distillation. Perchlorates are also obtained by electrolysis of chlorides or chlorates. Perchloric acid is explosive unless properly handled; it is of course a powerful oxidizing agent, but has a higher activation energy than the lower acids.

The chlorides range in character from ionic to covalent compounds, many of them having bonds of intermediate character. There are also a number of interhalogen compounds containing chlorine. Those of iodine and bromine are discussed under those entries. With fluorine, chlorine forms ClF, chlorine monofluoride, which is also obtained (along with ClF_3), when mixtures of the elements are subjected to spark discharge. It may also be obtained by heating a mixture of chlorine and chlorine trifluoride. It is a reactive gas, bp −100.8 °C, and with its bond having 20−30% ionic character. Chlorine trifluoride, ClF_3, is also obtained from the elements or from chlorine monofluoride and fluorine, by varying the conditions. It is a gas, bp of liquid 11.3 °C, and is a more powerful fluorinating agent than the monofluoride. Present views on its structure suggest a trigonal bi-pyramid having chlorine in the center, a fluorine atom at each apex and the third fluorine and two nonbonding pairs of electrons in the three equatorial positions, giving a T-shaped molecule. ClF_3 reacts with all elements except the noble gases, nitrogen, chromium, and certain noble metals, although some metals (e.g., copper) require elevated temperature. It does not react with oxides or salts as readily as fluorine, but nevertheless ignites such materials as asbestos.

Chlorine Products Used in Food Industry: Chlorine compounds are used effectively to sanitize food-processing equipment and food containers, for washing and conveying raw food products, and for cooling heat-sterilized cans of foods. The use of chlorinated-water sprays at selected locations in a plant reduces or prevents accumulation of microorganisms and off-odors. For sanitizing equipment, solutions of 100−200 micrograms of hypochlorite per milliliter usually are held in or circulated through equipment for at least two minutes. In addition to hypochlorite, chlorinated trisodium phosphates and chloramine compounds have antimicrobial properties. The effectiveness of chlorine-type sanitizers is dependent upon pH, temperature, exposure time, types of organisms, presence of organic matter, and concentration of compound used. Biocidal activity of free-available chlorine compounds is greater if the presence of organic matter is minimized. Further information is given in the Foregoing (1983) reference.

CHLORINITY. A measure of the chloride content, by mass, of seawater (grams per kilogram of seawater, or per mille). Originally chlorinity was defined as the weight of chlorine in grams per kilogram of seawater after the bromides and iodides had been replaced by chlorides. To make the definition independent of atomic weights, chlorinity is now defined as 0.3285233 times the weight of silver equivalent to all the halides. The chlorinity of seawater is generally determined in order to permit the calculation of salinity, although other methods of determining salinity can be used. By using normal water as a comparison standard, Knudsen burettes and pipettes for the analysis, and Knudsen's tables to compute the results,

determinations as accurate as those of a time-consuming gravimetric analysis can be made with a rapid titration of the seawater against silver nitrate solution, employing potassium chromate or other suitable indicator for the end point. It is customary to express chemical analyses of seawater in terms of chlorinity or of chlorosity.

CHLORITE. Chlorite is a ubiquitous mineral usually a product of secondary origin from the alteration of silicates containing aluminum, ferrous iron, and magnesium. Pyroxenes, amphiboles, biotite garnet, and idocrase within rocks that have undergone metamorphism are common source minerals for chlorite. Distinct crystals are extremely rare; more often found as foliated masses or fine scaly aggregates. Color includes various shades of green. Hardness of 2–2.5, and specific gravity of 2.6–2.9, with vitreous to pearly luster. Individual folia characterized by flexible, not elastic property. A general formula is (Mg, Fe^{2+}, Fe^{3+}, Mn)$_6$ $AlSi_3O_{10}(OH)_8$.

CHLORITE SCHIST. A schist whose color and foliation are chiefly due to the mineral chlorite. Other minerals common in this type of schist are quartz and epidote. Garnet and magnetite sometimes occur as idiomorphic crystals giving the schist a porphyroblastic texture.

CHLORITOID. A mineral that occurs as tabular crystals, probably triclinic, foliated masses or scattered scales and plates of a greenish-gray to greenish-black color. It is characteristic of the less intensely altered metamorphic rocks such as phyllites and quartzites. Chemically it is a hydrous iron-aluminum silicate, $Fe_2Al_4Si_2O_{10}(OH)_4$. Ottrelite contains some manganese as well. Chloritoid was originally noted as from the Ural Mountains and named for its greenish color from the Greek word meaning green. Ottrelite was named from Ottrez in Luxemburg.

CHLOROBIPHENYLS. See **Chlorinated Oraganics**.

CHLOROFLUOROCARBONS (CFCs). A family of compounds of chlorine, fluorine, and carbon, entirely of industrial origin. Also called *freons*. The major CFCs are CFC-11 ($CFCl_3$) and CFC-12 (CF_2Cl_2). CFCs include refrigerants, propellants for spray cans (this usage is banned in the U.S., although some other countries permit it) and for blowing plastic-foam insulation, styrofoam packaging, and solvents for cleaning electronic circuit boards. The compounds' lifetimes vary over a wide range, exceeding 100 years in some cases.

CFCs' ability to destroy stratospheric ozone through catalytic cycles is contributing to the depletion of ozone worldwide. Because CFCs are such stable molecules, they do not react easily with other chemicals in the lower atmosphere. One of the few forces that can break up CFC molecules is ultraviolet radiation, however the ozone layer protects the CFCs from ultraviolet radiation in the lower atmosphere. CFC molecules are then able to migrate intact into the stratosphere, where the molecules are bombarded by ultraviolet rays, causing the CFCs to break up and release their chlorine atoms. The released chlorine atoms participate in ozone destruction. A single atom of chlorine is able to destroy ozone molecules over and over again. See also **Stratospheric Ozone**; and **Tropospheric Ozone**.

International attention to CFCs resulted in a meeting of diplomats from around the world in Montreal in 1987. They forged a treaty that called for drastic reductions in the production of CFCs. In 1990, diplomats met in London and voted to strengthen the Montreal Protocol significantly by calling for a complete elimination of CFCs by the year 2000.

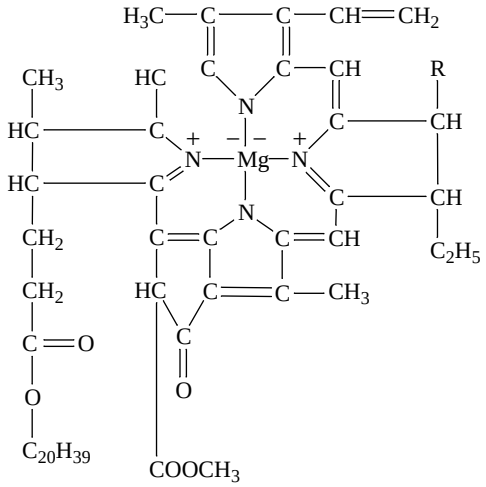
CHLOROFORM. See **Chlorinated Oraganics**.

CHLOROPHYLLS. A group of closely related green pigments occurring in leaves, bacteria, and organisms capable of photosynthesis. The major chlorophylls in land plants are designated *a* and *b*. Chlorophyll *c* occurs in certain marine organisms. Because of the overwhelming percentage of the total photosynthesis which is performed by marine organisms, it is possible that chlorophyll *c* is equivalent in importance to chlorophyll *b*. Chlorophyll *a* is several times as abundant as chlorophyll *b*. See also **Photosynthesis**.

The canonical form for chlorophyll *a* is R=CH_3 when substituted in the following formula. For chlorophyll *b*, R=CHO. These structures have been established by a long series of degradation studies mainly by R. Willstätter, Hans Fischer and their collaborators and by synthetic studies by Fischer.



The biological significance of the chlorophylls stems from their role in photosynthesis, the process by which plants fix the sun's energy in the form of organic matter. This process corresponds to the reversal of the combustion of hydrogen. The oxygen liberated is set free in the air. Under special conditions, some organisms are also capable of liberating the hydrogen, but usually this is used for chemical reductions in the plant. Atmospheric carbon dioxide is fixed enzymatically and is thus used as the source of the carbon in the synthetic process, but is not reduced directly. The path of the carbon from carbon dioxide in photosynthesis has been elucidated largely by the studies of Calvin and his collaborators. See references.

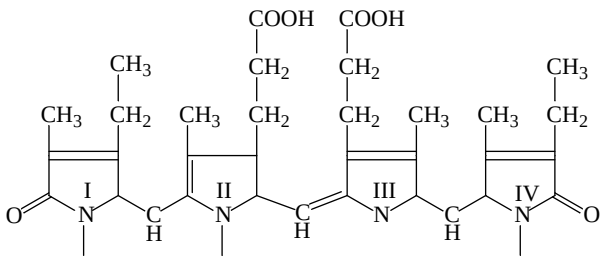
While it is known that most of the energy fixed in photosynthesis is absorbed originally by the chlorophylls, the exact reactions which they undergo to initiate the process of reduction are not fully understood. The photosynthetic sequence requires a high degree of organization within the plant cells where it occurs, and destruction of the organization of the chloroplasts by processes like grinding is sufficient to bring photosynthesis to a stop, even when the chlorophyll and the soluble enzymes participating in the process are still presumably intact.

Chlorophyll derivatives with the phytyl group intact are oil soluble and form a series of green dyes used in the coloring of oils and waxes. The chlorophyll soaps, resulting from combined saponification and cleavage of the isocyclic ring, form "water soluble" dyes useful in the coloring of soaps and similar products. Both the medical and cosmetic literature are replete with claims of therapeutic or physiological activity of "chlorophyll." The substances utilized in this work range from partially purified chloroplasts to mixtures of materials that have undergone deep-seated chemical alteration. Some of the types of activity claimed can be shown to be due to incidental impurities. The field for investigation of the action of pure chemical individuals produced by the action of various reagents on chlorophyll or its derivatives is largely unexplored. It is known, however, that neither chlorophyll nor hemoglobin in the diet is utilized by the body in the formation of the physiologically active pyrrole pigments. These are derived, instead, from such simple building blocks as glycine and acetate ion. Only the iron in dietary blood pigment can be utilized by the body.

The work of Granick has shown that, in the physiological processes of plants, chlorophyll is formed from protoporphyrin, which can be obtained in the laboratory by the removal of iron from hemin. The pathways to heme and to chlorophyll diverge at protoporphyrin. To form heme, an organism introduces iron into protoporphyrin. To form chlorophyll from protoporphyrin, an oxidation, a reduction, a ring closure and esterifications are performed and the magnesium is introduced. The end product of the enzymatic synthetic chain is presumably protochlorophyll, the magnesium

derivative of the porphyrin corresponding in structure to chlorophyll. The addition of the two hydrogens necessary to convert protochlorophyll to chlorophyll is accomplished under the influence of light.

Phytochrome is a blue-green protein that occurs in minute quantities in plant tissues. Phytochrome pigment is a photoreceptor for photomorphogenetic and photoperiodic responses in plants, and is found in many higher plants. It has been detected both in monocotyledonous plants, such as oats, barley, maize (corn), and at least one aquatic plant. It also occurs in dicotyledenous plants, such as sunflower, beans, peas, parsnip, soybean, lettuce, and radish. It is present in the aerial parts of plants (leaves, stems, buds, and inflorescences), such as in cauliflower. Phytochrome also occurs in some roots and in bryophytes, such as red algae and green algae. The structure of phytochrome is shown below.



Historically, lettuce seeds and cocklebur were the first two plants in which phytochrome was detected. Before isolation, the existence of phytochrome as a specific pigment was implied by physiological work with red and far-red light. The effect of red light (640–670 nm), which promotes germination in lettuce seeds, is reversible by far-red (710–740 nm). Thus, far-red radiation nullifies the promoting effect of the red light. It had been noted as early as 1935 that red light stimulated germination of lettuce seeds and that light of somewhat longer wavelengths inhibited germination. This knowledge was not elaborated further until 1952, when more exacting laboratory experiments were conducted.

CHLOROPLAST. A plastid containing chlorophyll as found in most of the green plants. Electron microscope studies show that the chloroplasts have a complex internal structure. There are many membranous layers, known as *grana*, arranged somewhat like stacks of coins. Apparently the chlorophyll molecules are spread in single layers on the grana, thus achieving a very great surface area for trapping the energy of light in photosynthesis. See also **Photosynthesis**; **Pigmentation (Plants)**; and **Plastids**.

CHLOROSITY. The chloride content of one liter (1.06 quarts) of seawater.

It is equal to the chlorinity of the sample times its density at 20°C (68°F).

CHOKE COIL. This term is applied to various types of inductances used in electrical circuits primarily to present high reactance at certain frequencies. Such coils usually have high reactance compared to their resistance and offer impedance to the flow of alternating currents by the induced counter electromotive force. Since this impedance will vary directly with frequency the choke may be designed to let certain lower frequencies through and stop or impede higher ones. An air-core choke coil is often used in electrical power circuits to block high-frequency transients produced by lightning surges. In communications circuits air-core chokes are used extensively to block radio frequencies from audio-frequency circuits or from dc parts of the circuit. In these applications they are often called radio-frequency chokes. Iron-cored chokes are frequently used in audio circuits in a similar manner. Iron-cored chokes are also important components of power supply filters as well as many wave filters.

CHOLERA. An acute diarrheal disease caused by enterotoxin secreted by Vibrio cholerae organisms, which are actively motile Gram-negative, curved, rod-shaped bacteria. Most species of this, if not all, are free-living in marine or brackish water. These organisms invade the proximal small bowel of the human host and adhere to, and multiply in, the mucosa. The organisms produce a protein enterotoxin part of which crosses the mucosal cell membrane where, in a process mediated by cyclic AMP (acid mucopolysaccharides), it inhibits sodium absorption and causes secretion of chloride and potassium. Loss of the latter ion sufficient to cause cardiac arrythmia is unusual in adults but can occur in children. Without effective treatment, the mortality rate is 50% or higher in some areas. Mortality can be reduced markedly by the application of therapy, as described later. Known since antiquity, cholera frequently occurs in an epidemic or pandemic fashion, and particularly in crowded urban areas and notably in India, southeast Asia, and China. In 1961, the disease made a significant spread westward from Indonesia, reaching much of the African continent, and more recently has been reported in Italy and Spain. The first outbreak in the United States since 1911 occurred in coastal Louisiana in 1978 and was attributed to the ingestion of contaminated crab. In 1981, there were two cases of cholera in residents of the Texas Gulf Coast and 17 cases on an oil rig in that area, where the drinking water (used in cooking rice) was contaminated with sewage containing *V. cholerae*.

Usually the principal path for transmitting the disease is the water supply, which can be less than sanitary in many crowded cities of the world. The disease is transmitted by the intestinal-oral pathway. Travelers to cholera-endemic areas can be protected (estimated 60–80%) by injections of cholera vaccine. Two injections about one week apart provide protection for 3–6 months. Nevertheless, travelers are advised to exert care in selecting water to drink.

During the 1879–1883 pandemic in Europe, Koch first demonstrated the causative organism. *V. cholerae* are short, comma-shaped, gram-negative bacilli and easily demonstrated in the laboratory. There are two major serotypes, Inaba and Ogawa. In addition, the El Tor strain was demonstrated in a recent cholera pandemic, causing somewhat less confidence in the degree of protection obtainable from commercial cholera vaccine.

The incubation period of the disease is short (24–72 hours). Usually the onset is sudden, commencing with diarrhea. The stools are loose and yellowish to green in color. There are no usual prodromal symptoms. Inasmuch as the organisms do not invade tissue, there is no tissue inflammatory infection. Fever, chills, and the usual symptoms of infection are absent. However, there may be severe vomiting. Diarrhea becomes severe over a very short period, with the stools (sometimes called "rice water stools") becoming essentially colorless. Stool volumes become excessive and can reach a volume up to 25 liters (6.6 gallons) in one day. Without treatment, diarrhea persists for 2–4 days, with accompanying dehydration and prostration. Because of electrolyte imbalance, there may be severe cramps in the lower extremities. Death can occur within a period of hours. There are numerous secondary clinical manifestations of the disease.

Therapy consists of massive fluid replacement. Glucose is also administered orally or by nasogastric tube to reduce the volume of water output in the stools. The recommended replacement solution contains 20 grams glucose, 3.5 grams sodium chloride, 2.5 grams sodium bicarbonate, and 1.5 grams potassium chloride per liter, given in a dose of 110 ml/kg body weight orally over four hours. Intravenously 5 grams sodium chloride, 4 grams sodium bicarbonate, and 1 gram potassium chloride per liter can be administered with the same dosage except that two liters should be administered during the first thirty minutes. Tetracycline may be administered parenterally to shorten the period of diarrhea. This therapy has been effective in saving many lives. Unfortunately, because of the nature of occurrence of the disease, many scores of cases may appear within a period of hours, far exceeding the facilities' capability for treatment and hence, in some locations, there may be many fatalities.

Inasmuch as humans are the only known hosts of the cholera-producing organism, it is logical to assume that the disease arises from fecal

contamination of either water or food. Persons who are achlorhydric (as by taking generous amounts of antacids) run a higher risk of infection because the organisms naturally are sensitive to gastric acid. Persons with chronic gallbladder disease are suspected carriers of the infection. For unknown reasons, severe disease occurs more frequently in persons with blood type O. The natural immunity to cholera of persons who have recovered from the infection appears to be long-lasting. Studies made in endemic areas such as Bangladesh and India show that the incidence of the disease is eminently high in small children, being up to 10 times that of persons over 20 years old. However, in epidemics, statistics show a relatively even distribution of cases among individuals of all ages.

CHOLESKY METHOD OF SOLVING EQUATIONS. The Cholesky method (also known as the square-root method) is a convenient way of solving a set of linear simultaneous equations when the matrix of coefficients on the left-hand side is symmetrical. As an example consider the three equations

$$a_{11}x_1 + a_{12}x_2 + a_{13}x_3 = y_1$$

$$a_{12}x_1 + a_{22}x_2 + a_{23}x_3 = y_2$$

$$a_{13}x_1 + a_{23}x_2 + a_{33}x_3 = y_3$$

The computational layout is shown below.

a_{11}	a_{12}	a_{13}	y_1	S_1
a_{12}	a_{22}	a_{23}	y_2	S_2
a_{13}	a_{23}	a_{33}	y_3	S_3
u_{11}	u_{12}	u_{13}	v_1	S_4
0	u_{22}	u_{23}	v_2	S_5
0	0	u_{33}	v_3	S_6

The upper array consists of the coefficients of the equations together with the right-hand sides and a check column of S's in which each entry is the sum of all the other entries in the same row. The elements of the lower array are found row by row from the rule:

sum of products of rth column with sth column of lower array

= element of upper array in rth row and sth column

Then, with

$r = 1, s = 1$ we have $u_{11}^2 = a_{11}$,

$r = 1, s = 2$ $\quad u_{11}u_{12} = a_{12}$

$\ldots$ $\quad \ldots$

$r = 3, s = 5$ $\quad u_{13}S_4 + u_{23}S_5 + u_{33}S_6 = S_3$

Thus

$$u_{11} = \sqrt{a_{11}};\ u_{12} = a_{12}/u_{11}; \ldots$$

$$u_{22} = \sqrt{(a_{22} - u_{12}^2)}u_{23} = (a_{23} - u_{12}u_{13})/u_{22}; \ldots$$

and the elements of each row can be calculated successively. As a check, the first four entries in any row of the lower array should add up to the corresponding S.

The original equations have now been replaced by an equivalent set given symbolically by the lower array. These can be readily solved, working upward from the bottom.

If there are several sets of equations with the same left-hand sides, the different columns of right-hand sides can all be included in the arrays and handled simultaneously. In particular, the inverse matrix of (a_{ij}) can be found by setting $(y_1,\ y_2,\ y_3)$ equal successively to (1, 0, 0), (0, 1, 0) and (0, 0, 1), the columns of the unit matrix. In this case, the elements of the inverse can be evaluated directly from the columns of v's by the rule:

sum of products of pth column with qth column of v's

= element of inverse in pth row and qth column

The Cholesky method provides an alternative to the Doolittle method for solving linear equations; its principal advantage is that fewer intermediate results have to be written down.

See also **Matrix (Mathematics)**.

CHOLESTERIC LIQUID CRYSTALS. See **Liquid Crystals**.

CHOLESTEROL. Also known as cholesterin or 5-cholesten-3-betaol, cholesterol is the most common animal sterol, a monohydric secondary alcohol of the cyclopentenophenanthrene (4-ring fused) system containing one double bond. It occurs in part as the free sterol and in part esterified with higher fatty acids as a lipid in the human blood system. The primary precursor in biosynthesis appears to be acetic acid or sodium acetate. Cholesterol itself in the animal system is the precursor of bile acids, steroid hormones, and provitamin D_3. Cholesterol is a white, or faintly yellow, almost odorless substance and may take the form of pearly granules or crystals. The substance is affected by light; mp 148.5 °C (299 °F); bp 360 °C (680 °F), but tends to decompose at lower temperatures. Specific gravity 1.067 (20/4 °C (68/39 °F); insoluble in water; slightly soluble in alcohol; soluble in fat solvents, vegetable oils, and in aqueous solutions of bile salts. Cholesterol occurs in egg yolk, liver, kidneys, saturated fats and oils. In addition to its importance in medicine and biology in general, cholesterol is used as an emulsifying agent in cosmetic and pharmaceutical products. It is the source of estradiol.

Research over the years has shown that cholesterol is carried in the bloodstream in complexes with other lipids and proteins. Based upon their density, there are four classes of lipoproteins; the chylomicrons; the VLDLs (very low density); the LDLs (low density); and the HDLs (high density). It is estimated that about 80% of the total blood cholesterol is carried by the LDLs. Most of the remainder is carried by the HDLs. Large quantities of triglycerides, but very little cholesterol, are carried by the chylomicrons and VLDLs.

As early as 1951, researchers at Cornell University Medical College observed that in males with coronary heart disease, the HDL concentrations were low. There were several confirmations of this during the 1950s and 1960s. However, for many years, the principal criteria in connection with heart attack and stroke with relation to cholesterol was considered to be total cholesterol and LDL levels, with little attention given to the HDLs. It

was not until 1975 researchers at the Royal Infirmary, Edinburgh, Scotland, reported an inverse correlation between blood concentration of HDLs and total body cholesterol. Miller hypothesized that HDLs may lessen body cholesterol by facilitating its excretion. Epidemiological studies were made shortly thereafter on Japanese-Hawaiian males, Israeli males, and black sharecroppers in Georgia. These studies showed that risk of heart attack increases as blood HDL level decreases. The average value for HDL levels in human males is 45 milligrams per deciliter (55 milligrams for females). The generally higher level of HDLs in females may partially account for their lower heart attack rates. For both sexes, ithas been estimated that a 5 milligram drop in the aforementioned HDL levels may increase the risk of heart attack by about 25%.

Cholesterol and Diet

People get cholesterol in two ways. The body — mainly the liver — produces varying amounts, usually about 1,000 milligrams a day. Foods also can contain cholesterol. Foods from animals (especially egg yolks, meat, poultry, fish, seafood and whole-milk dairy products) contain it. Foods from plants (fruits, vegetables, grains, nuts and seeds) do not contain cholesterol.

Typically the body makes all the cholesterol it needs, so people do not need to consume it. Saturated fatty acids are the main culprit in raising blood cholesterol, which increases the risk of heart disease. Trans fats also raise blood cholesterol. But dietary cholesterol also plays a part. The average American man consumes about 337 milligrams of cholesterol a day; the average woman, 217 milligrams.

Some of the excess dietary cholesterol is removed from the body through the liver. Still, the American Heart Association recommends that one limit average daily cholesterolintake to less than 300 milligrams. Those with heart disease should limit daily intake to less than 200 milligrams. By keeping dietary intake of saturated fats low, one can significantly lower one's dietary cholesterol intake. Foods high in saturated fat generally contain substantial amounts of dietary cholesterol.

People with severe high blood cholesterol levels may need an even greater reduction. Since cholesterol is in all foods from animal sources, care must be taken to eat no more than six ounces of lean meat, fish and poultry per day and to use fat-free and low-fat dairy products. High-quality proteins from vegetable sources such as beans are good substitutes for animal sources of protein.

Cholesterol-Lowering Medicines

Several types of medicine are used to treat high cholesterol levels. A physician will decide which type of medicine is right for you. He or she may prescribe more than one of these drugs at a time because combinations of these medicines can be more effective.

Statins (also called *HMG-CoA reductase inhibitors*) slow down your body's production of cholesterol. These drugs also remove cholesterol buildup from the arteries (blood vessels). Examples of statins include atorvastatin (brand name: Lipitor), fluvastatin (brand name: Lescol), lovastatin (brand names: Altocor, Mevacor), pravastatin (brand name: Pravachol), rosuvastatin (brand name: Crestor) and simvastatin (brand name: Zocor).

Resins (also called *bile acid sequestrants*) help lower the LDL cholesterol level. Some examples of bile acid sequestrants include cholestyramine (brand names: Prevalite, Questran), colesevelam (brand name: Welchol) and colestipol (brand name: Colestid).

Fibrates (also called *fibric acid derivatives*) help lower cholesterol by reducing the amount of triglycerides (fats) in the body and by increasing the level of "good" cholesterol (also called HDL, or high-density lipoprotein). Some examples of fibrates include fenofibrate (brand names: Antara, Lofibra, Tricor) and gemfibrozil (brand name: Lopid).

Niacin (also called *nicotinic acid*) is a B vitamin. When given in large doses, it can lower the levels of triglycerides and LDL cholesterol, and increase the HDL cholesterol level. Even though niacin can be purchased over the counter, it should not be taken unless a doctor prescribes it. It can cause serious side effects.

Cholesterol absorption inhibitors help lower cholesterol by reducing the amount that is absorbed by the intestines. Ezetimibe (brand name: Zetia) is a cholesterol absorption inhibitor. This type of medicine is often given in combination with a statin. The combination of ezetimibe and simvastatin (brand name: Vytorin) is an example.

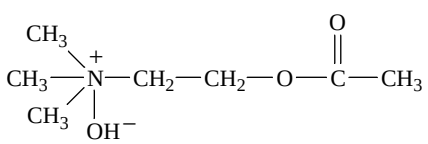
CHOLESTRTIC LIQUID CRYSTALS. See **Liquid Crystals**.

CHOLINE AND CHOLINESTERASE. An enzyme (acetylcholinesterase) is specific for the hydrolysis of acetylcholine to acetic acid and choline in the animal body. It is found in the brain, nerve cells and red blood cells and is important in the mechanism of nerve action. Acetylcholine was first synthesized in 1867. It consists of a combination of choline and acetic acid in an ester linkage. The component parts of the acetylcholine molecule are both normal constituents of the animal body. Acetylcholine has the structure:



Acetylcholine assumed no importance to biologists until 1899 when Hunt identified the presence of choline in extracts of the adrenal glands and suggested that some derivative of choline was capable of causing a fall in blood pressure. This stimulated interest in studying the physiological

effects of various choline derivatives and, in 1906, Hunt and Taveau found that acetylcholine was 100,000 times more effective than choline in causing a fall in blood pressure. Shortly thereafter, acetylcholine was identified in extracts of ergot, a fungus that grows on rye and other cereal grains. The first real proof of the role of acetylcholine in transmitting the effects of nerve stimulation did not come until 1921. The acetylcholine-cholinesterase system has served as the basis for the development of a number of drugs needed to alter the activity of the autonomic nervous system in certain disease states. Inhibitors of cholinesterase are used in insecticides. Parathion and malathion are examples of organic phosphate cholinesterase inhibitors that are effective for this purpose. Cholinesterase inhibitors are capable of producing poisoning and death in humans and domestic animals by the same mechanism.

Choline is an essential metabolic substance for building and maintaining cell structure. Choline is usually described along with B complex vitamins, although it is essentially a structural component of tissue rather than a metabolic catalyst. Choline is a part of the structure of phospholipids and acetylcholine.

Choline participates in normal fat metabolism and interrelates with methionine in a biochemical manipulation referred to as transmethylation. Choline, when in adequate quantity, can replace the essential amino acid methionine when the latter is in limited quantity; or the reverse may occur, that is, methionine can be dismantled to replace choline. Choline deficiencies result in numerous degradative physiologic changes in livestock. The usual dietary supplements are choline bitartrate and choline chloride.

Human Disease Implications

In Alzheimer's disease, neurochemical studies of cerebral cortex have shown specific reduction in choline acetyltransferase (CAT), the enzyme required for synthesis of the neurotransmitter acetylcholine (ACh). The degree of reduction of ACh correlates with the severity of dementia. This finding may reflect loss of the neurons in the substantia innominata of the basal forebrain that form the cholinergic projection to the hippocampus and cerebral cortex. Degeneration of the terminals of these neurons may initiate the formation of amyloid plaques.

In Huntington's disease, there is a progressive degenerative disease of the basal ganglia that is inherited as an autosomal dominant trait. In terms of the pathologic findings of this disease, there is a marked atrophy of the corpus striatum and depletion of interneurons in the striatum. The major neurochemical abnormalities in the basal ganglia are reduction of GABA (gamma-aminobutyric acid) and its synthesizing enzyme, glutamic acid decarboxylase; reduction of CAT; and reduction of postsynaptic receptors for these neurotransmitters.

CHONDRICHTHYES (Sharks, Rays, and Chimaeras). The chondrichthyans, or sharks, rays and chimaeras, are very successful animals that first appeared over 400 million years ago, long before the age of dinosaurs. They are related to the bony fishes, or osteichthyans, which are far more numerous and diverse — unlike bony fishes, sharks and rays have an internal skeleton composed of cartilage rather than bone. Sharks and rays, while not nearly as diverse as bony fishes, have nevertheless maintained their position as important predators in many marine and some freshwater environments. See also **Osteichthyes (Bony Fishes)**.

Sharks have maintained the same basic body plan (Fig. 1) throughout their 400-million-year-plus history. Sharks typically have a streamlined body with a long snout, an underslung mouth, five to seven pairs of gill slits, a small spiracular opening, paired pectoral and pelvic fins, one or two dorsal fins, an anal fin (absent in some groups), and a crescent-shaped caudal (tail) fin which is heterocercal, meaning the vertebral column is upturned and extends out to the tip of the fin's upper lobe. Male sharks have claspers — paired appendages used in mating — associated with their pelvic fins. Aristotle, in 350 BC, recognized important differences between sharks and bony fishes, including the observation that sharks have separate gill slits while the gills of bony fishes are covered by an opercular flap. See also **Aristotle of Stagira (384 BC–322 BC)**.

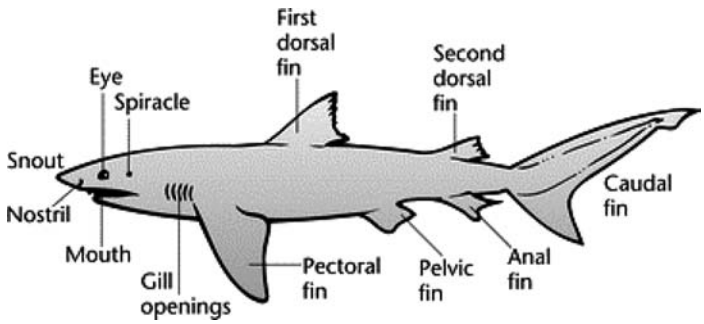

Fig. 1. External features of a generalized shark.

Rays, closely related to sharks, are primarily bottom-dwellers that have evolved a flattened, disc-shaped body, with eyes located on top of their heads. They use their greatly expanded wing-like pectoral fins to glide gracefully through the water. Many rays have modified their teeth into flat crushing plates for feeding on mollusks and crustaceans.

In addition to the sharks and rays, most modern systematic arrangements place another group within the Chondrichthyes– the Holocephali (or holocephalans), more commonly referred to as chimaeras, elephantfishes or ratfishes. There are around 35 living species, all marine and primarily found in relatively deep cold water. Holocephalans share with sharks and rays a cartilaginous skeleton, and males also have claspers associated with their pelvic fins. Holocephalans, however, are rather peculiar animals that differ markedly from sharks in a number of respects. Many have oddly shaped protruding snouts, and they generally have large heads and prominent eyes, ventrally positioned mouths, jaws with ridged knobby toothplates, smooth scaleless bodies, gills covered by a single opercular flap, and tapering whip-like tails. Holocephalans also have upper jaws that are firmly fused to the cranium, as opposed to the mobile upper jaws of sharks and rays.

A feature shared by all chondrichthyans is an internal skeleton of cartilage, rather than bone as in other vertebrates — the name Chondrichthyes means 'cartilaginous fish'. Sharks and rays uniquely possess prismatic cartilage, in which the cartilage's surface layer is composed of small crystalline prisms. Recent research has shown that the jaws of some mollusc-crushing rays are internally reinforced at stress points by struts (or trabeculae) of cartilage arranged in much the same way as the bone of other vertebrates, and that some primitive fossil sharks possess true bone as well as cartilage.

Cartilaginous fishes do not have swim bladders, which bony fishes use to maintain buoyancy, but instead rely on very large oily livers to help keep them from sinking. However, it is not true that all sharks have to swim continuously to keep alive — many species, including nurse sharks (Ginglymostoma cirratum) which are commonly kept in aquaria, regularly rest on the bottom. See also **Fishes**.

Most sharks are active predators and have sharp, triangular, cutting teeth. Sharks continuously produce and shed their teeth. It is estimated that some species may produce 50 000 or more in a single lifetime. The teeth are arranged in rows on the jaws, with each row always advancing toward the front edge of the jaw like a slow-moving conveyor belt, and newer replacement teeth taking the position of the older teeth as they are shed along the margin of the jaws. It has recently been discovered that some sharks begin producing, shedding, and replacing their teeth even before they are born. Rays and holocephalans have fundamentally the same kind of tooth replacement but the whole process is much slower and in holocephalans the old teeth are kept and overgrown by newer parts of the tooth plates. Along with teeth, most cartilaginous fishes have tiny placoid scales embedded in their skin, which gives the skin its prickly feel, and some species have sharp spines in front of their dorsal fins. See also **Sharks (Chondrichthyes)**; and **Skates and Rays (Chondrichthyes)**.

Diversity

Many different species of sharks and rays have evolved over the course of their very long history, but at present the group is not exceptionally diverse. There are nearly 600 living species of rays and approximately 350 shark species. In comparison, the living bony fishes (osteichthyans) number more than 23 000 species (about half of all known vertebrates).

Despite their relatively low overall diversity, living sharks and rays are important and conspicuous members of many marine and some freshwater ecosystems. Living sharks range in size from the tiny dwarf lantern shark (*Etmopterus perryi*), with a total length of 20 cm (8 in), to the gigantic planktivorous whale shark (*Rhincodon typus*), which grows to a length of at least 12 m (40 ft). According to recent classifications, living sharks and rays are divided between two major groups, the Squalea and the Galeomorphii. See Figure 2.

Habitats

Chondrichthyans are found in a wide range of aquatic, predominantly marine habitats. They are most common and have their greatest diversity in temperate to tropical marine environments, in coastal to shallow shelf areas of the sea. Very few species are found below 2,000 m (6,562 ft); among those that are the gulper sharks (*Centrophorus*), which can occur down to 4,000 m (13,123 ft). Many shark species occupy the medium-to-large marine predator niche, and as such are typically found in habitats with a wide diversity of fishes and other marine animals that are their potential prey. These habitats commonly include sandy-bottomed shallows off open beaches, lagoons, estuaries, rocky coastlines, coral and rocky reefs, and kelp forests. Particularly favored areas include biologically rich coastal upwelling zones and the mouths of rivers and deltas. A few species, most notably the bull shark (*Carcharhinus leucas*), enter freshwater environments — bull sharks are well known for swimming up rivers and also enter freshwater lakes. Some rays spend their entire lives in freshwater, including the river rays (Potamotrygonidae) of tropical South America.

Reproduction

Cartilaginous fishes are unusual compared to most bony fishes in that they produce a relatively small number of offspring, anywhere from one to a few dozen depending on the species (bony fishes often produce thousands or even millions of eggs at a time). The eggs are fertilized internally; males use their claspers to transmit sperm during copulation. Mating has only rarely been observed in sharks. It is thought to occur seasonally for only a brief time each year, and even less frequently in some species like the spiny dogfish (*Squalus acanthias*), which has a 2-year gestation period (the longest known for any animal). Female sharks are often observed with scars around their pectoral fins and on the top of their heads, probably the result of males seizing them during copulation.

In the majority of sharks, the eggs develop inside the female shark's uterus, with a long gestation period of up to 2 years, and with nutrition supplied by large yolk sacs. In a few species, for example sand-tiger sharks (*Carcharias taurus*), young inside the uterus may cannibalize their siblings while they are developing. Alternatively, some produce eggs covered in a tough, horny egg case. The young develop inside the egg case but outside their mother's body, and also receive nourishment via a yolk sac. Many aquaria now feature exhibits in which baby sharks can be watched developing inside egg cases. In both strategies, once born the young are fully functional and independent from their parents.

Special Sensory Adaptations

Sharks and rays are often regarded as very primitive, and therefore simple, animals. While they are primitive with respect to their systematic position, they nevertheless possess a number of very specialized and highly sophisticated sensory capabilities. Perhaps the most intriguing is their ability to detect the weak electrical signals produced by muscular activity in other animals, which helps them to detect and track prey and in some cases to locate potential mates. Sharks detect electrical signals using special electroreceptors called the ampullae of Lorenzini, small chambers filled with a gelatinous substance and lined with special sensory cells. These ampullae, which are clustered in the head region particularly on the sides and undersurface of the snout, can detect electric signals as weak as five-billionths of a volt. Along with electroreception, sharks also have a highly sensitive lateral line system for detecting movements and vibrations in the water, another very useful adaptation for a marine predator. The lateral line receptors run along the body on both sides, and have branches on the head. Sharks also have acute hearing, balance and vision, and an especially keen sense of smell capable of detecting just a few molecules of blood in seawater.

Fossil History

Our knowledge of fossil sharks is limited in many cases to their teeth, which are covered in hard enamel and produced in great numbers, supplemented by occasional spool-like calcified vertebral centra. Less commonly fin spines are found. The cartilaginous skeleton of sharks rarely fossilizes, although some preserved skeletons (ironically, usually of early primitive sharks, and also of some rays and chimaeras) have been found.

Cartilaginous fishes are a very ancient group with a fossil record that extends back into the Paleozoic era, to the Silurian period approximately 420 million years ago (Ma). The earliest fossil chondrichthyans are known only from isolated scales — the exact nature of these first representatives is a mystery, as is the origin of the group as a whole. Chondrichthyans

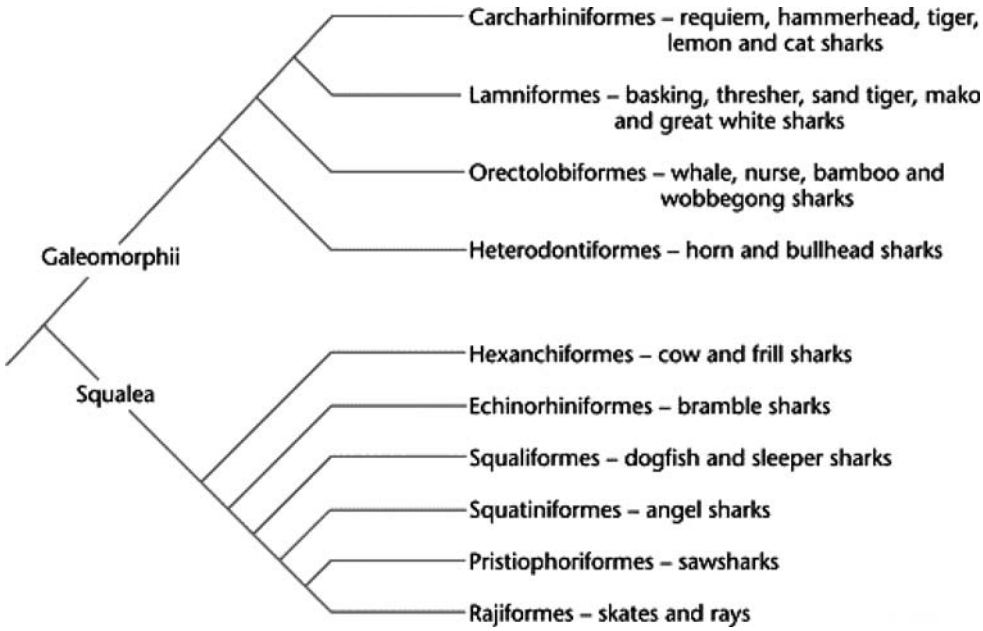

Fig. 2. Evolutionary relationships of the major groups of modern elasmobranchs or Neoselachii (adapted from de Carvalho, 1996)

may be closely related to an extinct Paleozoic group of jawless fishes called thelodonts which have somewhat similar scales, or possibly to the placoderms, early jawed fishes with bony armor. Understanding the early evolution of sharks remains problematic due to the lack of informative specimens of the earliest basal forms. See also **Placodermi (Armoured Fishes)**: and **Agnatha (Lampreys, Hagfishes, Ostracoderms)**.

The oldest well-known shark is *Cladoselache*, from the Devonian of Ohio (about 380 Ma). *Cladoselache* resembles modern sharks, with a streamlined body, five pairs of gill slits, paired large pectoral and smaller pelvic fins, two dorsal fins (each with a large spine), and a cartilaginous skeleton. If *Cladoselache* were alive today there would be no difficulty in identifying it as a shark. The teeth of *Cladoselache* and a number of related primitive sharks are distinctive, with a high central cusp flanked on either side by smaller lateral cusps.

Following the Devonian, the Carboniferous and Permian periods (c. 360–250 Ma) saw a great early radiation of sharks, including a number of bizarre forms characterized by unusually modified fins and odd dentitions. One group called the iniopterygians developed very long, wing-like pectoral fins, possibly used to 'fly' above the water like the living flying fishes. The stethacanthids and falcatids include species with elaborately modified dorsal fin elements that project out over their heads, probably used by males in courtship and/or as a threat display. The edestids have teeth arranged in a spiral whorl with the newest and largest teeth on the outside of the whorl. Some edestids may have grown very large, but only their peculiar tooth whorls are well known. Among the most unusual are the petalodontids, poorly known until recent discoveries, which have shown them to have deep bulbous bodies, short heads and strongly ridged teeth suitable for crushing shellfish and coral. Many of the unusual sharks of this era are known from superb specimens found at two very important Carboniferous sites — the Bear Gulch Limestone of Montana, USA, and the Bearsden deposit near Glasgow, Scotland. Along with these, freshwater deposits from this time interval commonly contain remains of the xenacanths — large, elongate sharks with tapering tails and prominent spines immediately behind their heads. Some xenacanths are known from well-preserved complete skeletons.

The unusual sharks of the Palaeozoic largely disappeared by the Mesozoic era (250–65 Ma). One Palaeozoic group that survives into the Mesozoic, the hybodonts, superficially look like *Cladoselache* but have a number of advanced skeletal features that link them more closely to modern sharks. By the middle of the Mesozoic, the first remains of rays are found, and by the latter part of the Mesozoic the 'new' sharks, or neoselachians, become established as the dominant chondrichthyans. Neoselachians are characterized by more mobile jaws relative to their primitive ancestors. A number of neoselachian species die out at the close of the Mesozoic era, 65 Ma, but some lineages survived into the next era — the Cenozoic. All Cenozoic sharks and rays, including those living today, are neoselachians (the group also includes some fossil forms that are now extinct). See also **Mesozoic**.

The most notorious neoselachian, and the most spectacular marine predator to have ever evolved, is the giant Carcharodon megalodon, or 'Megatooth', a close relative of living great white sharks (*C. carcharias*). Megatooth sharks are found worldwide in fossil marine deposits from about 25 to 3 Ma. These superpredators reached over 16 m (50 ft) in total length, but not 30.5 m (100 ft) or more as claimed in earlier exaggerated accounts, and may have had a mass in excess of 50,000 kg (110,231 lbs) (the equivalent of several Tyrannosaurus rex dinosaurs!). Particularly notable are their enormous serrated triangular teeth, which grew up to seven inches in length and were used to catch baleen whales and other large prey. The megatooth is probably the largest shark ever to have evolved — only the living whale shark (*Cetorhinus maximus*), a placid filter-feeding giant, reaches a comparable size.

Holocephalans have a fossil record extending back to the Devonian, suggesting a split from sharks and rays approximately 350–400 Ma.

Phylogeny

According to recent analyses, all living sharks and rays, and a few close fossil relatives, are members of a single monophyletic group, the Neoselachii (Fig. .2). The odd fossil forms that appeared in the Paleozoic are considered to be more primitive and lie outside the Neoselachii. Neoselachians are united as a monophyletic group by several shared characters, including features of the gill arches, jaw musculature, pectoral girdle and teeth. Within neoselachians, two main lineages of living sharks are recognized — the Galeomorphii, which includes the heterodontiforms, orectolobiforms, lamniforms and carcharhiniforms, and the Squalea, comprising the hexanchiforms, echinorhiniforms, squaliforms, squatiniforms, pristiophoriforms and rajiforms. The monophyletic status of both the Galeomorphii and the Squalea is supported by several shared derived features.

This current framework elaborates on and somewhat modifies what was the prevailing view for many years, which postulated four main groups of extant sharks — the Galeomorphii, Squalomorphii, Squatinomorphii and Batoidea. This earlier hypothesis left unresolved the question of the interrelationships of the 'batoids' (Rajiformes), which are now considered to be members of the Squalea, closely related to the pristiophoriforms (sawsharks).

Sharks and rays are grouped together within Chondrichthyes as the Elasmobranchii (or elasmobranchs), with holocephalans as their next most closely related (or sister) group. See also **Cladistics**.

CHONDRITE. A term proposed by Rose in 1864, a chondrite is a stony meteorite characterized by chondrules embedded in a finely crystalline matrix consisting of orthypyroxene, olivine, and nickel-iron, with or without glass. Chondrites constitute about 80% of meteorite falls and are usually classified according to the predominant pyroxene, e.g., "enstatite chondrite," "bronzite chondrite," and "hypersthene chondrite." Chondritic meteorites have been considered as among the most primitive objects in the solar system — on the basis of their age ($\sim 4.6 \times 10^9$ years) and because of their lack of extensive chemical differentiation. Since the early 1950s, radioactive dating methods have been applied more and more to problems for establishing the chronology of the earth, moon, and solar system. Some of these methods involved a fixed percentage of error, which made it impossible to resolve events occurring within $\sim 100 \times 10^6$ years of one another early in the history of the solar system. Two methods have evolved for the resolution of the finer structure in the time scale for the formation of the solar system: (1) an approach based on the xenon daughter products of the extinct radioactive isotopes ^{129}I (half-life $= 17 \times 10^6$ years) and ^{244}Pu (half-life $= 80 \times 10^6$ years); and (2) an approach that depends on the initial isotopic abundance of radiogenic ^{87}Sr, the daughter of ^{87}Rb (half-life $= 50 \times 10^9$ years). In the latter method, the assumption is made that when formed the solar nebula had a uniform $^{87}Sr/^{86}Sr$ ratio ($\sim$0.698). Thus, if the solar nebula had a $^{87}Rb/^{86}Sr$ ratio, typical of chondrites (0.75), the $^{87}Sr/^{86}Sr$ ratio of the solar nebula will increase at the rate of 0.0001 per 9×10^6 years. Following this line of reasoning and as abstracted in the aforementioned paper, "A sodium-poor, calcium-rich inclusion in the carbonaceous chondrite Allende had a $^{87}Sr/^{86}Sr$ ratio at the time of its formation of 0.69880, as low a value as that found in any other meteorite. The higher $^{87}Sr/^{86}Sr$ ratios found in ordinary chondrites indicate that their formation or isotopic equilibrium occurred tens of millions of years later." See also **Mass Extinctions**; and **Meteroids and Meteorites**.

CHONDRODITE. Chondrodite, a magnesium fluosilicate mineral $Mg_5(SiO_4)_2(F,OH)_2$, crystallizing in the monoclinic system is a product of metasomatic origin in metamorphosed dolomitic limestones. Crystals are uncommon, usually occurring as discrete grains within the limestone, of light yellow to red color. Vitreous luster, translucent, with hardness of 6–6.5, and specific gravity of 3.1–3.2. This mineral is the most prominent member of minerals falling within the chondrodite group. These are norbergite, chondrodite, humite and clinohumite. Individual members of this group require optical evaluation for positive identification.

Noteworthy world occurrences include Mt. Somma, Italy; Pargas, Finland; Kafveltorp, Sweden; and in the United States at Brewster, and Warwick and Orange Counties, in New York.

CHONDROSTEL. The paddle-fishes and sturgeons. An order with the skeleton made up largely of cartilage but with some bony components.

CHONOLITH. A term proposed by R.A. Daly in 1905 for irregular igneous intrusions which according to their shapes and field relationships cannot be classified as dikes, laccoliths, batholiths, or bysmaliths.

CHOPPER. The term chopper is commonly used for two devices: 1. A device, usually mechanical, that imparts a pulsating characteristic to a current or a beam of light by a regular and frequent interruption; and 2. A device that modulates a signal by opening and closing contacts periodically. The frequency of the chopper is usually greater than any frequency of interest in the signal.

CHOPPER AMPLIFIER. The term *chopper amplifier* has two connotations. In one type, the input signal is chopped (or modulated), amplified by an A.C. amplifier, demodulated, and filtered to provide a D.C. output signal. This type is described under **Carrier Amplifier**. In the second type, the error signal is chopped for the purpose of providing stabilization of gain and offset. Possibly, a more fitting term would be "chopper-stabilized amplifier."

With reference to Fig. 1, the unit is a chopper-stabilized amplifier with an overall gain A. The amplifier output is attenuated by a factor of $1/A$ and then compared with the input signal. An error may exist as the result of zero-offset drift, a change in the gain of the D.C. amplifier, or simply noise. The error is chopped (modulated), amplified by an A.C. amplifier, demodulated, and then summed with the input to the D.C. amplifier — in a manner to compensate for the disturbance causing the error.

Excellent zero offset and gain characteristics are features of the chopper-stabilized amplifier, along with the favorable wide-bandwidth characteristics of the direct-coupled amplifier. The modulator-demodulator circuitry is relatively complex and, consequently, the design is not extensively used in digital-data acquisition and instrumentation amplifiers. Comparable performance can be obtained from conventional direct-coupled amplifiers. One negative feature of the chopper-stabilized amplifier is the frequently encountered long saturation recovery time, a deterrent for use in time-shared systems.

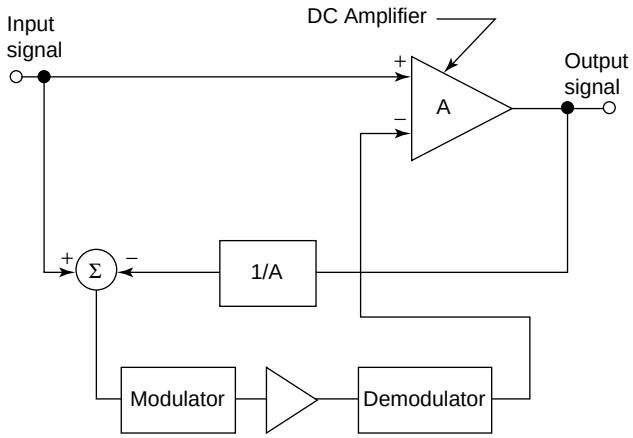

Fig. 1. Chopper-stabilized amplifier.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

CHORD (Aircraft). The length from the leading edge to the trailing edge of an airfoil. The chord is a basic reference axis for the geometric or aerodynamic properties of an airfoil. It is normal to the span and lies in the plane of the airfoil. There are two of these reference chords. The one used for general and structural reference is the *geometric* chord. The other is an *aerodynamic* chord, being an imaginary line through the airfoil parallel to the free air stream at zero lift and passing through the trailing edge. The length of this chord is of no importance. It is useful mainly in aerodynamic studies because the lift varies directly with the angle of attack of the aerodynamic chord.

If the airfoil has a flat lower surface, an element of this surface is taken as the geometric chord. The chord length is the overall projection of the profile on this chord. In double-cambered airfoils the geometric chord is taken as the longest straight line possible between leading and trailing edges, or as a straight line joining the ends of the profile median line. The angle of attack to the geometric chord at zero lift is the angle between these chords. This may be discovered by wind tunnel tests, although empirical constructions have been devised which locate the aerodynamic chord surprisingly well. If the wing is tapered there is a tip chord and a root chord. The location of the intermediate chord on which the aerodynamic forces could be assumed to act is called the mean aerodynamic chord and is important in studies of airplane balance and stability. When the coefficient of lift may be assumed to be constant over the semispan, the mean aerodynamic chord coincides with the mean geometric chord (i.e., the centroid of the semiwing plan form). This simplification is in error if the wing has twist, or if it is rectangular, in which case the uneven downwash causes decreased lift coefficient near the tips.

See also **Airplane**.

CHORDATA. The vertebrates and a few marine animals of simpler form, including the tunicates, salpians and lancelets. Although the true vertebrates make up most of this phylum the inclusion of the other forms is scientifically accurate. With these limits the distinctive characters of the phylum are few. The animals are triploblastic, coelomate, and metameric like the higher invertebrates but differ from them in three points: (1) the skeleton is internal. In its primitive state, it consists of a slender longitudinal rod lying above the alimentary tract and called the notochord; this structure is present at some stage in development in all of the included species; (2) the nervous system essentially is dorsal in position, lying in the body wall above the notochord; and (3) the alimentary tract includes a chamber, the pharynx, just behind the oral cavity, whose walls are perforated by openings associated with respiration and called the

gill slits or pharyngeal clefts. These openings appear or are indicated only in the embryos of terrestrial species.

It is difficult to estimate the relative importance of the phylum since man himself is one of the included species. The chordates include the most highly developed animals from the scientific point of view, and from the practical point of view they are equally important as the source of most of our animal foods, furs, feathers, wool, leather, and as beasts of burden. People have depended on the vertebrates, indeed, for much of their progress, and have taken their domestic animals from this group.

The classification of the phylum is briefly as follows:

Subphylum *Hemichordata*. Worm-like marine animals. *Balanoglossus*. Also named *Enteropneusta*.

Subphylum *Urochordata*. Sessile or free-swimming forms, marine, with larvae resembling tadpoles in which the characters of the phylum are evident. Also named *Tunicata*.

- Class *Larvacea*. Small floating animals with the larval form of the subphylum.
- Class *Ascidiacea*. The tunicates. Sessile or free, named from the investing test or tunic which encloses them.
- Class *Thaliacea*. The salpians. Free-swimming.

Subphylum *Cephalochordata*. The lancelets. Small fish-like animals which swim freely and also burrow in the sand.

Subphylum *Vertebrata*. The skeleton includes cartilaginous or bony components in addition to the notochord. Also named *Craniata*.

- Class *Cyclostomata*. The round-mouth eels: lampreys and hags.
- Class *Chondrichthyes*. The cartilage fishes, such as the sharks, dogfishes, rays, and chimaeras. Sometimes called elasmobranches.
- Class *Osteichthyes*. The bony fishes. *Pisces* is an obsolete term.
- Class *Amphibia*. The salamanders, frogs, toads, etc.
- Class *Reptilia*. The lizards, snakes, turtles, crocodiles, etc.
- Class *Aves*. The birds.
- Class *Mammalia*. Popularly called animals, without further qualification. They secrete milk for the nourishment of their young and the skin usually bears some hair, often a complete coat that may be in the form of fur or wool. Mice (mouse), horses, and cattle, monkeys, man, and many other forms.

CHORD (Mathematics). A segment of a straight line between two specified points of intersection of the line with a curve or surface. See also **Circle (Geometry)**. In topology, the chord is an element belonging to the complement of a tree. See also **Tree (Mathematics)**.

CHORDOTONAL ORGAN. An organ for the perception of vibrations — rod-like or bristle-like receptors for mechanical and sound vibrations — found in the insects where it may exist singly or in association with complex auditory organs. It consists of a nerve ending with accessory cells connected directly to the body wall or to some modified derivative of the body wall in an organ of hearing.

CHOREA (Huntington's). An inherited degenerative neurological disorder that usually is not manifested until the adult years. In this disorder, there is progressive dementia combined with choreoathetosis, characterized by irregular movements and speech difficulties. In some patients, there is progressive rigidity rather than chorea. The latter form generally commences during childhood. The disorder progresses steadily over a number of years and creates deep depression in the patient, in some cases leading to suicide. The disorder is caused by biochemical abnormalities causing atrophy of the caudate nucleus (collection of nerve cells), among several other disturbances involving glutamic acid decarboxylase, gamma-aminobutyric acid (GABA), and reduction in activity of choline acetyl transferase. Some researchers have found a reduction of acetylcholine and serotinin receptors, but a normal number of GABA receptors.

An effective therapy remains to be developed. For controlling involuntary movements, haloperidol and chlorpromazine have been helpful in some patients. It is of great urgency for persons with a family history of this disorder to receive genetic counseling and thus avoid passing this serious disorder along to future generations.

Dementia is prominent in Huntington's disease, but it is unlike that of Alzheimer's. First-degree relatives have 50% risk. On an average, the onset of the disease occurs near age 40. In the overall population, the incidence is considered to be quite low.

As early as 1983, Gusella (Massachusetts Institute of Technology) located the region of the Huntington's gene in chromosome 4 by using a new genetic mapping technique of that time. This greatly reduced the search because the gene could have been located on any one of 22 chromosomes. There were no prior clues, thus boding well for the mapping technique and the researcher. The attempt to narrow down the exact location of the gene continues.

A possible solution involving the normally dangerous herpes virus appears promising. For several years, neurobiologists have been seeking a way to use gene therapy in the brain. Such an accomplishment could lead to effective treatment of such diseases as Huntington's chorea, Parkinson's disease, and Alzheimer's. Active research along these lines is being pursued at the University of Pittsburgh and the Albert Einstein College of Medicine. Researchers state that human tests may not be feasible for a number of years.

Thus far, investigators have been able to delete more than 80% of the viral DNA. The target is to produce a harmless virus that cannot replicate itself and also to insert a desirable gene into a neuron. It has been observed that herpes simplex is the only known virus that can enter a neuron and remain latent. To assure such harmless latency, some investigators have been attempting to introduce genes that will inhibit replication. One researcher has observed that the virus seems absolutely tailored for gene therapy with tremendous potential.

CHOREA (Sydenham's). First described in 1686 and sometimes called St. Vitus' dance (following anglification of the Greek word), Sydenham's chorea is due to rheumatic fever in childhood and adolescence. Since the incidence of rheumatic fever has declined rapidly, Sydenham's chorea is now a rare disease. When it does appear, it affects patients between the ages of 3 and 20 years, most often in the spring months. The disease may recur in adult life, particularly in pregnant women or in those taking the contraceptive pill. Pathologically, the brain displays a diffuse inflammatory encephalitis.

Onset of the disease is usually gradual with symptoms initially being irritability, disobedience, and inattentiveness. Generalized chorea (involuntary and purposeless movements) then appears. Speech is impaired in about one-third of the patients and the chorea may be predominantly unilateral in about 20% of patients.

The chorea and psychological disturbances slowly recover over about three months and about one-third of the patients will show evidence of rheumatic cardiac involvement at the time of the illness and about the same number later develop chronic rheumatic heart disease.

Seizures may be controlled with diazepam (*Valium*) and a course of penicillin may be instituted to prevent further streptococcal infection. Bed rest and sedation are generally all that is necessary.

CHORION. 1. An accessory structure formed during embryonic development in mammals. It provides the connection with the tissues of the mother through which all interchange of materials between her blood and that of the embryo is carried on prior to birth.

The chorion is a composite structure formed of the serosa and the allantois, although the name is sometimes erroneously applied to the serosa

alone. In some mammals a specialized placenta develops from part of the chorion as the persistent connection with the mother. Like all other extraembryonic membranes, this structure is discarded at birth.

2. The shell of an insect egg.

CHOROIDAL MELANOMA. Choroidal melanoma is a primary cancer of the eye and is the most common intraocular tumor in adults. It arises from the pigmented cells of the choroid, a tissue full of blood vessels that nourish the retina at the back of the eye. Appearing as a small freckle beneath the retina, choroidal melanoma can grow in height and diameter and may, if not treated, eventually spread to other parts of the body.

Some choroidal melanomas appear to remain dormant. However, most enlarge slowly over time and lead to loss of vision if not treated. All choroidal melanomas should be treated as if they are malignant.

Because it occurs inside the eye and is not visible to patients, persons with a choroidal melanoma may not recognize its presence until the tumor has grown so large that vision is impaired.

The tumor is usually diagnosed during an eye examination. It is visible through the "window" of the eye provided by the pupil, and the eye doctor will recognize the choroidal melanoma by the degree of pigmentation of the tumor, its shape, location, and other features. Ophthalmologists can make a diagnosis based on clinical appearance, photographs, and an ultrasound exam.

Ultrasound is a test that transmits high frequency sound waves into the eye. The sound waves are reflected by ocular tissues and used to create a picture of the internal structure, which is displayed on a screen. The A-scan ultrasound is accurate in estimating the height of the tumor. The B-scan shows orbital shadowing, which is a dark area behind the tumor.

In fluorescein angiography, a fluorescent dye is injected into a vein in the arm. As the dye passes through the blood vessels in the back of the eye, rapid sequential photographs are taken through the pupil. The information provided by these tests describes the size of the tumor.

Treatment of choroidal melanoma is recommended when doctors determine that the tumor is likely to grow and spread to other parts of the body if left untreated. Traditionally, treatment for choroidal melanoma has been enucleation, which is removal of the eye. As long as the tumor has not spread to other parts of the body, eye removal eliminates the tumor. However, work has been done in the past 20 years to develop alternative methods of therapy, particularly for those eyes with good vision.

Radiation therapy is the most frequently used alternative for treating choroidal melanomas. Treatments, at the appropriate dose rates and in the proper physical forms, are intended to eliminate tumor cell growth without damage to normal tissue. The radiation kills a tumor either by producing free radicals that destroy cellular DNA immediately or by inducing mutations that kill tumor cells over a period of time. As the cells die, the tumor shrinks, but it usually does not disappear entirely. Radiation can serve as an alternative to enucleation or as a preliminary treatment before eye removal in order to decrease the likelihood of metastasis.

Other methods of therapy are available for selected tumors. Laser photocoagulation can be used to ablate small thin tumors. Cryotherapy, or freezing, is sometimes used to kill very small tumors. Under certain circumstances, small tumors, especially those located near the front of the eye, can be surgically removed using an eye-sparing technique known as an *eye wall resection*.

No treatment of choroidal melanoma is available that can guarantee to destroy the tumor, to preserve vision, or to assure a normal life span.

Vision Rx, Inc., Elmsford, NY

CHRISTOFFEL SYMBOL. One of certain quantities used in tensor analysis. They are not tensors themselves but relations involving the components and derivatives of tensors. They are of two kinds, often distinguished by bracket and brace, respectively:

$$[mn, q] = \frac{1}{2}\left(\frac{\partial g_{mq}}{\partial x^n} + \frac{\partial g_{nq}}{\partial x^m} - \frac{\partial g_{mn}}{\partial x^q}\right)$$

$$\{mn, q\} = \frac{g^{qs}}{2}\left(\frac{\partial g_{mq}}{\partial x^n} + \frac{\partial g_{nq}}{\partial x^m} - \frac{\partial g_{mn}}{\partial x^q}\right) = g^{qs}[mn, q]$$

where g_{mn} is a symmetric covariant tensor, $g^{qs} = G^{mn}/g$, with g the determinant of the components of g_{mn} and G^{mn} the cofactor of g_{mn} in g. See also **Tensor Contraction**.

CHROMA (or Munsell Chroma). The dimension of the Munsell system of color that corresponds most closely to saturation. Chroma is frequently used, particularly by English writers, as the equivalent of saturation.

CHROMATIC ABERRATION. The indistinct color effects observed along the edges of images formed by a simple lens constitute what is known as the chromatic aberration of the lens. This aberration is due to the fact that the glass, or any other substance, out of which the lens is constructed produces dispersion (i.e., refracts light of different colors by different amounts). In a convergent glass lens the focal length is greater for red light than for blue, while in a divergent (concave surface) glass lens the blue focus is longer than the red. The effect for the convergent (convex surface) lens is shown, highly exaggerated, in Fig. 1, in which the location of the image of a source, S, is shown for red light, R, to be in the plane, B, and for blue light, V, to be in the plane, A. An observer using an eyepiece focused for the plane A will see a sharp image of the source in blue light surrounded by the margin of a confused set of images of greater size in other colors.

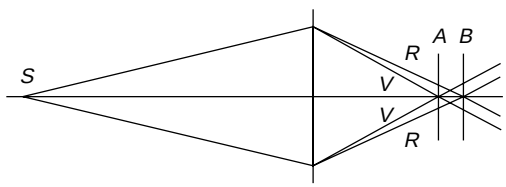

Fig. 1. Chromatic aberration.

Chromatic aberration is very bothersome to users of lenses either for telescopic, microscopic, or photographic purposes and ever since optical instruments came into use attempts have been made to design "achromatic" lenses. For relatively short focus instruments, such as cameras or binoculars, practically complete achromatism can be obtained by using, instead of a simple convex lens, a combination of a convex and a concave lens, the two lenses being constructed of glasses of different dispersive powers. Prospective purchasers of field glasses, opera glasses or binoculars should always examine them carefully to determine whether or not the lenses are properly achromatized. A simple test is to examine the edge of a white building, which is in full sunlight, through the instrument under consideration. Move the image of the edge well over to one side of the field of view, and, if the lenses are properly figured, no color effects will appear. If, however, chromatic aberration is present, the image of the edge of the white building will be found to be bordered with a bright-colored fringe which increases in width as the image is moved closer to the edge of the field. In passing, it might be said that the same test will indicate whether the field glasses are properly corrected for spherical aberration and other aberrations, for, in a poor lens, the image of the edge will become blurred and curved when moved to the side of the field of view.

In long focus instruments, such as astronomical telescopes, complete achromatism is virtually impossible. Partial achromatism may be obtained in such instruments by employing the combination of the divergent and convergent lenses of glass of different dispersive powers. See also **Dispersion (Radiation)**. Two types of partial achromatism are employed, depending upon the purposes for which the telescope is designed. In a telescope to be used for photographic purposes the colors which are most active photographically, i.e., the greens and blues, are all brought to the same focal point, whereas the reds and oranges are thrown well out of this focal plane.

In a so-called visual telescope the yellowish-green light is all brought to one sharp focus, while the blues and violets are bent well inside this visual focus. On looking at the image of a very bright object, such as the moon, a planet, or a bright star, a halo of bluish light can be observed due to the out of focus photographic light, but this halo is so diffuse that it is not objectionable when working with objects of the brilliance for which the instrument is designed. Instruments designed for visual observing (visual refractors) cannot be used satisfactorily for celestial photography without

employing yellow sensitive plates and color filters to eliminate the out of focus blue and green light.

The image formed by a concave metal or silver on glass mirror is free from chromatic aberration since all colors are reflected in the same direction. This is the most important advantage of the reflecting telescope over the refracting type.

CHROMATICITY. The color quality of light definable by its chromaticity coordinates (which are based on matching a sample of light in terms of three stimuli of different, standard colors) or by its complementary or dominant wavelength and its purity taken together. See also **Illumination**.

CHROMATICITY DIAGRAM. A plane diagram formed by plotting one of the three chromaticity coordinates against another. The most common chromaticity diagram at present is the CIE (x, y) diagram plotted in rectangular coordinates. It is shown in Fig. 1.

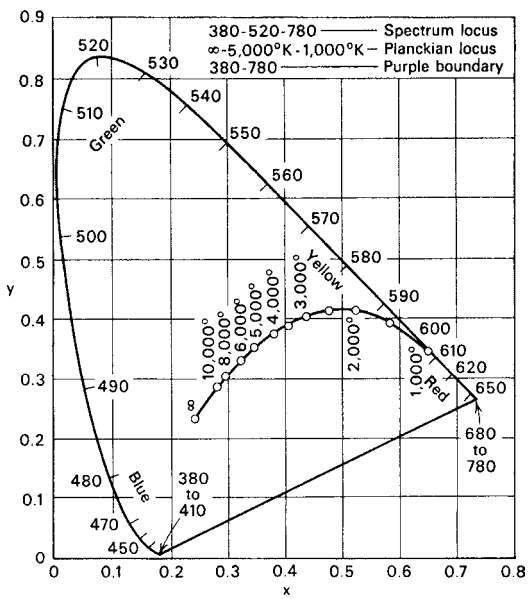

Fig. 1. CIE (x, y) chromaticity diagram plotted in rectangular coordinates.

CHROMATICNESS. The two attributes of visual sensation, hue and saturation, taken together; as distinguished from brightness.

CHROMATIN. This term was given by Flemming to denote that substance in cell nuclei which, in the usual treatment with nuclear dyes, takes up the color. In nondividing nuclei, chromatin is distributed throughout the entire nucleus (euchromatin), but in nuclei undergoing cell division, chromatin is confined to the chromosomes (heterochromatin). In Flemming's time, the chemistry of the nucleus was entirely unknown. Even in view of recent knowledge, it is not fully understood as to what particular substance(s) have the special affinity for the dyes. In isolation of chromatin from pea embryos by differential centrifugation and purified by sucrose gradient centrifugation, the composition of chromatin was found to be deoxyribonucleic acid (DNA), 31%; ribonucleic acid (RNA), 17.5%; histone protein, 33%; and the remainder, nonhistone protein. See also **Cell (Biology)**.

CHROMATOGRAPHY. An instrumental procedure based on physical absorption principles for separating various components from a mixture of chemical substances. In its broad interpretation, chromatography is a combination of separation, identification, and quantitative measurements. As of the late 1980s, chromatography is a giant among the numerous techniques for chemical analysis; high-performance liquid chromatography (HPLC) and gas chromatography are two of the leaders in the field of separation science. Modern chromatography plays three major roles in science and industry, separately or in combination. (1) As a means for identifying and quantifying the ingredients of a mixture of chemical substances — *as used in the laboratory* for quality control, for example, detecting impurities in chemicals, pharmaceuticals, foodstuffs, etc.; assisting researchers: in the study of biochemistry; measuring and identifying unsafe materials in the environment; and as an aid in forensic science, among scores of other specific applications. (2) As a means for *separating materials* where separation (not analysis per se) is the principal target. In this manner, specific chemicals, not easily obtainable in other ways, can be isolated and then, in turn, used to participate in the synthesis of other chemicals. Simply stated, chromatographic separations yield raw materials, notably for research in organic syntheses. (3) As an important, widely acclaimed process — stream chemical composition controller. For such industrial applications, a chromatograph is a complex transducer which not only puts out a signal that identifies the types and amounts of a given substance, but also first separates the target substances from a stream that may contain numerous other substances, some of which may be closely related physically (close boiling points, specific gravities, etc.) or chemically. The transducer output can be used for off-line quality control, or on-line so that the chromatograph becomes part of the total control loop.

In laboratory chemical analysis, where only minute samples may be available, only milligrams of material or less are required for some forms of chromatography. Chromatography is widely used in pollution control technology.

Beginnings of Chromatography

In 1906, a Russian botanist, Mikhail Tswett, first used the chromatographic principle to separate plant pigments. Tswett filled a vertical glass tube with an adsorbent. As a sample of the pigments was washed through the tube with a solvent, a series of colored *adsorption bands* was produced, in essence forming a colorgraphic display. Thus, the apt term, *chroma*tography, but no longer appropriate because frequently materials separated are colorless and the adsorption spectra are presented by way of electronic instrumentation.

Thin-Layer Chromatography (TLC). This format represented the first widespread employment of chromatography as an analytical tool. Surprisingly, even though decades old, the method (refined and improved) still persists and can be found in some pharmaceutical laboratories for drug testing, by medical laboratories, and in the chemical industry. TLC is a simple, low-cost technique. TLC, of course, has been replaced for a host of applications by the more sophisticated chromatographic apparatus available today that offers numerous advantages, disallowing cost, such as the conservation of laboratory workers' time, better performance, and speed. See Fig. 1. Highly engineered, sophisticated chromatographic apparatus did not become easily available until the 1950s and since that time has continually expanded apace. All of the advantages of computer and display technology have been applied to chromatography today.

Fundamentals of Chromatography

In chromatography, the *carrier* or *moving phase* may be a gas, liquid, or supercritical fluid. The separation is effected by distributing the mixture between the fixed, or stationary, phase in a column and the carrier. The stationary phase may be a solid or a liquid-coated solid packed into the column, or it may be attached to the walls of a capillary. Liquid samples that can be vaporized can be separated with a gas carrier. High-boiling liquids and unstable compounds can be separated with a liquid carrier. Some materials can be handled better in a supercritical fluid and may separate faster. This latter approach, however, requires much more skill, is expensive, and thus, at present, is limited. A liquid-column is shown in Fig. 2.

Components of the sample are retained in the column for different lengths of time due to adsorption-desorption, solution-dissolution, chemical affinity, size exclusion, and other mechanisms of varying nature. Various components are continually washed from one part of the stationary phase and recaptured by another by the moving phase. Different components elute in groups from the column with respect to time from injection. Dispersion in the system causes the bands of components to emerge with a Gaussian distribution or a distorted peak-shaped curve. A simplified diagram of the process is shown in Fig. 3. It becomes immediately obvious that chromatography not only is an analytical method, but also a separation method for substances that are difficult to separate by more conventional means.

Flow injection techniques are utilized to prepare samples, not only for chromatography, but also for numerous other analytical sensors that

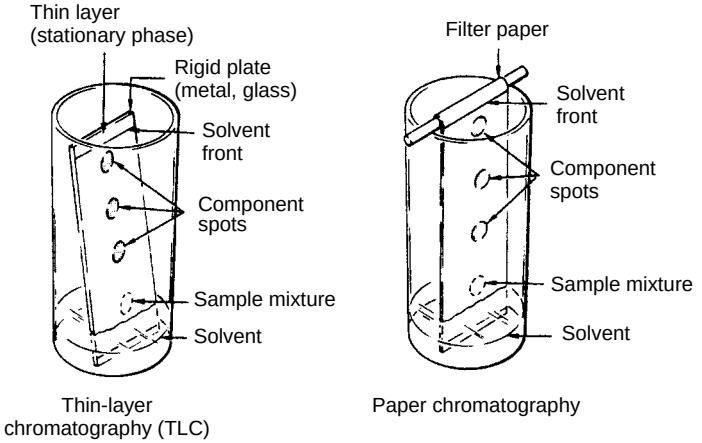

Fig. 1. Thin-layer chromatography (TLC), shown at left, and paper chromatography, shown at right, are similar in apparatus and technique. The sorbent bed is in the form of a thin layer or thin sheet of paper of a finely divided sorbent material. In TLC, the sorbent material is deposited on a supporting metal, glass, or plastic plate. The sample is spotted near one end of the bed, which is then brought in contact with a source of solvent. As the solvent moves through the bed by capillary action, the sample components are washed through the bed at different rates and are separated into spots of pure compound, which can be recovered after the solvent is allowed to evaporate. Spots can be detected visually if the substances are colored, or with ultraviolet light if they are fluorescent. Components can be reacted to give colored or fluorescent derivatives by spraying with reagents. Conventional quantitative determinations can be made after recovery of the substance of interest with solvent, or roughly estimated by comparison with spots produced with known quantities and concentrations. Recording densitometers may be used for quantitative measurements in situ. The paper may be drawn automatically past a slit in front of a photocell, and the transmitted or reflected light recorded. Radioactive compounds are detected by contact exposure with x-ray film, which after development can be measured with a densitometer. Quantitative measurements in situ can be made with apparatus similar to a densitometer in which a radiation detector is used in place of the photocell.

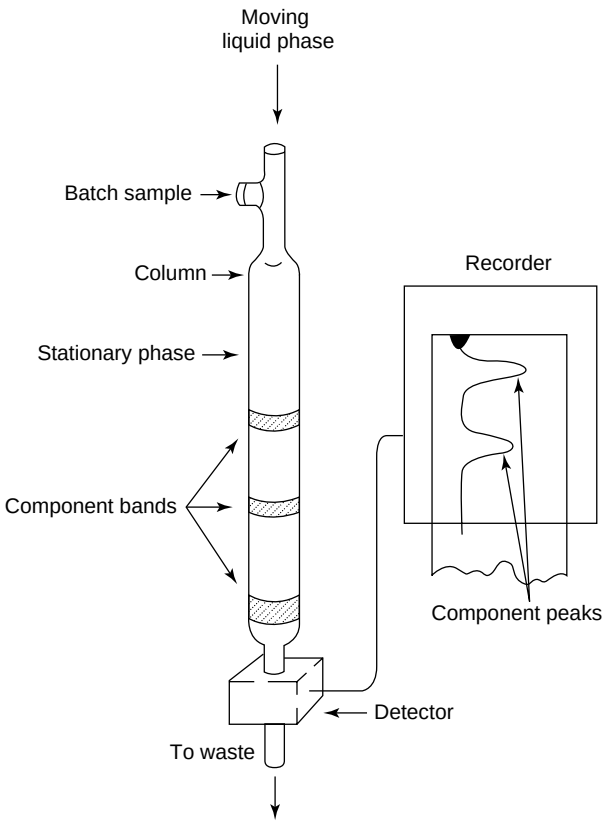

Fig. 2. Schematic of liquid-column chromatograph.

use thermal conductivity, flame ionization, and spectrometric principles. As important as these detectors may be, they must not overshadow the critical need to obtain a reliable sample. Flow injection analysis (FIA) is a technique for introducing a discrete sample into a flowing carrier, passing it through a conditioning "operator" system, measuring the concentration of one or more components in the modified sample, and displaying the results. Many different types of operators may be used, but component separation generally is associated with column chromatography. Flow injection is a procedure that was originally developed to automate wet lab test methods, but now has become a universal sample-preparation technique.

Advancements in Chromatography

When it first appeared as an industrial tool, the chromatograph was a single box with all of the components packaged together. Then it was considered an analyzer unto itself and required a separate sample conditioning system. Process engineers concerned with analysis began to develop techniques to modify the laboratory practice of using a single column. Multiple columns connected by switching valves were applied to backflush, foreflush, and cut components from the normal sequential elution scheme.

Some years later, laboratory chemists started to apply such techniques to specific industrial and process applications. Remote discrete sampling was developed in 1978. This allowed one to inject the small quantity of sample into a capillary hundreds of feet (tens of meters) from the "analyzer" and transport it to the column as a packet. The transfer line was viewed as a long oven and no longer constrained to a single box. Components of the original box now could be expanded into three-dimensional space by using several boxes with connecting capillaries. The programmer, which controls the system operation, became a main feature of the system.

In more recent years the capillary column, which now plays a major role in process applications, appeared. These columns produce significantly higher resolution of components and, in many cases, are faster and easier to use. Outer-surface-clad fused silica columns have been developed which are less fragile than those made of laboratory glass. Inert inner-surface metal capillary columns with cross-linked and chemically bound stationary phases also are available. The practice of technicians making their own columns has vanished into antiquity. Because there are numerous column types, details cannot be provided here. However, there are several buyers' guides available for the asking. The literature also is rich in terms of such factors as specific column selection, sample introduction techniques, analysis detectors, and overall performance qualities of a chromatographic system.

Control of chromatographic system operation has progressed from electromechanical and electro-optical devices to fully digital electronic components, which also incorporated computational capability. Microprocessors, personal computers, mini- and mainframe computers, as well as programmable logic controllers can be effectively integrated into chromatographic systems. However, for simple operations one still may use cam and digital timers.

A major improvement came with digital electronics, which allows high-resolution timing (0.1 second) and exact repeatability. Precise timing of sequential events is essential to multidimensional sample preparation utilizing column separation operators and switching valves.

Electronics for controlling instrument-operating parameters, such as temperature and pressure, have contributed to more stable operation. This produces better repeatability of the system for multiple cycles leading to higher precision of component isolation. Advantage of improved measurement devices can be realized once the sample preparation function is resolved. Computer hardware and software provide expanded capability for signal processing and data manipulation. Stable and precise sample preparation and measurement systems allow accurate analytical information provided that adequate maintenance and calibration practices are applied.

The wide range of measurement devices currently available makes almost any process chemical analysis possible. Column chromatographic techniques make interference-free determinations a reality.

Gas Chromatography

Almost any organic or inorganic compound that can be vaporized can be separated and analyzed with a gas chromatograph. As shown in Fig. 4, the minimum requirements for a system include: (1) a column that contains the substrate or stationary phase; (2) a supply of inert carrier gas (moving phase), which is continually passed through the columns; (3) a means for maintaining pressure and flow constant; (4) a means of admitting or

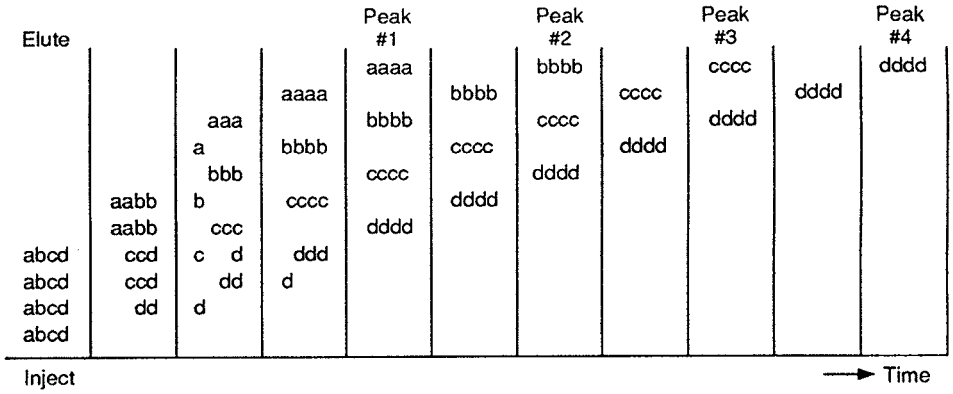

Fig. 3. Chromatographic separation process showing movement through column with time.

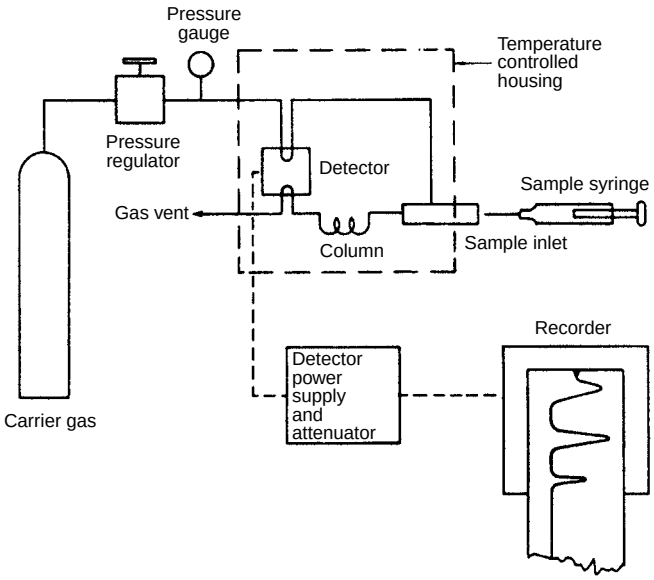

Fig. 4. Minimum requirements for a gas chromatographic system include: (1) a column which contains the substrate or stationary phase, (2) a supply of inert carrier gas (moving phase) which is continually passed through the columns, (3) a means for maintaining pressure and flow constant, (4) a means of admitting or injecting the sample into the carrier gas stream, (5) a detector which senses the sample components as they elute, and (6) a display (recorder). The carrier gas may be any gas that does not react with the sample or adversely affect the detector. Helium, hydrogen, nitrogen, and argon are often used.

injecting the sample into the carrier gas stream; (5) a detector which senses the sample components as they elute; and (6) a recorder. The carrier gas may be any gas that does not react with the sample or adversely affect the detector. Helium, hydrogen, nitrogen, and argon are most commonly used.

Microprocessor-Based Automation. Automatic systems now are used to carry out functions previously performed manually by the operator. These systems may take many forms: (1) integral to and dedicated to a single chromatograph and (2) as a separate unit which controls one or several chromatographs. The latter are also available for upgrading older manually operated chromatographs to provide automated data reduction and output.

Systems are equipped with read-only memory (ROM) for the operating system and random-access memory (RAM) for storage of user-specific methods, operating instructions, and analytical data acquisition and manipulation.

Depending on user requirements, one or more of the following functions can be provided:

1. Individual temperature control and indication of column, ovens, detectors, and sample inlets
2. Dynamic control of programmed temperature profiles, starting and ending temperatures, rate of temperature increase with one or more time-controlled segments of isothermal temperature, and cooling-down cycle.
3. Automatic integration of peak areas or peak height measurements, with a choice of several calibration methods for calibration of results.
4. Raw data storage with post-run calculation and manipulation of data for optimizing variables and methods development.
5. Integral printer-plotter for hard copy of chromatograms and analytical results.
6. Keyboard for input of analytical parameters and operator-selected variables.
7. Video terminal for display of chromatograms and analytical results,
8. Cassette or floppy disk extended memory for storage of files, methods, and user-specific applications programs.
9. High-level language for user programming of special calculations such as physical properties and comparison with alarm levels.
10. Serial communications via RS-232 ports with a central computer or other peripheral devices.
11. Timed output control signals to peripheral and ancillary devices such as sample valves, column switching valves, and other external functions which are part of the automated procedure.
12. On-board diagnostics to aid in troubleshooting and isolating and identifying failures.

Chromatograph Data Reduction — Qualitative Analysis. For a given substrate, under given conditions, each compound has a characteristic retention time, which can be used for tentative identification. However, two or more compounds may have the same elution time on a particular column. In such cases the compound may be rerun on a different column with other characteristics to reduce ambiguity. Extensive compilations of individual compound retention times on different substrates are available for reference. Positive identification can be made only by collecting the compound or transferring it as it elutes directly into another apparatus for analysis by other means, such as infrared or ultraviolet spectroscopy, mass spectrometry, or nuclear magnetic resonance. Commercially available apparatus is available which combines in a single unit both a gas chromatograph and an infrared, ultraviolet, or mass spectrometer for routine separation and identification. The ancillary system may also be microprocessor-based, with an extensive memory for storing libraries of known infrared spectra or fragmentation patterns (in the case of mass spectrometers). Such systems allow microprocessor-controlled comparison and identification of detected compounds.

Quantitative Analysis. This is based on the proportionality of detector response to the amount of component in the elution band. The most widely used measure of detector response is the area under the chromatogram peak. However, the peak height (amplitude of the detector signal at peak maxima) also may be used. Early methods for measuring the peak area included direct measurement on the chart with a planimeter, calculating from the height and width of the peak, and using a ball-and-disk integrator attached directly to the recorder. Electronic integrators have also been used to sense the detector signal directly, or after it is amplified, and to provide a digital printout of the peak area and time of peak maxima.

These methods of quantitation have been largely replaced by microprocessor-based data systems. The detector signal is directly coupled to a high-speed analog-to-digital converter which samples it at predetermined

rates as high as 40 Hz. The digitized values are stored in memory for subsequent manipulation. Slope sensing algorithms find the beginning and end of peaks, peak maxima, and valley points between incompletely resolved peaks and can differentiate between peaks and the baseline (absence of peaks) to correct the digitized signal for baseline drift. Tangent skimming algorithms can locate and digitize small "rider" peaks on tailing edges of larger peaks.

The microprocessor sums the digitized values for a given peak to obtain the peak area. Results are then calculated by various methods:

1. *Area Percentage, Normalized*. In this method, the area of each peak is determined as a percentage of the total of the areas of all peaks. Results must add up to 100 percent to indicate that all components have been detected.
2. *Concentration by Relative Response Factors, Normalized*. This is similar to area percentage, but each area is corrected by a relative response factor characteristic of a given compound.
3. *Internal Standard*. The results are calculated relative to a standard added to the sample in a known amount. Results are independent of sample size. The internal standard must be a compound not normally present in the sample and well separated from other components in the sample.
4. *Standard Addition*. The sample is analyzed with and without the addition of a known amount of a compound that is also in the sample (spiking). The concentration is calculated from the observed increase in area.
5. *External Standard*. The area of each component is compared to the area of a separately run standard with a known concentration of each component.

Process Gas Chromatography

This is a system for continuous, repetitive, and fully automatic on-line analysis of process streams; it is similar to the laboratory chromatograph in all essential elements of basic technique but different in design and appearance. Factors affecting design include the need (1) to comply with the National Electrical Code for operation in hazardous atmospheres, (2) to automate the procedure, and (3) for ready adaptability to closed-loop process control and communication with process control systems and computers. The demand for maximum reliability and minimum maintenance has emphasized simplicity of hardware and methodology. Emphasis is placed on analyzing for a few rather than a number of components and on minimizing analysis time. These design targets have resulted in the extensive use of multicolumn techniques for rapid separation of selected components, with large portions of the sample being discarded. As shown in Fig. 5 the major components of a microprocessor-based process gas chromatograph system are (1) the analyzer, (2) the data processor, (3) the sample conditioner system, (4) one or more recorders, and (5) analog and serial outputs to peripheral devices or process control systems and computers.

Analyzer. This equipment usually is located close to the sampling point, enclosed in a shelter for weather protection. An analyzer is typically designed to comply with NEC Class I, Groups B, C, and D, Division 1, requirements for operation in hazardous areas by combination of explosion-proof enclosures, air purging, and intrinsically safe electric circuits. Sections of the analyzer include a controlled temperature compartment (heated air bath) for the columns, sample and column switching valves, and a detector. A pneumatics section for pressure or flow controllers for the carrier gas and other auxiliary gases (such as hydrogen and combustion air for an FID), as well as service air for the heater, electronics purge, and valve actuation. The electronics compartment contains a microprocessor with a central processing unit (CPU) and RAM and ROM for program control, data acquisition and reduction, output, and all communications functions. The RAM is battery-backed to prevent loss of applications programs due to power failure.

In its most usual form, the microprocessor performs these functions:

1. Controls all sequenced analyzer functions, such as sample injection and valve switching, by means of the applications program stored in RAM.
2. Samples and digitizes the detector signal at up to 40 Hz; performs peak area integration or peak height measurement with baseline correction and deconvolution of incompletely resolved peaks.

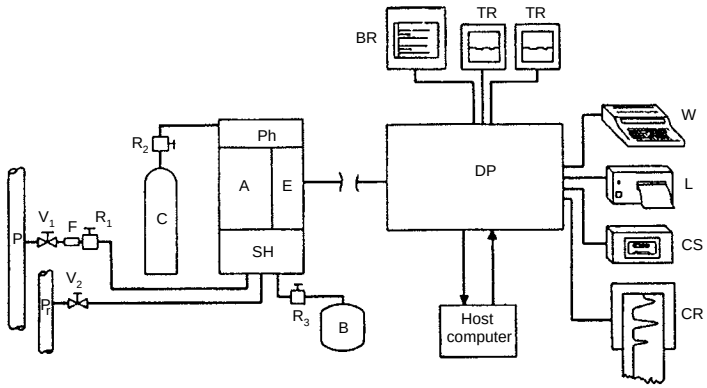

Fig. 5. Basic elements of process gas chromatograph. The vapor sample is continuously withdrawn at a high rate from process line *P*, circulated through sample conditioner *SH*, and returned to lower pressure point *P*, through shutoff valves V_1 and V_2. Particulate matter is removed by filter F_1 and the pressure reduced to a constant low level be regulator R_1. The sample conditioner contains flow control and other conditioning components and a valve for switching to synthetic calibration blend *B* through pressure regulator R_3. A sample slipstream is circulated to the sample valve in analyzer *A*, which also contains columns, detectors, and a temperature-control system. Carrier gas *C* is controlled by regulator R_2 and pneumatics control section *P*. A microprocessor in electronics module *E* stores an analytical program in RAM and controls analyzer functions and data acquisition and reduction. Analytical results are transmitted over a serial link to data processor *DP*, which converts results to an analog signal for presentation to bar graph recorder *BR* and as many as 30 to 40 trend recorders *TR*. Real-time constructed chromatogram is presented for maintenance on recorder *CR*. Serial outputs (RS-232) flow to writer or panel-mounted line printer *L* for data logging and to cassette recorder *CS* for storing applications programs. Results and alarm messages flow to host computer via serial link. An applications program is entered via data processor and downloaded to an analyzer RAM for execution in the analyzer. The processor controls several analyzers.

3. Identifies components by comparing elution times with values stored in memory.
4. Calculates the composition with a choice of several calibration and calculation methods stored in ROM.
5. Controls the sequencing of sample conditioner in multistream systems.
6. Performs automatic calibrations by analyzing calibration standards at user-selected intervals and automatically updating calibration factors.
7. Performs auxiliary calculations such as determining average molecular weight, specific gravity, heating (thermal units) value, or other properties based on the calculated sample composition.
8. Monitors electromechanical sensors in the analyzer and sample conditioner system to detect abnormal conditions: oven temperature out of limits, carrier gas flow failure, sample flow failure, etc.
9. Performs software diagnostics on the detector signal and analytical results to detect abnormal conditions: change in elution time, total peak area out of limits, excessive baseline noise or drift.
10. Communicates with data processor over a serial link to transmit analytical data and calculations and receives new or modified applications programs. A digitized form of the detector signal may also be transmitted for remote reconstruction of a real-time chromatogram.

In addition, the analyzer can accept analog signals from other field-mounted analyzers or sensors such as flowmeters and pressure transducers. The signal can be scaled, digitized, and incorporated into special calculations to determine mass flow, therms per day, reactor yields, and so on.

In alternative forms of these systems, the applications program is stored in the processor; the analyzer microprocessor digitizes only the detector signal and transmits the digitized values to the data processor. Applications program event commands are received in real time from the data processor and converted at the analyzer to electrical and pneumatic signals for sample valve actuation, column switching, sample conditioner control, and so on.

Data Processor. This unit commonly is located near or in the control room in a nonhazardous environment, and as much as 2000 to 3000 feet

(610 to 914 meters) from the analyzers. The data processor also has its own microprocessor with a CPU and a complement of ROM and RAM in which the operating system and user-specific applications programs are stored. Communication with the analyzers is by a serial link. In its most usual form, the processor is a special-purpose microprocessor and can control up to six or eight analyzers. In other forms the processor may be a microprocessor-based minicomputer and control as many as 32 analyzers.

The processor has several main functions:

1. Input of applications programs by means of a special-purpose keyboard, with an alphanumeric display and interactive dialogue. Prompting of the operator and screening of the input data ensures the input of all necessary parameters and prevents conflicting data inputs. The program is down-loaded into the analyzer memory and can be recalled for editing and modifications. In some versions, input may be accomplished through an ancillary video terminal with a keyboard and menu-driven operator communications.
2. Receives data from the analyzers and distributes them to the various output devices in analog or digital form as required.
3. Monitors the status of the analyzers and displays alarms and transmits them to peripherals.
4. Provides manual control of all analyzer functions during setup and maintenance and acts as a diagnostic center for troubleshooting and corrective maintenance. A real-time chromatogram is available.

Except for the initial setup and maintenance of the analyzer, all operations, including programming, manual operation, and calibration, take place at the processor location.

In some versions the applications program for all analyzers may be stored in the processor memory instead of the analyzer. Event commands are sent to the analyzer in real time over the serial link and converted to analog commands by the analyzer. Digitized data are received from each analyzer, with all data acquisition and reduction accomplished in the processor.

In yet other versions the processor is part of the analyzer and may be dedicated to, and integral to, a single analyzer at the analyzer location with all analyzer and processor functions described performed locally.

The simplest form of record is a bar graph. The record consists of a series of bars, one for each component, of height proportional to the component concentration. The output for each component is scaled to give a full-scale reading equivalent to a convenient concentration value. Each component may have a different full-scale range. A large number of components in one or many streams may be recorded on the same instrument. Different streams may be identified by the height of a flat-top bar preceding the series of bars for that stream.

Trend outputs consist of a continuous electrical signal [0 to 10 volts or 4 to 20 milli (mA)] from the processor. As many as 30 to 40 such outputs may be available from a single processor. Each output represents the concentration of a particular component in one of the sample streams on a given analyzer scaled to some convenient range. Component identity and scale factors for each output channel are user-assigned from the processor keyboard.

The output value is held constant at the last value until a new value is determined in a subsequent analysis, causing a stepwise change in the record as the signal is updated at the end of each analytical cycle. A separate recorder pen is required for each trend output recorded. Trend outputs may also be used to input analytical data to a process control system. A separate two-wire 4- to 20-mA output line is typically required for each component input.

A real-time chromatogram for any selected analyzer may be obtained at the data processor for setup and maintenance. The chromatogram is received in digital form at a rate of 10 or more data points per second and reconstructed into analog form and scaled at the processor.

Serial output ports (RS-232) are usually provided for serial transmission of data — usually in ASCII code as previously shown in Fig. 5.

Valves. Electrically or pneumatically operated valves are used for the injection of liquid or gas samples and column switching. Rotary, spool-and-O-ring, diaphragm, and sliding-plate valves with from 4 to 12 ports are used. Vaporizing liquid sampling valves mounted through the wall of the analyzer transfer the liquid sample from the cold exterior zone to the heated vaporizing zone within the oven. The sample valve meters a fixed volume of liquid or gas into the column with a repeatability of ± 0.25 percent. The sample size may vary from approximately 0.1 mL to 50 mL (with an external sample loop).

Liquid-Column Chromatography

This method is particularly useful for the separation and analysis of high-molecular-weight compounds beyond the range of gas chromatography. It is generally classified according to the stationary phase or to the nature of its interaction with sample components.

1. Liquid-liquid partition chromatography, where the sample components are partitioned between a moving liquid phase and a stationary liquid phase deposited on an inert solid. The two solvent phases must be immiscible. The stationary phase may be a large molecule chemically bonded to the surface of a solid (bonded liquid phase) to prevent loss by solubility in the moving phase. This method can also be subdivided into normal-phase systems, in which the moving phase is less polar than the stationary phase, and reverse-phase systems, in which it is more polar.
2. Liquid-solid or absorption chromatography, in which the sample components are absorbed on the surface of an adsorbent such as silica gel.
3. Ion exchange, in which ionic sample components interact with functional groups on a permeable ionic resin.
4. Exclusion or gel permeation, in which compounds are separated by molecular size into a range of pore sizes in a polymeric gel. This method is useful for measuring the molecular-weight distribution of polymers.

Isocratic elution uses a solvent of constant composition throughout the analysis. Gradient elution is a modification of the technique, in which the solvent is a mixture of two solvents that differ in solvent strength. The composition or ratio of the two is changed during the analysis in accordance with a predetermined program. The change may be continuous, linear or nonlinear, stepwise, or a combination.

Apparatus Required. The need for more efficient columns and faster separations has led to the development of stationary phase packings with particles as small as 2 mm, operating at pressures as high as 10,000 psig (69 MPa), and with solvent flow rates as low as 1 mL/min or less. This has in turn led to the development of detectors with internal volumes of only a few microliters and special fittings and connectors with minimum dead volume to prevent band spreading and loss of resolution. These improvements in apparatus and technique have resulted in an ability to achieve complex separations with speeds comparable to those of gas chromatography.

The solvent is moved through the system by constant-flow or constant-pressure pumps which are driven mechanically (screw-driven syringe or reciprocating) or by gas pressure with pneumatic amplifiers. For gradient elution two pumps may be synchronized and programmed to provide a controlled, reproducible composition change.

Samples may be introduced by syringe directly into the column through a septum or by means of valves with a fixed volume that has been prefilled with the sample. Valves may be of a rotary, sliding plug, or diaphragm design and of stainless steel and fluoroplastic construction for inertness. Auto samplers are used for unattended injection of samples loaded into vials and sequentially rotated into the injection mechanism.

CHROMATOPHORE. A general name for a definite body occurring in the cytoplasm of some cells. A characteristic of a chromatophore is that it should have a definite color, due to the pigment or pigments present in it.

In plants the most common chromatophore is the chloroplastid (see also **Chloroplast**). Other chromatophores, called chromoplastids, are of various colors, including yellow, brown, orange, and red. Not all plant pigments are found in chromatophores, however. Many occur dissolved in the cell sap.

Chromatophores found in the skin of animals of several groups, including arthropoda, mollusca, and vertebrata, are large cells, often extensively branched. They are well developed in the octopus and squid, in many amphibians and fishes, and in reptiles.

Rapid changes in color, such as those of squids and some lizards, have been ascribed to a contraction of the chromatophores, but it now seems evident that the cell itself does not contract, although the pigment within it may undergo a considerable change in distribution, revealing itself when widely distributed and otherwise concealed from view.

Starch is the first visible product of photosynthesis; in most cases it is elaborated as small grains visible within the chloroplast. In some life forms, the pigment is found in elaborate bands or nets (chromatophores). In these, the starch may accumulate about dense protein-aceous granules called pyrenoids. This starch is known as pyrenoid starch, while the more usually occurring starch grains are called stroma starch. Both types may occur in the same chromatophore. In some red algae, starch grains regularly occur outside of the chloroplasts in the general cytoplasm of the cell. In many plants, as the leaves or fruits mature, they change from green to red to brown. This is caused by the displacement of the chlorophyll within the chloroplasts by carotenes or xanthophylls, and the change is apparently not reversible. Plastids having a preponderance of these pigments are known as chromoplasts. In potatoes or iris roots, food may be stored in colorless plastids known as leucoplasts.

CHROMINANCE. The colorimetric difference between any color and a reference color of equal luminance, the reference color having a specified chromaticity.

CHROMITE. An important mineral in the chromite series of multiple oxides. The dominant compound is $FeCr_2O_4$, but most chromite also contains magnesium (Mg) and aluminum (Al). Crystallizes in the isometric system. Hardness, 5.5; specific gravity, 4.5–4.8; color, black. Associated with peridotite and serpentine (metamorphized peridotite). Commercial amounts occur as placer deposits in serpentine areas. In the United States chromite has been mined in Maryland, Pennsylvania, California, Montana, Oregon, Wyoming and North Carolina. Important deposits occur in Quebec, Canada. Valuable deposits occur in Asia Minor, Zimbabwe, New Caledonia, Cuba, India, and the Philippines; also in New South Wales, and in the Ural Mountains associated with platinum.

CHROMIUM. [CAS: 7440-47-3] Chemical element, symbol Cr, at. no. 24, at. wt. 51.996, periodic table group 6, mp 1837–1877 °C, bp 2672 °C, density 7.2 g/cm^3. Elemental chromium has a body-centered cubic crystal structure. The metal is silver-white with a slight gray-blue tinge, very hard (9.0 on the Mohs scale), capable of taking a brilliant polish, not appreciably ductile or malleable. The element is not affected by air or H_2O at ordinary temperatures, but when heated above 200 °C, chromic oxide Cr_2O_3 is formed. There are four stable isotopes: ^{50}Cr, and ^{52}Cr through ^{54}Cr. Four radioactive isotopes have been identified, all with comparatively short half-lives ^{48}Cr, ^{49}Cr, ^{51}Cr, and ^{55}Cr. The element was first identified by Vauquelin in 1797.

Ionization potential 6.76 eV; second, 16.6 eV. Oxidation potentials $Cr \rightarrow Cr^{3+} + 3e^-$, 0.71 V; $Cr^{2+} \rightarrow Cr^{3+} + e^-$, 0.41 V; $2Cr^{3+} + 7H_2O \rightarrow Cr_2O_7^{2-} + 14H^+ + 6e^-$, 1.33 V; $Cr + 3OH^- \rightarrow Cr(OH)_3 + 3e^-$, 1.3 V; $Cr + 4OH^- \rightarrow CrO_2^- + 2H_2O + 3e^-$, 1.2 V; $Cr(OH)_3 + 5OH^- \rightarrow CrO_4^{2-} + 4H_2O + 3e^-$, 0.12 V.

Other important physical properties of chromium are given under **Chemical Elements**.

Chromium occurs chiefly as chromite (ferrous chromite), $Fe(CrO_2)_2$, in Zimbabwe, the Republic of South Africa, the former U.S.S.R., New Caledonia, India, Philippine Islands, Japan, Turkey, Greece, Cuba, and California. (1) Heating chromite in the electric furnace with carbon yields ferrochrome for alloys, and (2) when chromite is heated with sodium carbonate and nitrate, sodium chromate is formed, which is then extracted with H_2O. This is the substance from which chromium compounds are obtained. See also **Chromite**.

Chromium is used extensively for (1) decorative and wear-resistant electroplating, (2) many important alloys, and (3) the manufacture of numerous chemicals and refractory materials.

Alloys. In constructional steels, chromium imparts hardness by improving hardenability and promoting the formation of carbides. These steels have exceptional wear resistance and are relatively stable at elevated temperatures. In stainless and heat-resisting steels, chromium improves corrosion and heat resistance. As shown in Table 1, stainless steels may be grouped into three principal classes (1) austenitic, (2) martensitic, and (3) ferritic stainless steels. The fundamentals of stainless steels are further described under **Iron Metals, Alloys**, and **Steels**. Stainless steels, as a group of major ferrous alloys, are characterized by their high degree of resistance to chemical attack. They possess a property commonly referred to as passivity, a property eminently displayed by elemental chromium. This property is manifested in steels when the chromium content exceeds about 11%. A very marked improvement in corrosion and heat resistance is achieved when chromium is added to this or a greater extent to low-carbon steels. The addition of nickel, along with chromium, enhances these properties even more. Although a steel that contains 12% chromium will stain, it will not undergo progressive rusting in normal atmospheres. When the chromium content is increased to 18%, staining will not occur in normal atmospheres, but may occur to a limited extent in particularly bad industrial environments. However, the addition of 8% nickel, along with the 18% chromium, will make the steel stain-resistant in all but the most rigorous industrial atmospheres. Additional resistance to corrosion and heat resistance may be obtained by the presence of molybdenum and other elements in smaller quantities.

An example of the effect of chromium content on the corrosion resistance of steel is demonstrated as follows:

TABLE 1. REPRESENTATIVE STAINLESS STEELS

Type	Composition and Characteristics
	Austenitic Stainless Steels
302	Basic alloy of the group: Cr, 17–19%; Ni, 6–8%
302B	Silicon (2–3%) added to increase scaling resistance
303	Sulfur (0.02–0.05%) added to improve machinability
303Se	Selenium (0.15%) added to improve machinability
304L	Extra low carbon for improved weldability
304	Lower carbon content to improve weldability and inhibit carbide formation: Cr, 18–20%; Ni, 10–12%
305	Nickel increased to lower work-hardening: Cr, 17–19%; Ni, 10–13%
308	Chromium and nickel increased to increase corrosion and scaling resistance: Cr, 19–21%; Ni, 10–12%
309S	Lower carbon content (0.08% max) for improved weldability
314	Silicon added for increased scaling resistance at high temperatures: Cr, 23–26%; Ni, 19–22%; Si, 2% max
316	Molybdenum added to improve resistance to pitting corrosion and strength at high temperatures: Cr, 16–18%; Ni, 10–14%; Mo, 2–3%
316L	Extra-low carbon content for improved weldability
317	Additional molybdenum to further improve resistance to pitting corrosion: Cr, 18–20%; Ni, 11–15%; Mo, 3–4%
321	Titanium added to prevent chromium carbide precipitation: Cr, 17–19% Ni, 9–12%; C, 0.08% max: Ti, 5 × C content
347	Columbium (niobium) or tantalum added to prevent chromium carbide precipitation
	Martensitic Stainless Steels
410	Basic alloy of the group: Cr, 11.5–13.5%; Ni, 0.5% max
405	Aluminum added to prevent weld hardening
414	Nickel (2%) added to improve corrosion resistance
416	Sulfur added to improve machinability
416Se	Selenium added to improve machinability
420	Carbon increased for higher hardness: Cr, 12–14%; Ni, 0.5% max; C, over 0.15%
431	Chromium increased to further improve corrosion resistance: Cr, 15–17%; Ni, 1.25–2.50%
440A	Carbon slightly decreased to improve toughness: Cr, 10–18%; Ni, 0.5% max; C, 0.6–0.75%
440B	Carbon decreased slightly to improve toughness even more
440C	Carbon increased to increase hardness; chromium increased to make up loss in corrosion resistance: Cr, 16–18%; Ni, 0.5% max; C, 0.95–1.2%
	Ferritic Stainless Steels
430	Basic alloy of the group: Cr, 14–18%; Ni, 0.5% max
430FSe	Selenium added to improve machinability
442	Chromium increased to improve resistance to scaling and corrosion: Cr, 23–27%; Ni, 0.5% max

A low-carbon steel placed in boiling 65% HNO_3 for one month:

4.5% chromium	corrosion rate, 12.9 in.
8.0% chromium	0.14
12.0% chromium	0.01
18.0% chromium	0.003
25.0% chromium	0.0006

The corrosion resistance of iron-chromium alloys was known in England and France in the early 1800s, but passivity was not clearly recognized and reasonably understood until 1910 as the result of studies by Borchers and Monnartz in Germany. Commercial stainless steels were introduced shortly thereafter in Germany, France, England, and a bit later in the United States. Worldwide production of stainless steels now is measured in terms of millions of tons annually.

Research programs worldwide are seeking to improve the performance of 8 to 14% chromium ferritic steels for high-temperature applications up to 650 °C (1200 °F), particularly with applications in advanced power plants as targets. Such alloys are needed for future coal-fired power plants as well as for fast breeder and nuclear fission reactors. In addition to traditional uses of high-temperature steels as found in steam and gas turbine and boiler tube uses, the new alloys will be intended for use as fuel cladding, wrapper and steam generator tubing for fast breeder reactors, and first-wall materials for fusion reactors as currently conceived.

In addition to ferrous alloys, chromium also is added to copper, vanadium, zirconium, and other metals to form several hundred chromium-bearing alloys. Nickel-chromium-iron alloys have high electrical resistance and are used widely as electrical heating elements. *Nichrome* and *Chromel* are examples.

Chromium Plating: Although the tonnage of chromium used for electroplating is far below its consumption for alloys, plating represents a major market for the element. In terms of special protective coatings, chromium is behind only copper, lead, and zinc in consumption. Generally, chromium plating is used for two purposes: (1) wear-resistance and (2) decorative effect, taking on polish and a much brighter surface than the other electroplated metals. The "bright work" of automotive hardware, plumbing fixtures, and electrical appliances are examples. Normally, chromium is plated over nickel where the nickel is about 100 × thicker than the chromium. In decorative plating, the thickness of the chromium plate ranges only from 0.00001 to 0.00002 inch (0.00025 to 0.00051 millimeter). Hexavalent chromium also forms protective chromate coatings over aluminum, cadmium, copper, magnesium, and zinc. These chromate conversion coatings are used on hot-dipped or electrogalvanized parts, on zinc die castings, and extensively on aluminum parts for aircraft.

In 1979, scientists at the General Motors Research Laboratories (Warren, Michigan) announced some interesting findings concerning chromium plating. The conventional process uses a bath containing Cr^{6+} ions. During plating, the Cr^{6+} ions reduce to Cr^{3+} and then to metallic Cr. Investigators wondered for years why the process will not succeed if one commences with Cr^{3+} ions, thus avoiding the double step. The GM scientists found that starting with Cr^{3+} fails because it immediately forms a stable complex with water molecules from which Cr cannot be deposited. Commencing with Cr^{6+} succeeds because during reduction a chemical film forms around the cathode (part being plated). Since Cr^{3+} is bound in that film, it does not react with water, but, instead, plates out as chromium metal. See Fig. 1.

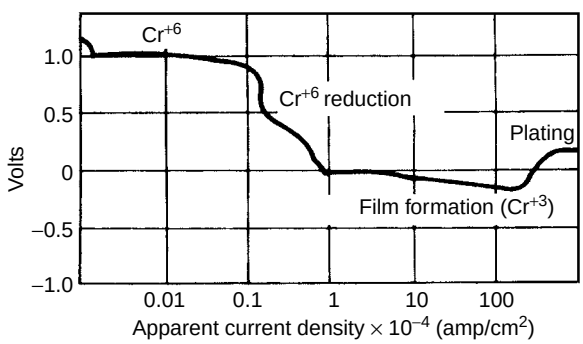

Fig. 1. Typical polarization curve made during investigation of chromium plating process. (*General Motors Research Laboratories*.)

As reported in 1983 by Dr. James Hoare, Research Fellow (General Motors Research Laboratories), the electrolyte for plating is a chromic acid solution which contains various chromate ions: chromate, dichromate, and trichromate. From a series of steady-state polarization experiments, Dr. Hoare concluded that trichromate is the ion important in chromium deposition. Sulfuric acid has been recognized as essential to chromium plating and has been assumed by some to be a catalyst for the process. In this strongly acidic solution, sulfate should be mostly present as the bisulfate ion (HSO_4^-). Dr. Hoare found, contrary to expectation, that the addition of sulfuric acid to the plating bath decreased the conductivity of the solution.

Combining these findings with the results of prior investigations, Dr. Hoare concluded that the electroactive species was a trichromate-bisulfate complex. See Fig. 2. From equilibrium considerations, he theorized that the maximum concentration of this species occurred at a 100-to-1 chromic acid/sulfuric acid ratio. The observation that the maximum rate of chromium deposition also occurred at this ratio supports the conclusion that this trichromate-bisulfate complex is the electroactive species. During the plating process, the complex diffuses from the bulk solution toward the cathode. See Fig. 3. Electron transport takes place by quantum mechanical tunneling through the potential energy barrier of the Helmholtz double layer, and the unprotected chromium in the complex (Cr atom on the left in Fig. 1) loses electrons by successive steps, going from Cr^{+6} to Cr^{+2}. Decomposition of the resulting chromodichromate complex takes place by acid hydrolysis to form a chromous-oxybisulfate complex:

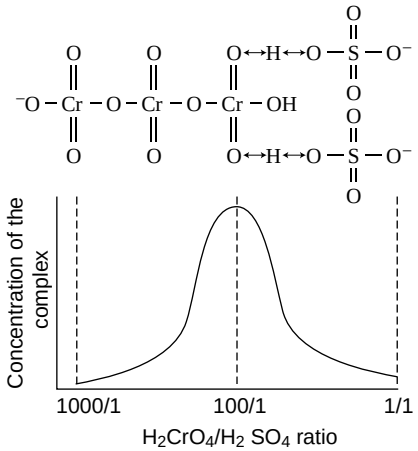

Fig. 2. The electroactive complex and a theoretical plot of its concentration as a function of chromic acid to sulfuric acid ratio. (*General Motors Research Laboratories*.)

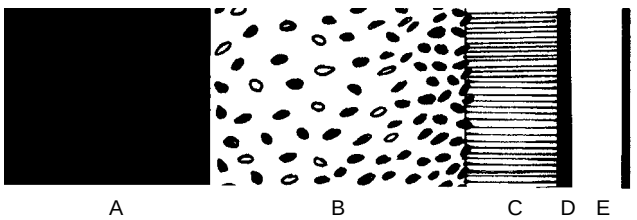

Fig. 3. The electroactive complex diffuses from the bulk electrolyte solution (A) through the diffusion layer (B) to the Helmholtz double layer (C) to be discharged as metallic chromium (D) on the cathode surface (E). (*After General Motors color sketch.*)

The positive end of this complex is adsorbed onto the cathode surface. Electrons are transferred from the cathode to the adsorbed chromium ion, forming metallic chromium and regenerating the HSO_4^- ion. Thus, Dr. Hoare's mechanism explains how sulfuric acid, in the form of the bisulfate ion, participates in the plating process. (Information regarding Cr plating furnished by General Motors Research Laboratories and gratefully acknowledged.)

Chemistry and Compounds: Chromium metal is soluble in dilute HCl or H_2SO_4 and made passive by dilute or concentrated HNO_3 or concentrated H_2SO_4.

In keeping with the $3d^5 4s^1$ electron configuration of the atom, chromium forms compounds in which it is in the stable 6+ state. The compounds of 2+ and 3+ chromium are also quite numerous. The compounds with chromium oxidation numbers of 4+ and 5+ are unstable except under extremely alkaline conditions. The one known chromium 1+ complex is also unstable.

As is evident from the oxidation potential for Cr^{2+} to Cr^{3+}, the Cr^{2+} ion in aqueous solution is an extremely strong reducing agent, readily reacting with atmospheric oxygen. It is therefore stable in aqueous solution only in a complex or a slightly ionized salt. It may be obtained by reducing hexavalent or trivalent chromium in acid solution with one of the active metals, such as zinc. The four halogens form halides of divalent chromium, CrX_2, which dissolve in water with the evolution of heat, although the fluoride is less soluble than the other halides. The ammoniacal solution of chromium(II) sulfate, $CrSO_4$, is particularly reactive with gases, not only with oxygen like the other Cr^{2+} compounds, but also acetylene. Chromium(II) acetate is only slightly soluble in H_2O.

The Cr^{3+} ion readily forms complexes; it exists in aqueous solution as $Cr(H_2O)_6^{3+}$, and forms other complexes with anions, such as $Cr(H_2O)_5Cl^{2+}$, $Cr(H_2O)_4Cl_2^+$, etc. Thus chromium(III) halides may be crystallized in a number of forms differing in color and other properties due to variation in the bonding. Compounds of the trichloride have been reported with the following arrangements: $Cr(H_2O)_6Cl_3$, $[Cr(H_2O)_5Cl]Cl_2 \cdot H_2O$, and $[Cr(H_2O)_4Cl_2]Cl \cdot 2\,H_2O$. Trivalent chromium also forms double salts, notably the chromium alums, hydrated double salts of Cr(III) sulfate and the alkali metal (or thallium or ammonium) sulfates.

The three oxides of chromium, CrO, Cr_2O_3, and CrO_3, are of interest in exhibiting the transition in properties from basicity to acidity and from electrovalence to covalence, with increasing oxygen content, and the consequent increase in charge upon the Cr atom. Thus Cr_2O_3, the middle oxide, is amphiprotic, dissolving either in strong alkali hydroxide solutions or in acids.

One of the most stable of the compounds of Cr(IV) is the tetrafluoride, CrF_4, brown solid, steel-blue vapor at 150 °C, prepared by direct reaction of the elements; even this compound readily undergoes hydrolysis. Chromium tetrachloride, $CrCl_4$, may be prepared as a gas by reaction of Cl_2 and $CrCl_3$ at elevated temperature, but decomposes at room temperature. Chromium(V) occurs in CrF_5, fire-red, volatile, and in the hypochromates, M_3CrO_4, green, which may be prepared by fusion of alkali chromate and alkali hydroxide at high temperature.

CrO_3 is the anhydride of chromic and dichromic acids, H_2CrO_4 and $H_2Cr_2O_7$, which have not been isolated, but whose anions are found in many salts. pK_{A1} and $pK_{A2} = 0.745$ and 6.49, and -1.4 and 1.64 respectively. They are strong oxidants in acid solution, and are readily obtained in basic solution by oxidation of Cr(III) compounds. The oxyhalogen compounds of chromium are chiefly the CrO_2X_2 (chromyl) compounds, which are acid halides of chromic acid. Chromyl chloride, CrO_2Cl_2, deep red, liquid, is prepared by heating sodium dichromate and sodium chloride with H_2SO_4, while chromyl fluoride undergoes polymerization to a white solid. Chlorochromates, e.g., $KCrO_3Cl$, and fluorochromates, e.g., $KCrO_3F$, are also known, but are hydrolyzed in water.

Chromates and Dichromates: Sodium chromate, Na_2CrO_4, potassium chromate, K_2CrO_4, ammonium chromate, $(NH_4)_2CrO_4$, calcium chromate, $CaCrO_4$, are yellow soluble solids; barium chromate, $BaCrO_4$, pale yellow, strontium chromate, $SrCrO_4$, pale yellow, lead chromate, $PbCrO_4$, yellow (used as a pigment, "chrome yellow"), zinc chromate, $ZnCrO_4$, yellow, used as a pigment, mercurous chromate, Hg_2CrO_4, yellow to red to brown, silver chromate, Ag_2CrO_4, reddish-brown, are insoluble solids. Sodium dichromate, $Na_2Cr_2O_7$, potassium dichromate, $K_2Cr_2O_7$, readily crystallized, ammonium dichromate, $(NH_4)_2Cr_2O_7$ (forming nitrogen gas and green chromic oxide solid upon heating) are red soluble solids, of important application as oxidizing agents, e.g., sulfurous acid causes reduction to chromic; silver dichromate, $Ag_2Cr_2O_7$, red insoluble solid, changing to silver chromate, Ag_2CrO_4 upon boiling with H_2O. Solutions of chromate in the presence of acid are changed to the corresponding dichromate.

A number of peroxychromates are known, including the deep-blue, organic soluble reaction product of H_2O_2 and acid $Cr_2O_7^{2-}$ solutions, which is H_4CrO_7, i.e., $CrO_3 \cdot 2H_2O_2$.

Trivalent chromium forms many complexes. The large number is due in part to the many possible arrangements in which the same elements may be present as part of a complex anion or as the cation, as was indicated for the chloride complexes of the hydrated Cr^{3+} ion. The ligands may also be present in various proportions. As in the case with Co^{3+}, Cr^{3+} forms complexes with ammonia in the various color series, e.g., a violeo-chloride, $[Cr(NH_3)_4Cl_2]Cl$, a purpureo chloride, $[Cr(NH_3)_5Cl]\,Cl_2$ and a luteo chloride, $[Cr(NH_3)_6]Cl_3$. In addition to NH_3 many amines, especially ethylenediamine and its derivatives, form stable complexes with Cr^{3+}. In the oxalato complexes, the tripositive chromium ion coordinates with oxalate groups to form such anions as $[Cr(C_2O_4)_3]^{3-}$ and $[Cr(C_2O_4)_2(H_2O)_2]^-$. There are many cyano, thiocyano, nitrato, fluoro, bromo, iodo, azido, acetylido and nitro complexes.

Organometallic Compounds: These include a large number of cyclopentadienyl compounds. In addition to dicyclopentadienyl chromium itself, $(C_5H_5)_2Cr$, there are many derivatives of it with additional radicals or molecules such as $(C_5H_5)_2CrBr$, $(C_5H_5)_2CrNH_3$, $C_5H_5Cr(NO)_2CH_2Cl$, $H(C_5H_5)Cr(CO)_3$ and $C_5H_5(CO)_3CrCr(CO)_3\,C_5H_5$. The compounds of Cr with other hydrocarbon radicals are fewer ($Cr(C_6\,H_6)_2$ is known), such as $(C_6H_5)_5CrOH \cdot H_2O$ and $(C_6H_5)_3Cr \cdot 3$ THF (THF = Tetrahydrofuran).

Besides $Cr(C_6H_6)_2$, chromium hexacarbonyl, $Cr(CO)_6$, white, solid, bp (extrap.) 145.7 °C, represents chromium in the zero oxidation state. This is

a nonpolar compound, insoluble in H_2O, freely soluble in organic solvents. The zero-valent compound $K_6Cr(CN)_6$ has also been made by the reaction of $K_3Cr(CN)_6$ and potassium metal in liquid NH_3.

Cermets. The term *cermet* derives from the combination of ceramic and metal. Cermets are produced by powder metallurgy techniques and represent the bonding of two or more metals. They are particularly useful at high temperatures (850−1250 °C). Chromium is used in several cermet combinations, including chromium-bonded aluminum oxide, metal-bonded chromium carbide, and metal-bonded chromium boride.

Biological Aspects. The first indication for a biological role of chromium in metabolism was derived from the enzymatic studies in 1939. The succinate-cytochrome dehydrogenase system, an important enzyme system for the production of energy, requires certain inorganic cofactors. Of various elements tested, chromium produced the greatest increase of enzyme activity. A significant stimulation of the activity of phosphoglucomutase by chromium was described by Strickland in 1949. This system which has an important function in the early steps of carbohydrate metabolism requires magnesium and one other metal for optimal activity. Chromium was outstanding as a "second metal" because it produced the highest enzyme activation and supported a measured amount of activity even when given alone.

Chromium also stimulates fatty acid and cholesterol synthesis from acetate in liver. That chromium is an essential cofactor for the action of insulin on the rat lens was shown by Farkas in 1964. In the absence of the element, no significant insulin effect on glucose utilization of lens can be demonstrated. Chromium supplementation to the donor animals results in a significant response of lens tissue to the hormone. Numerous other findings indicate that chromium may play several vital roles in biological systems.

Chromium levels in biological matter have been studied extensively. In contrast to findings with other metals, chromium concentrations in the United States population are highest at the time of birth, with a pronounced decline during the lifetime, whereas they appear to remain high in some other countries, such as Thailand and the Philippines. These findings suggest the possibility of a relative chromium deficiency in the United States. The relationship of this to disturbances of carbohydrate metabolism in humans, while under study, remains to be established.

Not all of the various chemical forms of chromium are effective in improving sugar metabolism, and the exact nature of the compound or compounds involved in activating insulin is not established. Some of the chromium in plants may not be present in nutritionally effective forms. It has not been established that chromium is essential to plants, but high concentrations of the metal are toxic. Most agricultural crops, especially their seeds, contain only low levels of chromium.

Chromium Use in Strain Gage. Strain measurements at high temperatures are required in developing designs for turbine engines and hypersonic aerospace vehicles. Operating temperature may exceed 1000 °C (1830 °F). Reliable strain gages for this range have not been available. Maximum operating temperature of traditional gages is 400 °C (750 °F). Thus, engineers were required to research a number of metal combinations that would perform reliably at such high temperatures. The ideal strain gage must change its electrical resistance only in response to strain and be unaffected by temperature changes.

Researchers at NASA (National Aeronautics and Space Administration, Cleveland, Ohio) tested a large number of alloys, such as iron-chromium-aluminum, platinum-tungsten, platinum-palladium-molybdenum, and palladium-chromium. The search was narrowed to the palladium (Pd)-chromium (Cr) combination. Ultimately, the combination of Pd-13% Cr (wt) was selected as optimal. A platinum wire that is wound around the periphery of the gage grid provides the required temperature compensation.

CHROMIUM STEELS. See **Iron Metals, Alloys, and Steels**.

CHROMIZING. Production of a high chromium content surface layer on iron and steel by heating at high temperatures in a solid packing material containing chromium powder, or in an atmosphere containing chromium chloride. The surface layer is formed by diffusion of chromium into the iron in the same manner as carbon diffuses into iron in carburizing; however, the process is much slower and requires higher temperatures than carburizing. A similar result can be obtained by high-temperature diffusion of electrodeposited chromium. Chromized coatings have corrosion resistance and elevated temperature oxidation resistance similar to the high chromium types of stainless steels.

CHROMOGENIC COUPLERS. Couplers are used in secondary color development. See also **Dyes (Textile)**. The term "coupler" is applied to a large number of organic compounds that combine with a limited number of chromogenic developers to produce dye images with a wide range of color and intensity. Couplers are dye intermediates but differ from chromogenic developing agents in that they do not as a rule have the ability to develop a silver image.

Couplers may be hydroxy or amine derivatives of aromatic compounds, such as benzene, naphthalene or anthracene. Phenol, napthol, aniline, cresol, paraaminophenol and dimethylparaphenylenediamine are examples. With these compounds coupling takes place with the hydrogen atom which is in the ortho or para position to the hydroxy or amino group on the coupler.

Compounds having active methylene, $=CH_2$ groups, with strong polar groups for other valences as the cyano $-CN$, the carbonyl $=CO$, the aceto CH_3CO-, the acid ester $-COOC_2H_5$, and the phenyl, $-C_6H_5$ groups will couple. Acetoacetic ester and paranitrophenylacetonitrile are illustrations.

The methylene group may be part of a ring structure as in coumarine and indoxyl, or may be part of a heterocyclic ring attached to a phenyl group as in 1-phenyl-3-methyl-5-pyrazolone.

Compounds having an N in the ring will couple if there is a methyl $-CH_3$ group, attached to the ring in the alpha position to the nitrogen. Two illustrations for this type are picoline and 2-methylthiazole.

Because secondary color development has been particularly successful in the development of color materials, and because of the ease by which it is possible to control color by this method, the field of couplers has expanded rapidly.

CHROMOPHORE. Certain groups of atoms in an organic compound cause characteristic absorption of radiation irrespective of the nature of the rest of the compound. Such groups are called chromophores or color carriers.

CHROMOPHORIC ELECTRONS. Electrons in the double bonds of the chromophore groups. Such electrons are not bound as tightly as those of single bonds and can thus be transferred into higher energy levels with less expenditure of energy. Their electronic spectra appear at frequencies in the visible or near ultraviolet region of the spectrum.

CHROMOPLASTS. See **Plastids**.

CHROMOSPHERE. The thin (10,000 kilometers (6,214 miles) layer of relatively transparent gases, predominantly hydrogen and helium, above the photosphere and below the corona of the sun. It is best observed during total solar eclipse when its emission spectrum may be studied. See also **Sun (The)**.

CHRONIC. Of long duration, applied to a disease that is not acute.

CHRONIC FATIGUE SYNDROME (CFS). Chronic fatigue syndrome, or CFS, is a debilitating and complex disorder characterized by profound fatigue that is not improved by bed rest and that may be worsened by physical or mental activity. Persons with CFS most often function

at a substantially lower level of activity than they were capable of before the onset of illness. In addition to these key defining characteristics, patients report various nonspecific symptoms, including weakness, muscle pain, impaired memory and/or mental concentration, insomnia, and post-exertional fatigue lasting more than 24 hours. In some cases, CFS can persist for years. The cause or causes of CFS have not been identified and no specific diagnostic tests are available. Moreover, since many illnesses have incapacitating fatigue as a symptom, care must be taken to exclude other known and often treatable conditions before a diagnosis of CFS is made.

A great deal of debate has surrounded the issue of how to best define CFS. In an effort to resolve these issues, an international panel of CFS research experts convened in 1994 to draft a definition of CFS that would be useful both to researchers studying the illness and to clinicians diagnosing it. In essence, in order to receive a diagnosis of chronic fatigue syndrome, a patient must satisfy two criteria: 1. Have severe chronic fatigue of six months or longer duration with other known medical conditions excluded by clinical diagnosis; and 2. concurrently have four or more of the following symptoms: substantial impairment in short-term memory or concentration; sore throat; tender lymph nodes; muscle pain; multi-joint pain without swelling or redness; headaches of a new type, pattern or severity; unrefreshing sleep; and post-exertional malaise lasting more than 24 hours. The symptoms must have persisted or recurred during six or more consecutive months of illness and must not have predated the fatigue.

A number of illnesses have been described that have a similar spectrum of symptoms to CFS. These include fibromyalgia syndrome, myalgic encephalomyelitis, neurasthenia, multiple chemical sensitivities, and chronic mononucleosis. Although these illnesses may present with a primary symptom other than fatigue, chronic fatigue is commonly associated with all of them. In addition, there are a large number of clinically defined, frequently treatable illnesses that can result in fatigue. Diagnosis of any of these conditions would exclude a definition of CFS unless the condition has been treated sufficiently and no longer explains the fatigue and other symptoms. These include hypothyroidism, sleep apnea and narcolepsy, major depressive disorders, chronic mononucleosis, bipolar affective disorders, schizophrenia, eating disorders, cancer, autoimmune disease, hormonal disorders, subacute infections, obesity, alcohol or substance abuse, and reactions to prescribed medications.

In addition to the eight primary defining symptoms of CFS, a number of other symptoms have been reported by some CFS patients. The frequencies of occurrence of these symptoms vary from 20 to 50% among CFS patients. They include abdominal pain, alcohol intolerance, bloating, chest pain, chronic cough, diarrhea, dizziness, dry eyes or mouth, earaches, irregular heartbeat, jaw pain, morning stiffness, nausea, night sweats, psychological problems (depression, irritability, anxiety, panic attacks), shortness of breath, skin sensations, tingling sensations, and weight loss.

Several studies have helped to establish the distribution and frequency of occurrence of CFS. While no single study can be considered definitive — each approach has inherent strengths and weaknesses — epidemiologic studies have greatly improved our understanding of how common the disease is, which individuals are the most susceptible to developing it, whether it can be transmitted to others, and how the illness typically progresses in individuals. One of the earliest attempts to estimate the prevalence of CFS was conducted by the Centers for Disease Control and Prevention (CDC) from 1989 to 1993. Physicians in four U.S. cities were asked to refer possible CFS patients for clinical evaluation by medical personnel participating in the study. Who gets CFS is a complex question and does not have a definitive answer. The CDC four-city surveillance study of CFS identified a population of patients that was 98% Caucasian and 85% female, with an average age at onset of 30 years. More than 80% had advanced education and one-third were from upper income families. However, these data included only patients who were under a physician's care. There is now evidence that CFS affects all racial and ethnic groups and both sexes. The Seattle study found that 59% of the CFS patients were women. Eighty-three percent were Caucasian, an underrepresentation, since over 90% of the patients in the study were white. CDC's San Francisco study found that CFS-like disease was most prevalent among women, among persons with household annual incomes of under $40,000, and among blacks, and was least common among Asians and whites. Adolescents can have CFS, but few studies of adolescents have been published. A recently published CDC study documented that adolescents 12 to 18 years of age had CFS significantly less frequently than adults and did not identify CFS in children under 12 years of age. CFS-like illness has been reported in children under 12 by some investigators, although the symptom pattern varies somewhat from that seen in adults and adolescents. The illness in adolescents has many of the same characteristics as it has in adults. However, it is particularly important that the unique problems of chronically ill adolescents (e.g., family social and health interactions, education, social interactions with peers) be considered as a part of their care. Appropriate dissemination of CFS information to patients, their families, and school authorities is also important. CDC and the National Institutes of Health (NIH) are currently pursuing studies of CFS in children and adolescents.

Is CFS Contagious?

There is no evidence to support the view that CFS is a contagious disease. Contagious diseases typically occur in well-defined clusters, otherwise known as outbreaks or epidemics. While some earlier studies, such as investigations of fatiguing illness in Incline Village, Nev., and Punta Gorda, Fla., have been cited as evidence for CFS acting as a contagious illness, they did not rigorously document the occurrence of person-to-person transmission. In addition, none of these studies included patients with clinically evaluated fatigue that fit the CFS case definition; therefore, these clusters of cases cannot be construed as outbreaks of CFS. The CDC worked with state health departments to investigate a number of reported outbreaks of fatiguing illness and has yet to confirm a cluster of CFS cases. Implicit in any contagious illness is an infectious cause for the disease.

Carefully designed case-control studies involving rigorously classified CFS patients and controls have found no association between CFS and a large number of human disease agents (see Possible Causes of CFS). Finally, none of the behavioral characteristics typically associated with contagious disease, such as intravenous drug use, exposure to animals, occupational or travel history, or sexual behavior, have been associated with CFS in case-control studies. It therefore seems unlikely that CFS is a transmissible disease. Nevertheless, the lack of evidence for clustering of CFS, the absence of associations between specific behavioral characteristics and CFS, and the failure to detect evidence of infection more commonly in CFS patients than in controls do not rule out the possibility that infectious agents are involved in or reflect the development of this illness. For example, important questions remain to be answered concerning possible reactivation of latent viruses (such as human herpesviruses) and a possible role for infectious agents in some cases of CFS.

It is vital to understand the clinical course of CFS. This knowledge is required to facilitate communication between physicians and patients, to evaluate possible new treatments, and to address insurance and disability issues. The clinical course of CFS varies considerably among persons who have the disorder; the actual percentage of patients who recover is unknown, and even the definition of what should be considered recovery is subject to debate. Some patients recover to the point that they can resume work and other activities, but continue to experience various or periodic CFS symptoms. Some patients recover completely with time, and some grow progressively worse. CFS often follows a cyclical course, alternating between periods of illness and relative well being. The CDC continues to monitor the patients enrolled in the four-city surveillance study; recovery is defined by the patient and may not reflect complete symptom-free recovery. Approximately 50% of patients reported "recovery," and most recovered within the first five years after onset of illness. No characteristics were identified that made one patient more likely to recover than another. At illness onset, the most commonly reported CFS symptoms were sore throat, fever, muscle pain, and muscle weakness. As the illness progressed, muscle pain and forgetfulness increased and the reporting of depression decreased.

Possible Causes of CFS

The cause or causes of CFS remain unknown, despite a vigorous search. While a single cause for CFS may yet be identified, another possibility is that CFS represents a common endpoint of disease resulting from multiple precipitating causes. As such, it should not be assumed that any of the possible causes listed below has been formally excluded, or that these largely unrelated possible causes are mutually exclusive. Conditions that have been proposed to trigger the development of CFS include virus infection or other transient traumatic conditions, stress, and toxins.

Infectious Agents. Due in part to its similarity to chronic mononucleosis, CFS was initially thought to be caused by a virus infection, most

probably Epstein-Barr virus (EBV). It now seems clear that CFS cannot be caused exclusively by EBV or by any single recognized infectious disease agent. No firm association between infection with any known human pathogen and CFS has been established. CDC's four-city surveillance study found no association between CFS and infection by a wide variety of human pathogens, including EBV, human retroviruses, human herpesvirus 6, enteroviruses, rubella, *Candida albicans*, and more recently bornaviruses and Mycoplasma. Taken together, these studies suggest that among identified human pathogens, there appears to be no causal relationship for CFS. However, the possibility remains that CFS may have multiple causes leading to a common end point, in which case some viruses or other infectious agents might have a contributory role for a subset of CFS cases.

Immunology. It has been proposed that CFS may be caused by an immunologic dysfunction, for example, inappropriate production of cytokines, such as interleukin-1, or altered capacity of certain immune functions. One thing is certain at this juncture: there are no immune disorders in CFS patients on the scale traditionally associated with disease. Some investigators have observed anti-self antibodies and immune complexes in many CFS patients, both of which are hallmarks of autoimmune disease. However, no associated tissue damage typical of autoimmune disease has been described in patients with CFS. The opportunistic infections or increased risk for cancer observed in persons with immunodeficiency diseases or in immunosuppressed individuals is also not observed in CFS. Several investigators have reported lower numbers of natural killer cells or decreased natural killer cell activity among CFS patients compared with healthy controls, but others have found no differences between patients and controls.

T-cell activation markers have also been reported to have differential expression in groups of CFS patients compared with controls, but again, not all investigators have consistently observed these differences. One intriguing hypothesis is that various triggering events, such as stress or a viral infection, may lead to the chronic expression of cytokines and then to CFS. Administration of some cytokines in therapeutic doses is known to cause fatigue, but no characteristic pattern of chronic cytokine secretion has ever been identified in CFS patients. In addition, some investigators have noted clinical improvement in patients with continued high levels of circulating cytokines; if a causal relationship exists between cytokines and CFS, it is likely to be complex. Finally, several studies have shown that CFS patients are more likely to have a history of allergies than are healthy controls. Allergy could be one predisposing factor for CFS, but it cannot be the only one, since not all CFS patients have it.

Hypothalamic-Pituitary Adrenal (HPA) Axis. Multiple laboratory studies have suggested that the central nervous system may have an important role in CFS. Physical or emotional stress, which is commonly reported as a pre-onset condition in CFS patients, activates the hypothalamic-pituitary-adrenal axis, or HPA axis, leading to increased release of cortisol and other hormones. Cortisol and corticotrophin-releasing hormone (CRH), which are also produced during the activation of the HPA axis, influence the immune system and many other body systems. They may also affect several aspects of behavior. Recent studies revealed that CFS patients often produce lower levels of cortisol than do healthy controls. Similar hormonal abnormalities have been observed by others in CFS patients and in persons with related disorders like fibromyalgia. Cortisol suppresses inflammation and cellular immune activation, and reduced levels might relax constraints on inflammatory processes and immune cell activation. As with the immunologic data, the altered cortisol levels noted in CFS cases fall within the accepted range of normal, and only the average between cases and controls allows the distinction to be made. Therefore, cortisol levels cannot be used as a diagnostic marker for an individual with CFS. A placebo-controlled trial, in which 70 CFS patients were randomized to receive either just enough hydrocortisone each day to restore their cortisol levels to normal or placebo pills for 12 weeks, concluded that low levels of cortisol itself are not directly responsible for symptoms of CFS, and that hormonal replacement is not an effective treatment. However, additional research into other aspects of neuroendocrine correlates of CFS is necessary to fully define this important, and largely unexplored, field.

Neurally Mediated Hypotension. Rowe and coworkers conducted studies to determine whether disturbances in the autonomic regulation of blood pressure and pulse (neurally mediated hypotension, or NMH) were common in CFS patients. The investigators were alerted to this possibility when they noticed an overlap between their patients with CFS and those who had NMH. NMH can be induced by using tilt table testing, which involves laying the patient horizontally on a table and then tilting the table upright to 70 degrees for 45 minutes while monitoring blood pressure and heart rate. Persons with NMH will develop lowered blood pressure under these conditions, as well as other characteristic symptoms, such as lightheadedness, visual dimming, or a slow response to verbal stimuli. Many CFS patients experience lightheadedness or worsened fatigue when they stand for prolonged periods or when in warm places, such as in a hot shower. These conditions are also known to trigger NMH. One study observed that 96% of adults with a clinical diagnosis of CFS developed hypotension during tilt table testing, compared with 29% of healthy controls. Tilt tabletesting also provoked characteristic CFS symptoms in the patients. A study (not placebo-controlled) was conducted to determine whether medications effective for the treatment of NMH would benefit CFS patients. A subset of CFS patients reported a striking improvement in symptoms, but not all patients improved. A placebo-controlled trial of NMH medications for CFS patients is now in progress.

Nutritional Deficiency. There is no published scientific evidence that CFS is caused by a nutritional deficiency. Many patients do report intolerances for certain substances that may be found in foods or over-the-counter medications, such as alcohol or the artificial sweetener aspartame. While evidence is currently lacking for nutritional defects in CFS patients, it should also be added that a balanced diet can be conducive to better health in general and would be expected to have beneficial effects in any chronic illness.

Diagnosis of CFS

How Physicians Diagnose CFS. If a patient has had 6 or more consecutive months of severe fatigue that is reported to be unrelieved by sufficient bed rest and that is accompanied by nonspecific symptoms, including flulike symptoms, generalized pain, and memory problems, the physician should further investigate the possibility that the patient may have CFS. The first step in this investigation is obtaining a detailed medical history and performing a complete physical examination of the patient. Initial testing should include a mental status examination, which ordinarily will involve a short discussion in the office or a brief oral test. A standard series of laboratory tests of the patient's blood and urine should be performed to help the physician identify other possible causes of illness. If test results suggest an alternative explanation for the patient's symptoms, additional tests may be performed to confirm that possibility. If no cause for the symptoms is identified, the physician may render a diagnosis of CFS if the other conditions of the case definition are met. A diagnosis of idiopathic chronic fatigue could be made if a patient has been fatigued for six months or more, but does not meet the symptom criteria for CFS.

Appropriate Tests for Routine Diagnosis of CFS. Although the number and type of tests performed may vary from physician to physician, the following tests constitute a typical standard battery to exclude other causes of fatiguing illness: alanine aminotransferase (ALT), albumin, alkaline phosphatase (ALP), blood urea nitrogen (BUN), calcium, complete blood count, creatinine, electrolytes, erythrocyte sedimentation rate (ESR), globulin, glucose, phosphorus, thyroid stimulating hormone (TSH), total protein, transferrin saturation, and urinalysis. Further testing may be required to confirm a diagnosis for illness other than CFS. For example, if a patient has low levels of serum albumin together with an above-normal result for the blood urea nitrogen test, kidney disease would be suspected. The physician may choose to repeat the relevant tests and possibly add new ones aimed specifically at diagnosing kidney disease. If autoimmune disease is suspected on the basis of initial testing and physical examination, the physician may request additional tests, such as for antinuclear antibodies.

Psychological/Neuropsychological Testing. In some individuals it may be beneficial to assess the impact of fatiguing illness on certain cognitive or reasoning skills, e.g., concentration, memory, and organization. This may be particularly relevant in children and adolescents, where academic attendance, performance, and specific educational needs should be addressed. Personality assessment may assist in determining coping abilities and whether there is a co-existing affective disorder requiring treatment.

Theoretical and Experimental Tests. A number of tests, some of which are offered commercially, have no demonstrated value for the diagnosis of CFS. These tests should not be performed unless required

for diagnosis of a suspected exclusionary condition (e.g., MRI to rule out suspected multiple sclerosis) or unless they are part of a scientific study. In the latter case, written informed consent of the patient is required. No diagnostic tests for infectious agents, such as Epstein-Barr virus, enteroviruses, retroviruses, human herpesvirus 6, *Candida albicans*, and Mycoplasma incognita, are diagnostic for CFS and as such should not be used (except to identify an illness that would exclude a CFS diagnosis, such as mononucleosis). In addition, no immunologic tests, including cell profiling tests such as measurements of natural killer cell (NK) number or function, cytokine tests (e.g., interleukin-1, interleukin-6, or interferon), or cell marker tests (e.g., CD25 or CD16), have ever been shown to have value for diagnosing CFS. Other tests that must be regarded as experimental for making the diagnosis of CFS include the tilt table test for NMH, and imaging techniques such as MRI, PET-scan, or SPECT-scan. Reports of a pathway marker for CFS as well as a urine marker for CFS are undergoing further study; however, neither is considered useful for diagnosis at this time.

Terms Most Often Encountered in Relation to CFS

Acute Phase: A short, sharp, and relatively severe course of a disease; not chronic.

Anti-inflammatory: Agents that reduce inflammation without directly antagonizing the agent that caused it.

Antidepressants: Pharmaceutical agents used to treat clinical depression.

Anxiety Disorders: Also known as anxiety neurosis or anxiety reaction. A condition that can be caused by both psychologic and physiologic factors. It can take two general forms: (1) acute anxiety (panic disorder), marked by repeated occurrences of intense self-limited anxiety lasting usually a few minutes to an hour, or (2) chronic anxiety, characterized by less intense reactions of much longer duration (days, weeks, or months).

Bipolar Affective Disorder: A mood disorder that commonly begins with depression and is characterized by at least one period of elation sometime during the course of the illness.

***Borrelia*:** A genus of bacteria with numerous species that cause disease in humans. The diseases associated with these organisms are typically relapsing fevers.

***Candida Albicans*:** A common saprophyte of the digestive tract and female urogenital tract. It does not ordinarily cause disease, but may do so following a disruption of bacterial flora of the body, or in patients with depressed immune systems.

Case definition: In the example of CFS, a combination of symptoms, signs, and physiologic characteristics that serve to distinguish a case of chronic fatigue syndrome from other disease states.

Case-control study: An epidemiologic study that examines selected patients who have a defined disease (cases) with persons without the disease (controls).

Chronic: Of long duration, denoting a disease of slow progress and long continuance.

Chronic Fatigue and Immune Dysfunction Syndrome (CFIDS): A synonym for chronic fatigue syndrome used by some patients and physicians. It should be stressed, however, that no immune dysfunction or aberration has been persuasively linked to chronic fatigue syndrome.

Coenzyme: A substance that enhances or is necessary for the action of enzymes. They are generally much smaller than enzymes themselves.

Connective Tissue Disorder: A variety of inflammatory diseases of connective tissue, the most common of which is rheumatoid arthritis. Much, if not all, of this disease is now attributed to autoimmune processes.

Connective Tissue: The supporting tissues of the body, such as tendons, ligaments, bone, and cartilage.

Control: A device used to verify or regulate a scientific experiment or study. A case-control study serves as a useful example. Since patients with a specific illness are examined for various characteristics, a group of healthy individuals who otherwise have as much in common with the patients as possible must be examined in parallel for the same characteristics.

Cross-sectional study: In epidemiology, a study in which participants are examined at only a single time for characteristics of a disease.

Cytokine: Proteins manufactured by cells of various lineages that, when secreted, drive specific responses (e.g., proliferation, growth, or maturation) in other susceptible cells.

Cytomegalovirus (CMV): One of the eight known types of human herpesviruses, also known as human herpesvirus 5 (HHV-5). It belongs to the beta subfamily of herpesviruses. CMV can cause severe disease in patients with immune deficiency and in newborns when the virus is transmitted in utero.

Depression: A neurotic or psychotic condition marked by an inability to concentrate, insomnia, and feelings of dejection and guilt.

Enterovirus: A genus of RNA viruses with over 70 types identified in humans. They reproduce in the intestinal tract, and various members can cause a variety of human diseases, including poliomyelitis, aseptic meningitis, hepatitis, inflammatory heart disease, and rhinitis.

Epidemiology: The branch of medical science that deals with the indicence, distribution, and control of disease in a population.

Epstein-Barr virus (EBV): One of the eight known types of human herpesviruses, also known as human herpesvirus 4 (HHV-4). It belongs to the gamma subfamily of herpesviruses. It commonly causes acute mononucleosis, and less commonly chronic mononucleosis. It some populations EBV is causally associated with life-threatening malignancies (Burkitt's lymphoma, nasopharyngial carcinoma).

Etiology: Causal association of a disease with an agent. The study of the cause of diseases.

Fibromyalgia: Also known as myofascial pain syndrome and fibromyositis. A group of common rheumatoid disorders (not involving the joints) characterized by achy pain, tenderness, and stiffness of muscles.

Herpesvirus: A family of large DNA viruses that infect a wide range of animal species. Eight distinct types have been associated with a variety of human diseases.

Human Herpesvirus 6: A virus of the herpesvirus beta-subfamily, discovered in 1985, that infects more than 95% of people by the age of 2 years. It has been causally associated with roseola, mononucleosis-like illness, inflammation of lymph glands. There is also suggestive evidence for a role in multiple sclerosis.

Idiopathic: Denoting a disease of unknown cause.

Immune Globulin: A crude preparation of antibody molecules collected from pooled multiple blood donations, used as a means for passively transferring antimicrobial resistance to susceptible individuals.

Immune Suppressants: Agents that block or restrict the activity of one or more components of the immune system, usually leading to increased susceptibility to infectious disease.

Lymph Node: Secondary immune organs distributed at discrete locations throughout the body. These organs play a central role in the activation and trafficking of immune lymphocytes in the body.

Lymphocyte: Small white blood cells that are uniform in appearance, but very diverse in function. Collectively, they are responsible for antibody production, direct cell-mediated killing of virus-infected cells and tumor cells, and for the regulation of virtually every other component of the mammalian immune system.

Malaise: A feeling of general discomfort or uneasiness, an out-of-sorts feeling, often the first indication of an infection or other disease.

Myalgic Encephalomyelitis: A synonym for chronic fatigue syndrome in common usage in the United Kingdom and Canada.

Natural Killer Cell (NK): A lymphocyte which, unlike other lymphocytes, does not require specific activation by foreign antigen. They are considered to play a "front line" role in controlling infection, curbing infection until a specific, coordinated immune response can be mounted.

Neurasthenia: Nervous exhaustion. A functional neurosis marked by intense nervous irritability and weakness.

Neuromyasthenia: Muscular weakness, usually of emotional origin.

Neuropsychiatric: Relating to organic and functional diseases of the nervous system.

Retrovirus: A family of RNA viruses that have the unique characteristic of producing an enzyme that makes a DNA copy of its genetic information from an RNA template (the opposite of what normally takes place). The most widely recognized of these viruses is HIV, the causative agent in AIDS. Another virus from this family (HTLV-1) has been associated with T cell leukemia. Initial reports of an association of an HTLV-II-like retrovirus with CFS could not be confirmed in subsequent studies.

Sentinel Surveillance: A monitoring method that employs a surrogate indicator for a public health problem, allowing estimation of the magnitude of the problem in the general population.

Systemic Lupus Erythematosus: An inflammatory disease of connective tissue occurring predominantly in women (90%). It is considered to be an autoimmune disease.

T lymphocyte, T cell: The most common type of lymphocyte, itself divided into at least three subpopulations on the basis of function: cytotoxic, or killer T lymphocytes, helper T lymphocytes, and suppressor T lymphocytes. T cells play a cardinal role in regulating the immune system.

Titer: The concentration of a substance in a solution, or the strength of such a substance detected by titration. In the current context, the term is most likely to refer to antibody titer, which is a measure of the concentration of specific antibodies to selected microbes that are circulating in an individual's bloodstream.

Vitamin: A group of organic micronutrients, present in minute quantities in natural foodstuffs, that are essential to normal metabolism.

CHRONOGRAPH. A wristwatch or pocket watch that displays time of day and incorporates the functions of the stopwatch or sports timer. A chronograph permits the measurement of elapsed time-either continuously or interruptedly for periods of up to several minutes or hours. Normally, the elapsed-time reading is in fifths of a second. For certain sports and industrial applications, a display is scaled into 1/100ths of a minute instead of seconds. Certain chronographs, like some stopwatches, can display more than one elapsed time reading; others also incorporate tachometer or other special-scale displays that report computed velocities or distances.

Logically, the term chronograph is also used in connection with recording timed events. In this regard, almost all process variables, such as temperature, pressure, flow, machine operations, etc., are recorded against time. Normally, however, these instruments are not thought of as chronographs, although the term certainly is not inappropriate. More often, chronograph is applied to very special types of instruments which are precisely time-driven (where a very exact time reference is important), as in the case of seismic recorders for placing the exact time of arrival of earthquake information, for seismic mineral exploration operations, etc.

CHRONOMETER. A special type of clock used as a reference by a ship's navigator. Also known as a marine chronometer. A chronometer displays Greenwich Mean Time (GMT) and is characterized by a very constant daily rate (usually within 0.1 second per day) although the timepiece may gain or lose several seconds per day. See also **Time**.

The navigator checks the chronometer periodically (usually every week or ten days) against radio time signals to confirm its rate and error. From this information, the correct GMT can be calculated at any instant. This provides a basic time reference. Using a sextant, the navigator makes an astronomical reading, usually of the position of the sun, which is then correlated with tables given in a nautical almanac to find local mean time. Comparison of local time with the GMT readings provides the longitude. Since the advent of navigation satellites, the determination of ship and aircraft positions has altered the importance of earlier procedures, particularly with reference to commercial and military operations. See also **Navigation**.

CHRONOTRON. A device that utilizes a measurement of the position of the superposed loci of a pair of pulses on a transmission line to determine the time between the events that initiate the pulses.

CHRYSALIS (or Chrysalid). The third stage in the development of butterflies, also properly called the pupa. The caterpillar of a butterfly spins no cocoon but hangs itself by a silken button or by a belt and button. The skin of the pupa into which it changes is often brightly colored or protectively colored and marked, unlike the mahogany-colored pupae of most moths. Although some moths form similar naked pupae the term chrysalis is applied only to those of the butterflies.

CHRYSOBERYL. The mineral chrysoberyl, an aluminate of beryllium corresponds to the formula $BeAl_2O_4$, crystallizes in the orthorhombic system with both contact and penetration twins common, often repeated resulting in rosetted structures. Hardness, 8.5; specific gravity, 3.75; luster vitreous; color various shades of green sometimes yellow. A variety which is red by transmitted light is known as alexandrite. Streak colorless; transparent to translucent, occasionally opalescent. Chrysoberyl also is known as *cymophane* and *golden beryl*.

Chrysoberyl occurs in granitic rocks, pegmatites and mica schists; often is found in alluvial deposits. The Ural Mountains yield alexandrite. Other localities for chrysoberyl are Czechoslovakia; Ceylon; Rhodesia; Brazil; and Madagascar, where it occurs of gem quality in the pegmatites of that island. In the United States it is found in Maine, Connecticut, and New York. The word chrysoberyl is derived from the Greek words meaning golden and beryl. Cymophane has its derivation also from the Greek words meaning wave and appearance, in reference to the opalescence exhibited at times.

CHRYSOCOLLA. This mineral, a hydrous silicate of copper probably corresponding to the formula $Cu_2H_2Si_2O_5(OH)_4$, is perhaps a mineral gel, for it usually appears as an amorphous mass, in veins, or as incrustations. Common occurrence as massive cryptocrystalline character, possibly orthorhombic; extremely rare as small acicular crystals.

Chrysocolla is generally some shade of blue or green but if impure may be brown or black. It has a characteristic conchoidal fracture; hardness, 2–4; sp gr, 2.24; vitreous to dull luster; translucent to opaque.

Chrysocolla is a secondary mineral and associated commonly with other copper minerals of similar origin. It is one of the less important ores of copper and has a minor use as a gemstone. Among the localities for excellent specimens may be mentioned Cornwall and Cumberland, England; Congo; Chile; Lebanon and Berks Counties, Pennsylvania; the Clifton-Morenci Globe and Bisbee districts in Arizona; Dona Ana County, New Mexico, and the Tintic district, Utah.

The word chrysocolla is derived from the Greek words meaning gold and glue, formerly the name for gold solder.

CHRYSOTILE. A delicately fibrous variety of serpentine which separates easily into silky, flexible fibers of greenish or yellowish color, with formula $Mg_3Si_2O_5(OH)_4$. It crystallizes in the monoclinic system; hardness, 2.5; sp gr, 2.55. Its name is derived from the Greek words meaning gold and fibrous. Most of the common asbestos of commerce is chrysotile. It is mined in Thetford, Province of Quebec, and in the Republic of South Africa. See also **Asbestos**; and **Serpentine**.

CHUBASCO. A severe thunderstorm with vivid lightning and violent squalls coming from the land on the west coast of Nicaragua and Costa Rica in Central America. Chubascos are especially frequent in May, with a secondary maximum in October. Soon after noon, dark, heavy clouds form over the mountains, becoming denser and lower. At about 4 p.m. the southwesterly sea breeze veers to east-northeast, and the storm breaks, usually continuing until about 8 p.m.

CHUCK. A rotating vise that may be attached to the spindle of a machine. There are two important varieties of lathe chucks, independent and universal. In general, the *independent chuck* has four jaws, each of which is separately actuated and adjusted. It may be employed for almost any type of work, cylindrical, square, or irregular. In turning cylindrical work, it is necessary to adjust the jaws very carefully, and test the concentricity of the work and spindle axes with some form of indicator. When a 4-jaw independent chuck is employed for repetitive work, only two adjacent jaws are actuated as each new part is placed in the chuck after the initial adjustment and alignment of the jaws have been obtained.

Three-jaw *universal* or self-centering chucks are employed for cylindrical and hexagonal bar stock. The jaws are simultaneously advanced or retracted by turning the scroll plate in which the jaw teeth fit. On account of the curvature of the scroll, it is necessary to have separate sets of jaws for inside and outside clamping, in contrast to the independent chuck where the jaws may be reversed. Combination chucks combine an independent chuck for holding odd-shaped work; a universal chuck for self-centering and gripping round or square work; 2-jaw universal chucks have jaws to which special adapters may be fitted and are employed principally in turret lathe work.

Independent and universal chucks may be attached to a threaded adapter which screws on the spindle nose. These chucks may also be obtained with adapters to fit heavy-duty taper spindle noses; the chuck is drawn on the spindle nose by the engagement of the "pull-on" nut with the externally threaded hub of its adapter.

Air-operated chucks have a body with two jaws and work-holding adapters with an actuating wedge, which closes and opens the jaws by moving parallel to the chuck axis. The actuating wedge is threaded so that a draw-rod may be attached. The other end of the draw-rod is attached to a piston operating in an air cylinder, which is attached to the lathe headstock. The piston is double-acting so that the chuck jaws may be both opened and closed by the action of compressed air. The chuck is operated by a valve convenient to the machine operator. Air- and oil-operated chucks are generally employed for production work, as in turret and chucking lathes.

Draw-in chucks and collets are used for bar work, and are designed to fit on the heavy-duty spindle nose if the live center is removed. The collets, which are of various sizes, fit in the chuck and are clamped with a removable key or wrench. Drawing in the spring collet forces its outer surface against the taper on the inside of the chuck; releasing the collet causes its jaws to open by their spring action. Bars of any length may be held in the chuck, extending entirely through the hole in the spindle if necessary. Collets for all standard sizes of circular rod are available as well as collets for hexagonal bar stock and cylindrical metric sizes. Magnetic chucks of both the electrically actuated and the permanent-magnet type may also be employed on the lathe.

Three-jaw universal chucks are used on drill presses. Rotating the outer sleeve by hand or by a key fitted to the sleeve gear teeth, opens and closes the three self-centering jaws. The arbor hole in the drill chuck fits the tapered end of the drill press spindle. *Bayonet chucks* are single-purpose chucks and are used on automatic drilling machinery. They are equipped with a bayonet slot for rapid attachment and release.

CHUCK-WALLA *(Reptilia, Sauria).* A common lizard, *Sauromalus obesus*, of the southwestern deserts, ranging into Utah and Nevada. It attains a length of 11 inches (28 centimeters) and is sometimes eaten.

CHUGGING. A form of combustion instability in a rocket engine, characterized by a pulsing operation at a fairly low frequency, sometimes defined as occurring between particular frequency limits; the noise made in this kind of combustion. Also called chuffing, bumping.

CICADA *(Insecta, Homoptera).* Large insects of many species. They are stoutly built and have two pairs of membranous wings, which are folded roof-like over the body when at rest. They are best known for the loud songs of the males, which are produced by a pair of elaborate organs located on the under surface at the base of the abdomen. These organs have a vibrating structure controlled by special muscles and thin resonating parts, which result in a peculiarly penetrating sound.

The female has a powerful ovipositor with which she punctures the twigs of trees and shrubs to deposit her eggs. The young cicada does not remain in the twig but drops to the ground and burrows, feeding on the roots of plants. In the case of one species, *Tibicina septendecim*, the duration of the larval period is unusually long and has resulted in the name seventeen-year locust. The name locust is inaccurately but very commonly applied to these insects and some are called harvest flies.

Great damage is sometimes done to young orchard trees by the breaking of twigs where the eggs have been deposited, especially after one of the great broods of the seventeen-year locust, or periodical cicada, has passed. There are approximately 20 different broods in the United States. The only effective protection is to cover young trees with inexpensive cloth when such a brood is imminent; the years of emergence are known by economic entomologists and can readily be learned for any part of the country.

In taking approximately 17 years for the nymph to fully materialize, the cicada has the longest life of any known insect. The body measures from $\frac{3}{4}$ to 1 inch (2 to 2.5 centimeters) in length; the wings are about $1\frac{1}{2}$ inches (4 centimeters) long. The eyes are large and are situated above the antennae. The insect has six legs for walking, leaping, digging, paddling, and cleaning. Most cicadas have claws on their feet with a pad between each claw. The pad is reinforced with hair moistened by glandular secretions.

CICHLIDS *(Osteichthyes).* Of the order *Percomorphi*, family *Cichlidae*, the cichlids number approximately 600 species and are found in South America, parts of the southwestern United States, and Africa. One genus, *Etroplus*, occurs in India and Sri Lanka. They generally are quite small and consequently many species are favorites of tropical-fish fanciers. Included are: *Pterophyllum scalare* (fresh water angelfish); *Symphysodon discus* (pompadour fish; also South American discus), whose habits of feeding their young are quite strange (the young obtain secretions from mucous cells of the skin of both parents as food); the genus *Tilapia*, mouthbreeders weighing from 2 to 20 pounds (0.9 to 9 kilograms); *Cichlasoma cyanoguttatum* (Rio Grande perch) occurring in Mexico and southward and attaining a length of 10 inches (25 centimeters); *Astronotus ocellatus* (oscar or peacock-eyed cichlid); and the *Steatocranus casuarius* (Congo bumphead cichlid) which is about 4 inches (10 centimeters) in length. In addition to the oscars and discus, other favorites of tropical-fish fanciers include: *Cichlasoma biocellatus* (the greenish-black Jack Dempsey); *C. festivum* (the flag cichlid); and *C. meeki* (the dramatic firemouth possessing a beautiful red chest).

The African mouthbreeders (*Tilapia mossambica*) are extremely prolific and, if competition from other species does not interfere, can become a good source of low-cost protein. They were introduced into Indonesia in the late 1930s and now are a popular pond fish.

CICONIIFORMES *(Aves)*. Most birds of this order differ conspicuously by their long legs from birds living on or near the water, like the loons and grebes, and the penguins, tubenoses, and *Pelecaniformes*. Unlike the ratites, the *Ciconiiformes* cannot, however, use their legs for swift running; their gait is a much more measured walk.

Their length ranges from 30–160 centimeters (12–63 inches); in normal posture the height of the crown is 20–130 centimeters (8–51 inches). The weight is 100–6000 grams ($3\frac{1}{2}$-211 ounces). They are almost always long-legged and long-necked. They have 16–20 cervical vertebrae, and the hind toe is well developed. All species live on animal food. The crop is absent but there is a well-developed proventriculus and small caeca. The eggs are usually plain-colored (exceptions are the hermit ibis and the spoonbill). The young remain in the nest for a comparatively long time.

There are five families: The Herons, Egrets, and Bitterns (*Ardeidae*); The Shoebills (*Balaenicipitidae*); The Hammerheads (*Scopidae*); The Storks (*Ciconiidae*); The Ibises (*Threskiornithidae*). Altogether there are 59 genera and 115 species.

The Heron family (*Ardeidae*) is distributed over all parts of the world. The weight varies between that of the least bittern, which weighs just over 100 grams (3.5 ounces), and the Goliath heron, which weighs 2600 grams ($5\frac{1}{2}$ pounds). There are 20–22 cervical vertebrae; the neck, which is almost immovable laterally, is S-shaped in flight and is wedged in between the breast and the wings when the bird is at rest. There are 24 genera with 63 species, found mostly in the tropics and subtropics; they do not exist in the far north or in Antarctica. See Fig. 1.

Fig. 1. Mangrove heron (*Butorides striatus*). (*Sketch by Glenn D. Considine*.)

Herons stalk their prey carefully or stand and wait for it, their long necks in the resting position, drawn back into an S-shape. The cervical spine is so constructed that a heron can thrust its head forward in a flash to stab its prey or to seize it with the beak.

Herons are easily distinguishable from storks in flight by the way they draw their necks back. They fly well and with endurance in slow, quiet wing beats, but they do not soar like storks, even though some species know how to utilize thermals. Temperate-zone herons are generally migrants. Many species that breed in the tropics also migrate regularly according to the wet and dry seasons.

Most species of herons breed in colonies; many are also social outside of the breeding season and spend the night in communal roosts. The nests are built in trees, in shrubs or reeds, or even on rocks. Usually both parents build the nest and relieve one another during incubation. The clutch usually consists of 3–5 eggs. The eggs are white, greenish, blue, or olive-brown; a few species have spotted eggs.

The food of most species consists predominantly of fish, as well as frogs, salamander larvae, small mammals, and insects. Herons swallow their prey whole and digest fish almost completely. See also **Bittern and Heron**.

The members of the remaining four families of the *Ciconiiformes* are somewhat less adapted to life near the water than are the herons. Among them the Shoebill (*Balaeniceps rex*) differs so much from the usual type of heron and stork that it is regarded as the representative of a separate family, *Balaenicipitidae*.

The standing height of the Shoebill is about 115 centimeters (45 inches), the length is 120 centimeters (47 inches), and the wing length is 68 centimeters ($26\frac{1}{2}$ inches). The beak is extraordinarily high and wide; in connection with this, the skull is much enlarged and thus is pelican-like. A slight crest is found at the back of the head.

The shoebill occurs only in the marshlands of tropical Africa and in general seems to be quite rare, but is more common in Uganda and the Sudan. It is easily overlooked, since it stays along river shores in dense papyrus, but is also seen on flat-flooded grassland with short grass. Its calm temperament makes it possible to approach it rather closely before it flies off. It flies well and sometimes soars in an updraft. It holds the beak pressed against the chest in flight and does this also on the ground. It lives mainly on river fish, but also on frogs and snails. The eggs are bluish white and covered with a calcareous layer; the clutch consists of 2–3 eggs.

The relationships of the Hammerheads (family *Scopidae*) are obscure, but they are generally placed with the order *Ciconiiformes*. There is only one species, the Hammerhead (*Scopus umbretta*). The length is about 50 centimeters ($19\frac{1}{2}$ inches). The head, with its medium long, laterally compressed beak and its crest pointing to the rear, looks somewhat hammer-like. The hammerhead inhabits swamp and shallow water areas, generally looks for food in the water, and occasionally swirls up the mud with its feet to stir up prey. It is found singly or in pairs; family units of up to seven birds remain together for only a short time.

Their flight is slow, as if swimming in air, and they frequently utter a shrill cry, particularly before it rains. They are active in the twilight and at night, and more rarely during the day. The nest of the hammerhead is an extraordinary, enormous structure. Its diameter is $1\frac{1}{2}$ meters (5 feet), and inside there is a small cavity only 30 centimeters (12 inches) across with an entrance that opens downward to one side. Three to six white eggs are incubated for about 30 days, and the young hammerheads leave the nest about 50 days after hatching.

The Storks (family *Ciconiidae*) are birds of medium size to very large. The beak, neck, and legs are long. The large and wide wings enable them to fly well and to soar, which saves much energy. They feed only on animals, and they build very large nests for their white eggs. There are species that have penetrated far into the temperate latitudes, and migrate far; others migrate over short distances. There are 10 genera with 18 species.

The best known species is the White Stork (*Ciconia ciconia*). Males and females look alike. The young at first have blackish beaks and legs. The length is 110 centimeters (43 inches); the wing length is 53–63 centimeters (21–25 inches); the wing span reaches over 220 centimeters (87 inches); and the weight is from 2.3–4.4 kilograms (5–10 pounds).

Storks generally feed while walking; they wander over open shallow swamps, meadows, and fields searching for food. As a rule, prey is seized with a forward thrust of the beak, but animals may also be seized under water with sideways beak movements. The diet is quite varied. Earthworms play a great role in spring, and for feeding the young. In the summer storks catch many insects, even crickets, which are difficult to catch, but mainly they feed on the more easily caught grasshoppers. Vertebrates are of lesser importance as food; however, where dead fish drift ashore, or where fish are sick and generally less mobile and hence are easily caught, storks certainly eat fish. Lizards and snakes, even vipers, are caught. Birds are occasionally taken.

Although well adapted in many respects, storks suffer greatly from cold and rainy weather. The climate, therefore, determines the northern boundary of distribution. Storks also need warm temperatures because they are dependent on thermal updrafts for soaring, as are many raptors. See also **Storks**.

The Ibises (*Threskiornithidae*) are related to the storks, with the wood ibises forming a sort of link with the true ibises. Although the ibises, with their slender curved beaks, differ strikingly from the flat-billed spoonbills, they are nevertheless closely related to them as well.

All members of the family *Threskiornithidae* are of medium size, with a length of 50–90 centimeters ($19\frac{1}{2}$-35 inches). The face and throat are more or less bare of feathers; the medium-length legs are sturdy. They are distributed over all warmer and tropical areas. Being very sociable they breed in large colonies and wander about or migrate in troops. In flight the

neck is carried extended forward, as in storks. Two subfamilies are readily distinguishable by external characteristics: The Ibises (*Threskiornithinae*), with their long, narrow, and markedly down-curved beak, probe for insects, mollusks, crustacea, and worms in mud and soil; occasionally they also catch larger prey. There are 17 genera with 20 species. The Spoonbills (subfamily *Plataleinae*), with a beak which is flattened and widened at the tip, seize prey in side-to-side movements of the bill. See Fig. 2. There are two genera with six species. See also **Ibis**.

CIENEGA. Cienega is both a hydrologic and ecological term used primarily in the southwestern United States and northwestern Mexico to designate a riparian marshland. The term cienega derives from the Spanish phrase *cien aguas* (literally "hundred waters" or more figuratively, "place of one hundred springs"). The modern Spanish equivalent is *ciénaga* ("marsh, swamp").

Most often, the term cienega refers to broad riparian areas of slowly flowing or ponded water, populated by dense vegetation. Such hydrologic conditions are unique in the Southwest because of the limited and declining number of perennially flowing stream reaches in the arid Southwest. Cienegas may also result from the discharge of springs or other conditions involving shallow or discharging groundwater. The term has also been applied to more diverse aquatic habitats throughout areas of Hispanic influence.

In South America, cienega generally refers to floodplain lakes that have open water. Thus, any marshy area within the Chihuahuan-Sonoran-Mohave desert region may be called a cienega. In upland environments in Arizona, the term cienega has been used to refer to marshy to bog-like meadowlands fed by seepage, precipitation, or moving waters bordering headwater streams. A database maintained by the Arizona Chapter of The Nature Conservancy (TNCA) lists 160 named cienegas in the Arizona region, including two in New Mexico; 34 in Sonora, Mexico; and one in Chihuahua, Mexico. Efforts are underway to verify and characterize each site.

Like many other wetland habitats, cienegas have been characterized as vanishing landforms, owing primarily to certain anthropogenic factors. However, increasing awareness of the significance and uniqueness of wetlands in general has resulted in various programs to maintain and restore such areas.

Hydrologic Conditions

As in all wetland environments, perennial moisture at shallow soil depths, if not standing water, is requisite for a cienega. These conditions, however, are rare in arid or semiarid landscapes, where surface drainage is typically ephemeral and flows only in response to direct surface runoff. In such dry climates, the water table is generally found at considerable depth below the base of the streambed, and groundwater discharge is thereby unable to contribute baseflow. Ephemeral streams are often incised due to high loading during high intensity, short duration precipitation. Historical information indicates that arroyo cutting and incisement of many stream reaches in the Southwest began near the end of the nineteenth century from both climatic and anthropogenic changes. In contrast to typical ephemeral drainages, groundwater beneath cienegas is generally at, or very near the surface, thereby supporting baseflow and a variety of wetland species. Additionally, the cross-channel profile in cienegas is comparatively shallow and broad, sometimes extending thousands of feet across.

Cienegas can form as a result of various hydrologic, geologic, and/or ecological conditions. To sustain indigenous wetland species, cienegas require replenishment of water at rates in excess of evaporation and transpiration rates. This replenishment is supplied from shallow or discharging groundwater that occurs due to structural and/or topographic factors underlying the streambed. Hendrickson and Minckley have noted various in-stream conditions that may form cienegas along stream courses. These include alternating aggradation and degradation by floods, causing alternating concave/convex stream profiling; beaver damming; slope breaks, such as at the toes of bajadas or alluvial fans; upfaulted bedrock causing localized thinning of alluvial material; channel base level adjustments with time; and impoundments caused by debris such as from slumps and landslides. Efforts to restore former cienega areas have involved constructing various types of dams and impoundments.

Environmental Conditions

Cienegas are wetland ecosystems and thereby represent transitional environments from terrestrial to aquatic systems. Classified wetland ecosystems require three conditions: (1) the land environment supports predominantly aquatic flora at least periodically, (2) the substrate comprises mostly saturated soils, and (3) submergence and/or saturation of the substrate persists at least for some time during the annual growing season (3). Hendrickson and Minckley defined three types of cienegas in the Southwestern United States initially based on elevation. Their elevation tiers included

- High-elevation (>2,000 m (>6,562 ft) cienegas described as marshy to bog-like alpine and cold temperate meadowlands.
- Midelevation (1,000 to 2,000 m (3,281 to 6,562 ft) cienegas resulting from perennial springs and headwater streams, typically found in semidesert grasslands and evergreen woodlands.
- Low-elevation (<1,000 m (<3,281 ft) cienegas occurring as subtropical marshes in oxbows, behind natural levees, and along margins of major streams.

TNCA has noted features and characteristics common to all tiers, including groundwater at or very near the soil surface; perennial surface water; occurrence within basins, usually within unincised channels; and dominant herbaceous, perennial flora, including terrestrial, aquatic, or semiaquatic species, where scattered, less dominant woody species occur. These characteristics further demonstrate that cienegas meet the wetland classification criteria of Cowardin et al.

Because cienegas represent comparatively lush, moist areas, they offer sharp contrast to adjacent dryland ecology. The combination of slow to stagnant water, the baffle effect of dense emergent flora, and the senescence and decay of this vegetation results in accumulation of rich organic detritus in the cienega basin. This detritus comprises a nutrient-rich substrate that enhances the overall productivity of these wetland areas.

A typical botanical progression from wettest to driest zones in a desert cienega might include emergent flora such as reeds (cattails, sedges, rushes) within the wettest areas. Salt-tolerant species such as salt grass might be found along the margins of the wetted areas, where remnant salts accumulate after evaporation. Broadleaf trees, such as various species of willow, cottonwood, and the invasive tamarisk, if present, might be found farther upland. These species adapt to less saline, less saturated soil conditions. Still farther upland, as depth increases to the water table, one might find a progression toward mesquite bosques. The availability of water and resultant luxuriance of forage in such semiarid regions often result in increases in herbivore populations. In turn, this has been cited as a potential factor in the demise of these habitats.

Examples

Cienega Creek, Pima County, Arizona. Cienega Creek, located in southern Arizona, represents a discontinuous stream that has perennial flow along certain reaches. Perennial flow along this reach supports a rich

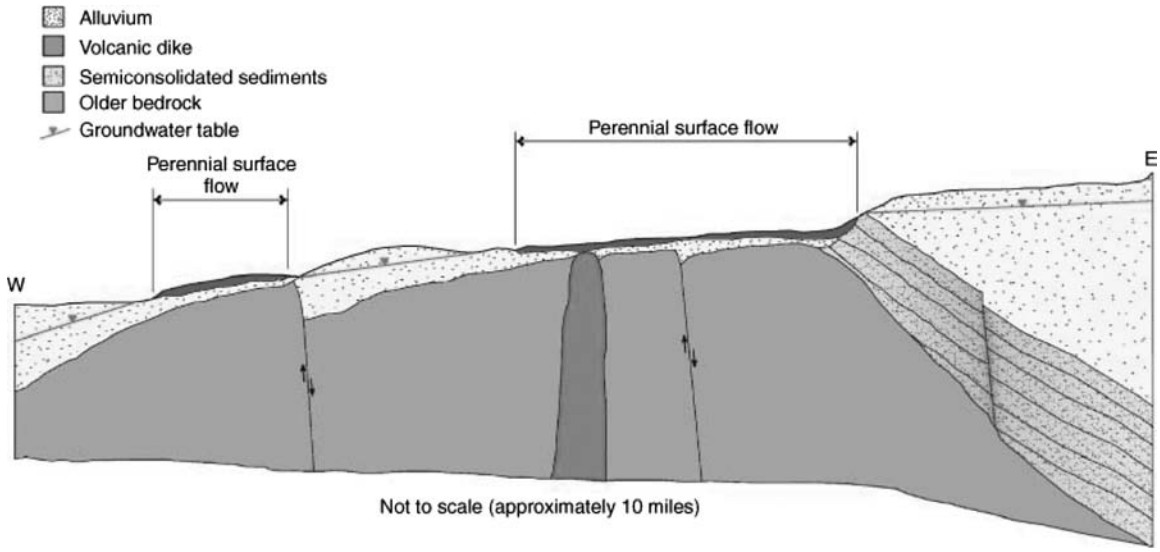

Fig. 1. Conceptualization of structural components producing intermittent flow in Cienega Creek, Pima County, AZ. (*Nature Conservancy of Arizona*)

riparian habitat that has prompted the county to designate a portion of the reach as Cienega Creek Natural Preserve. The cienega exists primarily as a result of bedrock structural control over groundwater flow. Gravimetric investigations within the Cienega Creek basin have indicated that flow occurs as a result of upwardly dipping, low permeability bedrock that results in thinning of the overlying alluvium so as to force groundwater to daylight through the streambed. These sudden changes in depth to bedrock have been associated with high-angle faulting. A longitudinal profile of this regime is illustrated in Fig. 1.

Southern Arizona. Cienegas similar to Cienega Creek have been noted historically throughout southern Arizona including the San Simon, Sulphur Springs, Aravaipa, and San Pedro Valleys. Extensive archaeological research within these areas has shown that human settlements in the vicinity of such areas date back to 8000 B.C. and use continued through recent native American cultures. Accounts of the Mormon Battalion tell of grassy bottomlands with "... salmon trout, up to three feet long," "... profuse and luxuriant [cane grass up to six feet high]," along the San Pedro River. Accounts of stream conditions in the San Pedro River near St. David, Arizona, in the late nineteenth century suggest that the channel profile was flat and marshy, in contrast to its present-day incisement. The incisement has been attributed to a variety of anthropogenic factors including groundwater pumping, grazing, agriculture, and removal of beaver dams. There have been also been accounts of significant changes in the overall hydrologic conditions attributed to a 1887 earthquake centered to the south in Sonora, Mexico. Reports of liquefaction, new springs, disappearance of former surface water and springs, and changes in water levels in wells have all been noted.

Cienega de Santa Clara, Colorado River Delta. The Cienega de Santa Clara is a remnant of the former desert estuary of the Colorado River. This nearly 15,000-acre wetland habitat occupies an oxbow area of the Colorado River. Diversions from the river now limit its replenishment; the remaining flow represents irrigation drainage pumped from agricultural land in the United States. Thus, the existence of the cienega is primary the result of anthropogenic water management. Owing to the high rate of evaporation as well as the salinity of the influent agricultural drainage, the Cienega is mildly brackish. Recent concerns over the survivability of the habitat have arisen from consideration of diverting the irrigation outflow through a desalination plant in the United States. This would have the combined impact of reducing the quantity of flow and increasing salinity as a result of splicing in saline blowdown from the desalination plant.

Related Terms

Other equivalent or related terms are billabong, bog, bottomland, carr, fen, heath, marsh, pantano, riparian, mangrove, mire, moor, muskegs, oxbow, peatland, playa, pocosin, pothole, salt marsh, slough, swamp, vernal pool, and wetland. These terms relate to various types of wetland environments, but the hydrologic conditions that form them and the ecological communities that inhabit them may differ greatly. Many terms are local and regional. See also **Forests and Wetlands**.

Within the Southwestern United States and Northwestern Mexico, there have been numerous such water-related terms referred to in the journals of Spanish explorers, including those of Father Eusibio Kino, a late seventeenth century missionary, who made more than 150 *entradas* ("journeys" or "reconnaissance") across the Sonoran desert during his 24-year residence. During such journeys along *El Camino del Diablo*, Kino made various references to *cienegas*, *tinajas*, or *tanques* ("water tanks" or "jars"), and *aguajes* ("watering holes") along the way.

CILIA. Fine thread-like hairs located in various parts of the body, which serve as filtering mechanisms to protect body areas from foreign particles, e.g., the eyelashes. See also **Cilium**.

CILIOPHORA. A subphylum of the phylum *Protozoa* containing species which have cilia or cirri during some stage of life. They vary greatly in form and habits. Some are sessile, some free swimming, and some parasitic.

The following is a brief summary of a classification of ciliates now widely used:

Class *Ciliata*. With cilia or cirri throughout life.
- Subclass *Protociliata*. Leaf-like species with two to many nuclei.
  - Parasitic in the intestines of fishes and amphibians. *Opalina* and related forms.
- Subclass *Euciliata*. With two kinds of nuclei, large and small (macronucleus and micronucleus).
  - Order *Holotrichida*. Cilia uniformly distributed. *Paramecium* and many other genera.
  - Order *Heterotrichida*. With a zone of cilia of larger size, or membranelles, associated with the mouth. *Stentor*.
  - Order *Oligotrichida*. With cilia about the mouth but few on the body.
  - Order *Hypotrichida*. Flattened, with cilia or cirri on the under surface. *Stylonychia*, etc.
  - Order *Peritrichida*. Oral end of body enlarged, ciliated, many species stalked. *Vorticella*, etc.

Class *Suctoria*. With cilia only during early life. Adults sessile, with tentacles for ingesting food and for piercing.

CILIUM. A slender hair-like process of minute size on the surface of a cell. It is part of the living cytoplasm. In association with their minute size, cilia occur in relatively large numbers and act in unison to produce aggregate effects. They are capable of waving movement. Commonly they bend consecutively in the same direction so that a wave of movement passes along the ciliated surface, followed by the return of the cilia to the resting position and this again by their bending. This type of movement is said to be metachronal. The successive waves follow each other closely so that several may be apparent at the same time.

Cilia are found in many species of *Protozoa* and give the name *Ciliophora* to one subdivision of the phylum. Among the multicellular animals they occur on the surface of the body in a few groups (e.g., coelenterates, turbellarian worms and molluskans) during adult life and in many larvae such as those of the echinoderms, the annelid worms, coelenterates, and others. They are also found on epithelia of limited distribution in many complex animals, as in the mantle cavity of mollusks and the trachea of humans.

Cilia on the surface of small animals, such as the Protozoa and larvae of greater complexity, are able by their action against a surrounding liquid to propel the animal and so serve as organs of locomotion. In animals of larger size, in those not surrounded by a liquid medium, on sessile forms, and where the direction of their movement is contrary to the movements of propulsion, they act to set up currents either in liquids secreted by the body or in the surrounding medium. Thus some cilia in Protozoa, coelenterates, and mollusks direct a current bearing food and oxygen into the gullet and in humans cilia carry toward the throat the mucus secreted by glands in the lining of the trachea. This secretion may bear foreign particles that have been inhaled.

CINCHONA. A tall tree (*Cinchona succirubra* Pav.), or various hybrids, of the *Rubiaceae* family is the source of quinine. The tree is indigenous to Peru, but is presently cultivated throughout the Central and South American countries as well as in Madagascar and certain regions of Africa. The commonly used drug quinine is obtained from the bark of branches, generally of trees that are 15 years old or older. Cinchona and its derivatives are also widely used in the manufacture of liqueurs, some nonalcoholic beverages, ice creams, baked goods, bitters, and condiments, primarily for their characteristic bitter-tonic flavoring action. Tonic waters are prepared largely with quinine salts. In the United States, not more than 83 parts per million total chichona alkaloids can be used in finished beverages.

CINNABAR. The mineral cinnabar, mercuric sulfide (HgS) occurs in small and often highly modified hexagonal crystals, usually of rhombohedral or tabular habit. It is found chiefly in crystalline crusts, granular or simply massive. The overture of cinnabar is subconchoidal; hardness, 2−2.5; specific gravity, 8−8.2; luster, adamantine tending toward metallic, sometimes dull. This mineral has a characteristic cochineal-red color which, however, may be brownish at times, occasionally dull lead gray. The streak is scarlet; it is transparent to opaque.

Cinnabar occurs in veins or may be in masses in shales, slates, limestones and similar rocks due to the impregnation by mineral-bearing solutions or as replacements. The former U.S.S.R., former Czechoslovakia, Bohemia, Bavaria, Italy and Spain have furnished excellent specimens. The most important of the world's mercury deposits is at Almaden in Spain. Italy, Peru, Surinam, China and Mexico have commercially valuable occurrences of cinnabar. In the United States this mineral is found in California (most important deposit), Nevada, Utah, Texas and Oregon. Cinnabar is the chief ore of mercury. Its name is supposed to be of Hindu origin.

CINNAMON. See **Laurel Family**; and **Spices**.

CIPOLIN. A metamorphic rock transitional between a marble and mica-schist in which the principal mica is phlogopite.

CIRCADIAN CLOCK. Most living organisms exhibit circadian rhythms in their biochemistry, physiology, and behavior, though familiar kinds of bacteria apparently do not. These rhythms derive from genetically-controlled internal mechanisms that work even in the absence of external time-cues. They have a spontaneous period near 24 hours that stays almost the same at any ambient temperature in the physiological range. The period can be remarkably consistent over many cycles. For example, the ups and downs of human core body temperature during "temporal isolation" (living without any hints of time of day) can be anticipated scores of cycles in advance with accuracy of a few hours, given the individual's period (typically a few tenths of an hour longer than 24 hours).

In the 1970s it was found that the mechanism underlying these "biological clocks" exhibits the key features of a kind of nonlinear dynamics called an "attracting limit-cycle oscillator" (Lakin-Thomas, 1994). For example, they lock onto the period of a stimulus repeated at regular intervals near their spontaneous period. Visible light is particularly effective as such a cueing stimulus. A single flash of light during temporal isolation turns the oscillator on or off or resets its phase and amplitude, depending on the timing and magnitude of the flash. The new, reset phase plotted in three dimensions over stimulus size and the "old" phase at which the stimulus is presented, is periodic on both the phase axes and resembles a "time crystal" with a helicoid in each unit cell. See Fig. 1. For small stimuli the new, reset phase of the clock is little changed: it ranges smoothly upward through one cycle (so it is called "Type 1") as old phase ranges smoothly horizontally through one cycle in the foreground of Figure 1. In the background, at large stimulus size, however, new phase smoothly varies up and down around a fixed level as old phase scans one cycle. This "Type 0" resetting is expected if the underlying mechanism is a limit-cycle oscillator or a population of independent cell-autonomous oscillators of any kind. An unavoidable consequence is that there must be a unique combination of stimulus size and timing after which the clock's new phase is extremely sensitive to details of the experiment (along the axis of the helicoid) and its amplitude of biochemical oscillation is reset near zero. This "phase singularity" was not foreseen under any other vision of the clock mechanism. These features were first confirmed in the fruit fly, *Drosophila*, then in diverse other organisms, including man (Winfree, 1986; Czeisler et al., 1989).

In the 1980s most of what had been learned about diverse animal and plant circadian clocks was found to apply also in humans, in fact remarkably closely. This includes the pattern of phase- and amplitude-resetting in response to a single light exposure. It should accordingly be possible to promptly reset the human body clock to the appropriate new phase after travel across time zones, thus eliminating jetlag. See also **Jet-Lag**. In humans the essential clock tissue is a nerve complex in the brain called the suprachiasmatic nucleus. It receives input from light-sensitive cells in the retina, distinct from the ones that mediate vision. When the

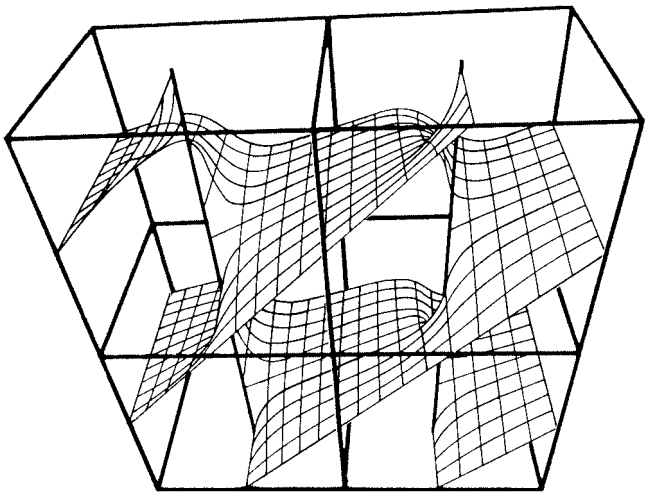

Fig. 1. This three-dimensional graph from Winfree 1986 (p. 79) summarizes thousands of measurements of the clock-controlled time when the fruit fly emerges as an adult at the end of its metamorphosis. That time (measured vertically from the moment of a light flash, and repeating at 24-hours intervals according to the developmental age of the individual at the start of the experiment) depends in a periodic way (again with 24-hour period, horizontally) upon the time when it was exposed to a flash of light of magnitude ranging from 0 in the foreground to two minutes in the background. The key feature is the vertical pole in each unit cell of this "time crystal" around which the times wrap: a phase singularity.

clock's biochemical mechanism is fully understood it may become possible to reset clock phase pharmaceutically by suitable dosage at the right time.

In the 1990s the clock's biochemical mechanisms were explored by the methods of molecular genetics, with spectacular success in a wide variety of organisms. Results appear to confirm that the clock has a cell-autonomous limit-cycle mechanism, functioning in a wide variety of tissues within the individual organism. In all cases the mechanism entails transcription of the genetic message and feedback repression of that process by the translated protein product, much as foreseen by Goodwin (1963). The fruit fly provides a well-studied example. At least seven genes and their products are currently known to be crucially involved. mRNA transcript of the "period" gene, *per*, migrates from nucleus to cytoplasm, where it is translated to the protein PER. Meanwhile the "timeless" gene, *tim*, similarly exports TIM. When their concentrations become high enough these two find each other in the cytoplasm and the dimer migrates back into the nucleus, where it binds to a pair of transcription factors, CLK and CYC, made by the "clock" and "cycle" genes. This composite then attaches to the promoter site for *per* and the one for *tim*, repressing their transcription. Meanwhile in the cytoplasm the DBT protein product of the "doubletime" gene is binding and phosphorylating PER, leading to its degradation. Eventually so little remains that nuclear repression is ineffective, and transcript for PER and TIM is again made and exported from the nucleus. This cycle takes about 24 hours. Blue light hastens it by hastening the degradation of TIM; without TIM, PER is prematurely released to encounter DBT. The photoreceptor is cryptochrome; from the number of photons needed for resetting, it can be inferred that only a small fraction of cryptochrome molecules become excited (well under 1%), and these must be sufficiently abundant to bind a substantial fraction of PER-TIM duplexes. Quantitative modeling, however is not quite yet within reach.

In organisms other than *Drosophila*, even in diverse cell types of one organism, mechanisms differ substantially, though many of them use nearly the same molecules in different roles (Dunlap, 1999; Winfree, 2000). The cyanobacteria ("blue-green algae", eubacteria), of 3 billion year evolutionary antiquity, predating even cells with nuclei and multicellular organisms, use entirely different molecules, but the mechanism still involves feedback repression of genetic transcription, takes a temperature-independent 24 hours, and is reset by light. The presumed selective advantage of circadian clocks at the dawn of evolution remains speculative. Circadian clocks have not been found in the other major phylum of bacteria, the archaebacteria, embracing those that cause infectious diseases. However, taking hints from the known epigenetic mechanisms of circadian clocks, it has proven possible to genetically engineer a biological clock with a period of a few hours as foreseen by Goodwin (1963) in the archaebacterium of the human gut, *E. coli*. See Fig. 2.

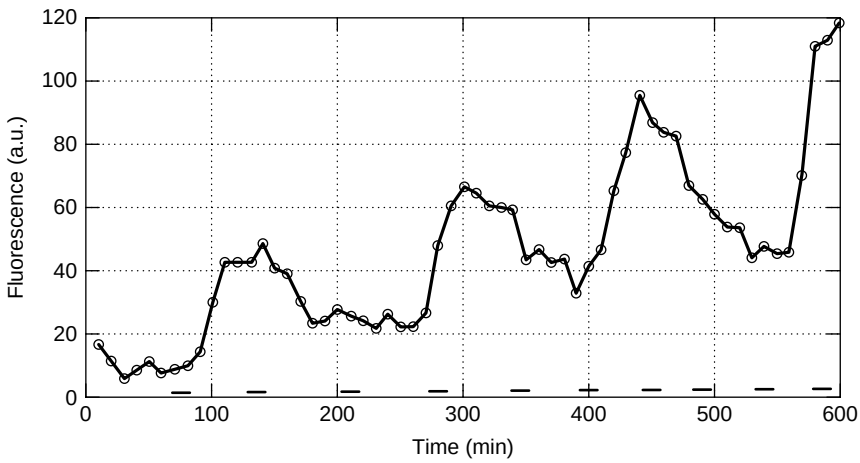

Fig. 2. Elowitz and Leibler constructed such an oscillator in *E. coli*, using its LacI, tetR (tetracycline resistance), and a gene from lambda phage. This three-gene "repressilator" circuit makes the bacterium glow dramatically with green fluorescent protein at 2–3 intervals (Figure a), in the range Goodwin foresaw. On a time scale spanning 600 minutes, cell divisions of *E. coli* bacteria carrying the repressilator circuit are indicated by short bars. Following each, one daughter cell was chosen at random for plotting GFP fluorescence intensity of that single cell (ordinate, in arbitrary units). Nature **403**, 335–338, Figure 2, with permission.

CIRCLE (Geometry). A plane curve such that all of its points are at a fixed distance, its radius, from a fixed point, its center. The line bounding the circle is its circumference. A diameter is a straight line through the center of the circle with its ends on the circumference and of length twice that of a radius of the circle. Further definitions pertaining to a circle are: secant, a straight line of any length intersecting the circumference in two points; tangent, a straight line of any length touching the circle at only one point; arc, any portion of the circumference; chord, a straight line with end points in the circumference; segment, a part of the circle bounded by an arc and its chord; semicircle, a segment equal to half of the circle; sector, a part of the area within the circle bounded by two radii and the intercepted arc; quadrant, a sector equal to one-fourth of the area within the circle. The area within a circle is commonly spoken of as "the area of the circle."

The ratio of the length of the circumference of a circle to its diameter is denoted by the Greek letter π (pi). This symbol is apt, since it recalls the efforts made by the Greeks to find an exact value for the ratio-since their mathematics was essentially geometric, this quest took the form of an effort to "square the circle," that is, to construct, with straight edge and compass, a square and circle of identical areas. After the Greek period, other mathematicians sought to find an exact value, until it was proved impossible by Lindemann in 1882. In the course of the search, values were obtained to hundreds of decimal places, and in recent years the value has been extended to tens of thousands as a computer exercise, but not, however, with a view to finding an exact value.

To five decimal places, $\pi = 3.14159\ldots$. There are a number of series for π, one of the most common being $\pi = 4(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}\ldots)$. See also **Pi**.

A central angle has its vertex at the center of the circle and radii for its sides; an inscribed angle has its vertex on the circumference of the circle and chords for its sides.

Characteristics of a Circle (see Fig. 1).

Arc. A portion of the circumference. $S = r\theta = \frac{1}{2}D\theta$
Area of Circle. $\pi r^2 = \frac{1}{4}\pi D^2$

Area of Sector. $\frac{1}{2}rS = \frac{1}{2}r^2\theta$
Area of Segment. A (sector) $- A$(triangle) $= \frac{1}{2}r^2(\theta - \sin\theta) = r^2 \cos^{-1}(r - H/r) - (r - H)\sqrt{2rH - H^2}$
Chord. $l = 2\sqrt{r^2 - d^2} = 2r\sin(\theta/2) = 2d\tan(\theta/2)$
Circumference. The perimeter of a circle. $C = 2\pi r = \pi D$
Pi. $\pi = 3.14159\ldots$
Secant. A line cutting across a circle at two points.
Tangent. A line touching a circle at a single point.

The space between the perimeters of two circles of different radii is known as *annulus*. Where the two circles are concentric, the shape commonly is referred to as a ring. The *area of the ring* (or space) between two circles of radius r_1 and r_2, where one circle fully encloses the other although the two circles need not be concentric, is $\pi(r_1 + r_2)(r_1 - r_2)$.

According to analytic geometry (see also **Conic Section**), the general equation of a circle in rectangular coordinates is given by

$$x^2 + y^2 + 2Ax + 2By + C = 0$$

provided $D = A^2 + B^2 - C$ is positive and does not vanish. Under these circumstances, the radius of the circle is $\sqrt{D}$ and its center is at $x = -A$, $y = -B$. If $D = 0$, the circle degenerates into a point; if D becomes negative the circle is imaginary.

Since the equation for the circle contains three arbitrary parameters, three conditions must be imposed in order to determine the circle uniquely. If the chosen conditions are: center $x = 0$, $y = 0$ and radius r, the standard equation of the circle becomes $x^2 + y^2 = r^2$. Parametric equations are $x = r\cos\phi$, $y = r\sin\phi$. In polar coordinates, the equation is $r^2 - 2rr_1\cos(\theta - \theta_1) + c_1^2 = a^2$, where the center of the circle is at (r_1, θ), its radius is a, and (r, θ) is any point on the circumference. See also **Evolute**; and **Involute**.

CIRCUIT BREAKER. A specially designed mechanical switching device for making, carrying, and breaking electrical circuits — under normal conditions as well as performing in a special way under abnormal conditions. A circuit breaker, for example, may make and maintain circuit contact for a specified time (usually quite short) under abnormal conditions (short circuit would be an extreme case) and, if the cause of the abnormal condition has not been corrected during the short interval, then break the circuit. A fuse may be considered a form of circuit breaker with the specific purpose of providing protection against overcurrents. Ordinary switches of many designs, of course, make and break circuits routinely, but they are not designed to handle abnormal conditions and to provide special functions under such conditions. A circuit breaker need not incorporate any automatic features to qualify under the definition, but must be designed to make and break circuits under abnormal conditions quickly and without excessive arcing.

Electrical circuit breakers for both residential and industrial use are required to interrupt currents many times their rated values.* For example, the most widely used residential breakers have 15- and 20-ampere ratings. For a 15-ampere-rated breaker to pass the required tests (Underwriters Laboratory), the breaker must sustain a 15 ampere current indefinitely, must open within one hour at 18.75 amperes, must open within two minutes if the current rises to 30 amperes, and must interrupt (without change to itself) a current flowing from a source capable of 10,000 amperes. Because many loads are inductive (motors, fluorescent lights, etc.), breakers must be tested at various power factors (PF). In general, the more inductive the load, the lower the power factor and the greater the difficulty of interrupting the current. When the power factor is unity, the load is pure resistance; when a power factor is zero, the load is pure inductance. With unity PF, the power dissipated is given in watts (W), equal to the product of volts × amperes. With lower power factors, the equipment muse be rated in volt-amperes (VA, not equal to watts), in kilovolt-amperes (kVA), or in million-volt amperes (MVA). Transformers of large capacity are commonly energized by medium-voltage feeders from the power grid, often in the 13,200-volt range and usually expressed as 13.2 kilovolts (kV).

* This description by permission from longer article by V.C. Oxley, GTE Laboratories.

The principal categories of circuit breakers in common use are (1) *low-voltage air circuit breakers*, generally designed for use on D.C. circuits and low-voltage A.C. circuits up to about 600 volts. Air circuit breakers can be used for voltages up to about 3,000 volts for dc breaking in connection with railway circuits; (2) *oil power breakers*; (3) *oilless power breakers*.

The air circuit breaker commonly uses two fixed terminals. A bridging member, operated by a linkage system, maintains these contacts under heavy pressure. Auxiliary arcing contacts are arranged to close before and open after the main contacts. This prevents damage of the main contacts from arcing. The auxiliary arcing contacts are usually easily replaceable. For the main contacts, most modern breakers incorporate spring-mounted, self-aligning contacts (silver) attached to a solid bridging member. The arcing contacts may be a silver-tungsten or copper-tungsten alloy although a carbon alloy was used in earlier designs. The breakers may be hand- or electrically operated, the latter accomplished by means of solenoids or motorized mechanisms. Multiple-pole circuit breakers are widely used, with a pole for each ungrounded line of a circuit. In connection with a compound-wound generator or converter paralleled with other units, an extra pole is needed for the equalizer connection.

The so-called molded-case air circuit breaker largely has become standard in large building and industrial installations. Large units are available that will open a circuit up to 42,000 amperes at 600 volts A.C., or 50,000 amperes at 250 volts D.C. Smaller versions of the molded-case circuit breaker are commonly used for residence protection in place of former fuse boards.

A dead-tank type oil power breaker is comprised of a steel tank partially filled with oil. Porcelain or composition bushings pass through the cover of the device, serving as the circuit connections. Contacts located well below the oil level are bridged by a conducting crosshead, the latter being carried by a lift rod. In many designs, the rod drops by gravity after contact separation by spring action and thus the breaker is opened. To increase the rate of opening over much of the total travel, accelerating springs are commonly used. In some designs, allowance is made to provide two and up to six or more breaks per pole, thus reducing the length of stroke needed for adequate arcing distance. A special tank liner of insulating fibrous composition prevents the arc from striking the walls of the tank. In single-tank breakers, with all poles of a three-pole breaker in one tank, rating up to 69,000 volts and 3,500,000 kilovolt-amperes interrupting ratings are available. For higher voltages, multitank breakers are used, in which each pole is in a separate tank. Where "isolated-phase" construction is needed, the multitank breakers are available in lower ratings.

Special arc-control devices have been developed during the last 40 years to replace plain-break breakers. Numerous schemes have been considered. In all of the commonly used breakers, advantage is taken of the oil pressure that is generated by the gas created by the arc. This pressure is used to force fresh oil through the path of the arc in sufficient quantity to provide the needed insulation at current zero, thus preventing a restrike of the arc with consequent interruption of the circuit. Special interrupting chambers contain these high pressures, thus reducing stress on the main oil tank. After cooling, the gases generated are vented to atmosphere.

Oil used in circuit breakers must have particular characteristics, including a flash point of about 133 °C; a burning point of about 148 °C; a freezing point of about −40 °C, and a dielectric strength of at least 30,000 volts.

Since the early 1940s, the acceptance of oil-less power breakers has increased greatly, to the extent that most indoor installations are of this type as well as a rapidly gaining acceptance for outdoor installations. In fact, for extra-high-voltage needs, only oil-less breakers are obtainable.

In the magnetic-air circuit breaker, the main circuit is interrupted by the action of a strong magnetic field, which forces the arc deep into a specially designed arc chute. The purpose of the chute is to cool and lengthen the arc to the point where the circuit no longer can be maintained by the system voltage, thus effecting interruption. Inasmuch as the zone between the main contacts is free of ionized air by the time interruption is achieved in the arc chute, there is no problem of possible restriking of the arc. See also **Electric Shock**; and **Electrical Ground Fault Circuit Interrupters (GFCI)**.

CIRCUITS, FUNDAMENTAL (Mathematics). Let G be a connected graph containing v vertices and e edges and T a tree of G. The end points of each chord (with respect to T) are connected by a unique *tree path*. A chord together with its corresponding tree path forms a fundamental circuit. The number of fundamental circuits is equal to the number of chords or $e - v + 1$. If G is finite but not *connected* it consists of P maximal connected subgraphs, each of which possesses a tree and its associated fundamental circuits. See also **Graph (Mathematics)**; and **Tree (Mathematics)**.

CIRCULAR CURVES. From a mathematical standpoint, a circular curve is an arc having a constant radius; but it is used in civil engineering as a general heading to cover simple, compound and reversed curves.

A circular arc joining two tangents (straight lines) is called a simple curve (Fig. 1). Large radius simple curves are used in highways to provide a means of gradually changing the direction of the center line of a roadway. Simple curves connected by tangents were formerly used on railroads but they have been superseded by the combination of spiral and simple curves. This practice is also followed in modern highways built for high speeds. In Fig. 1, point *A* is called the point of curvature (P.C.) and point *B* the point of tangency (P.T.). Point *C* is known as the point of intersection (P.I.) of the tangents. In highway practice the length of the curve is generally represented by the length of the circular arc but in railroad practice it is given in terms of chord lengths.

A curve made up of two or more simple curves, each having a common tangent point at their junction and lying on the same side of the tangent, is called a compound curve. Compound curves have an advantage over simple curves since they may be easily adapted to the natural topography of a particular location.

A curve made up of two simple curves, having a common point of tangency at their junction and lying on opposite sides of the common tangent is called a reversed curve (Fig. 2). This type of curve is advantageous for use in connection with railroad crossovers and spur tracks but should never be employed for main lines. Reversed curves are used in highway location when the alignment requires an abrupt reversal in direction.

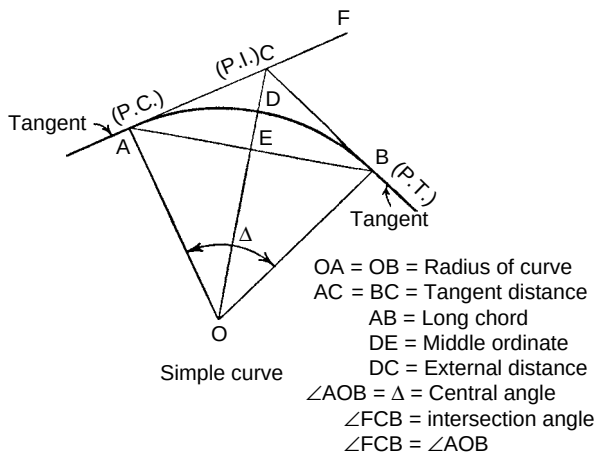

Fig. 1. Simple curve.

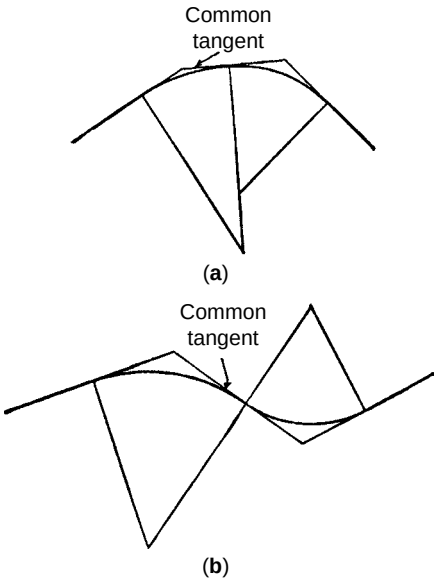

Fig. 2. (**a**) Compound curve; (**b**) reversed curve.

CIRCULAR DISTRIBUTION. A frequency distribution of a variate that ranges from 0 to 2π, so that the frequency may be regarded as distributed around the circumference of a circle. The term is used especially for phenomena that have a period of 2π (by a suitable change of scale if necessary), so that the probability density at any point a is the same as that at any point $a + 2\pi r$ for integral values of r. It is usually expressed in terms of an angle q. The analogue of the normal distribution in this class, the so-called circular normal distribution, given by

$$f(\theta) = \exp[k\cos(\theta - \theta_0)]/2\pi I_0(k), \quad 0 \le \theta \le 2\pi$$

where I_0 is a Bessel function of the first kind of imaginary argument.

CIRCULARLY POLARIZED SOUND WAVE. A transverse wave in an elastic medium in which the displacement vector at any point rotates about the point with constant angular velocity and has a constant magnitude. A circularly polarized wave is equivalent to two super-posed plane polarized waves of sinusoidal form in which the displacements have the same amplitude, lie in perpendicular planes, and are in quadrature.

CIRCULATION THEOREM. 1. V. Bjerknes's circulation theorem: 1) With reference to an absolute coordinate system, the rate of change of the absolute circulation dC_a/dt of a closed individual fluid curve, that is, one that will consist always of the same fluid particles, is equal to the number of pressure–volume solenoids $N_{\alpha,-p}$ embraced by the curve

$$\frac{dC_a}{dt} = N_{\alpha,-p},$$

where the circulation has the same sense as the solenoids, the sense of the rotation from volume ascendent to pressure gradient.

2) With reference to a relative coordinate system (specifically, the rotating earth), the rate of change of circulation relative to the earth dC/dt of an arbitrary closed individual fluid curve is determined by two effects: a) the solenoid effect that tends to change the circulation in the sense of the solenoids by an amount per unit time equal to the number of solenoids embraced by the curve; and b) the inertial effect that tends to decrease the circulation by an amount per unit time proportional to the rate at which the projected area of the curve in the equatorial plane expands:

$$\frac{dC}{dt} = N_{\alpha,-p} - 2\Omega\frac{dA}{dt},$$

where Ω is the angular speed of the earth's rotation and A is the equatorial projection of the curve. This is the most useful form of Bjerknes's circulation theorem. It permits the qualitative examination of many types of frictionless atmospheric motion that are too complicated for complete analytic treatment, for example, the sea breeze.

2. Kelvin's circulation theorem: The rate of change of the circulation dC/dt of a closed individual fluid curve is equal to the circulation integral of the acceleration $N_{\alpha,-p}$ around the curve:

$$\frac{dC}{dt} = \oint \dot{v} \cdot dr,$$

where $d\mathbf{r}$ is a vector line element of the curve.

3. Höiland's circulation theorem: An arbitrary closed tubular fluid filament with constant cross section has a total mass acceleration along itself equal to the resultant of the force of gravitation along the filament:

$$\oint \rho\dot{v}_a \cdot dr = -\oint \rho d\phi_a,$$

where is the fluid density, $\dot{\mathbf{v}}_a$ is the absolute vector acceleration, and $d\psi_a$ is the variation of the gravitational potential from the initial to the terminal point of the vector element $d\mathbf{r}$. This theorem is particularly useful in the study of the stability of fluid flow.

AMS

CIRCULATOR (Microwave). A nonreciprocal circuit element employing the Hall effect or Faraday rotation to produce phase shift which is a function of the direction of energy travel through the device. An application of the Faraday ferrite circulator is a radar duplexer in which the phase shift produced in the circulator can effectively switch the antenna from the transmitter to the receiver. See Fig. 1.

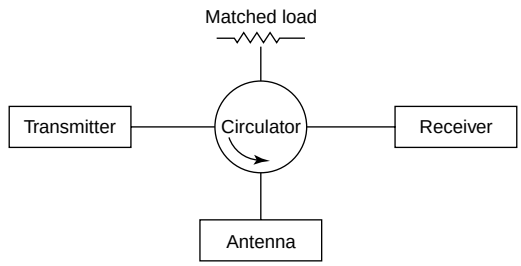

Fig. 1. Ferrite circulator used for switching antenna from transmitter to receiver.

A circulator also may be defined as a waveguide component with several terminals so arranged that energy entering one terminal is transmitted to the next adjacent terminal in a particular direction. The terms *microwave circulator* and *ferrite circulator* also are used.

CIRCULATORY SYSTEM. The system of passages and chambers through which materials are distributed in the body in a liquid mixture (blood or hemolymph). In humans the circulatory system is highly refined and complex. See **Heart and Circulatory System (Physiology)**.

Animals of very simple structure and small size secure adequate distribution by the diffusion of materials from cell to cell and so have no need for a special circulatory system. In more complex bodies, however, the principal centers of interchange, such as the alimentary tract, respiratory organs, and excretory system, are far removed from some of the parts that they serve; here more rapid transportation is necessary.

This need is met in some animals by the extension of centers of interchange. In the flatworms, for example, the alimentary tract branches through the body and no other structure is far from some part of it.

Other forms, as the roundworms, have extensive spaces within the body in which liquid contents are moved to some extent by the movements of the body. This type of circulation extends to animals with a true body cavity or coelom but here it is associated with the development

of a closed tubular circulatory system, a condition that exists in the earthworm.

In this simple state the tubular system consists of a longitudinal vessel above the alimentary tract and others at different levels in the ventral part of the body. Other tubes running around the alimentary tract associate the longitudinal vessels, and muscular walls of certain regions, together with valves in the cavities of the tubes, propel the blood they contain. In the earthworm the contractile vessels are principally the dorsal vessel and a series of five pairs encircling the esophagus and known as hearts. The blood flows forward in the dorsal vessel, down through the hearts, and back in the ventral vessels, reaching the dorsal vessel again after following various routes through the tissues which it serves.

In such systems as this several types of vessels are developed. Those leading from the central pumping organ receive the blood under its highest pressure and have the strongest walls, containing elastic and muscle fibers. These vessels are called arteries. They lead into smaller branches known as arterioles and these in turn into minute vessels with very delicate walls made up chiefly of a single layer of thin cells. In the human body these delicate capillaries are from $\frac{1}{200}$ or $\frac{1}{90}$ of a millimeter in diameter. Some of the blood-fluid passes between the cells of their walls into spaces in the surrounding tissues where interchange with the various cells is possible. In some parts of the body, as in the liver of vertebrates, the ultimate tubular passages are even simpler than the capillaries and are called sinusoids. Their walls are, at least in part, merely the surrounding tissues; whether a special lining exists in some parts is disputed. From such small vessels the blood is collected into veinlets and these converge to form veins which carry it to the heart. The veins have strong walls of complex structure but in vessels of the same caliber the walls are thinner in veins than in arteries.

Some of the fluid from tissue spaces is gathered into a type of vessel resembling a vein but more delicate; it flows into trunk vessels which rejoin the veins. This system of vessels is known as the lymphatic system.

In the vertebrates the fishes present the basic plan of the circulatory system. The heart has two principal chambers, an atrium, which receives the blood and a ventricle, which pumps it out to the body. A single large artery, the ventral aorta, leads forward and branches into a series of afferent branchial arteries, which break up into capillaries in the gills. Efferent branchial arteries lead out of the gills to the dorsal aorta, which runs back to the body. The head is supplied by extensions of the dorsal aorta, the carotid arteries. From the arterial system, branches conduct the blood to the capillaries of all parts of the body. The blood from the alimentary tract is collected into a hepatic portal vein, which breaks up into sinusoids in the liver, and is carried thence to the heart by a hepatic vein. In a like manner some of the blood from the caudal part of the body is conveyed to the kidneys by a renal portal vein before entering the veins which carry it to the heart. From all other regions of the body the blood is collected by veins flowing directly to the heart. See also **Fishes**.

The vertebrate heart is a specialized region of the tubular system whose subdivision into chambers is complicated above the fishes by some degree of longitudinal splitting. In the amphibians the atrium has become two, right and left, in the reptiles the splitting involves the ventricle, and in the birds (Aves) and mammals the division into four chambers is complete. Blood entering the right auricle comes from the body and passes on into the right ventricle to be pumped to the lungs. It returns by the pulmonary veins to the left auricle, enters the left ventricle, and is pumped to the body. In other respects the most striking difference between the circulatory system of the fish and that of man is the elimination of the renal portal system in the higher classes of vertebrates.

The circulatory system of arthropods differs from that of other complex animals in the limited extent of the closed tubes and their association with extensive blood spaces constituting a hemocoele or blood cavity and hence an open system. Insects have a single longitudinal tube lying in the dorsal region of the body. It pumps the blood into the head and is known as the heart or dorsal vessel.

CIRCULATORY SYSTEM (Fishes). See **Fishes**.

CIRCUMCISION. The excision of the foreskin or prepuce that covers the head of the penis in the male. The operation is indicated when the foreskin is too tight, although it is commonly done for hygienic reasons.

CIRCUMHORIZONTAL ARC. An arc parallel to the horizon and found at least 46° below the sun (or moon). It is produced by the refraction of light through the 90° prisms of ice crystals, having entered through the vertical sides and passing out through the horizontal bases. Normally, the crystals are large, oriented, hexagonal plates. The circumhorizontal arc is the low sky counterpart of circumzenithal arc. The circumhorizontal arc is low in the sky when the sun is high (above 58° elevation); the circumzenithal arc is high in the sky when the sun is low (below 32° elevation). The most colorful circumhorizontal arcs occur when the refraction is close to the minimum angle of deviation, and this corresponds to a solar elevation angle of about 68°. In the midlatitudes, the sun only climbs to that elevation for a few hours mid day around the summer solstice.

AMS

CIRCUMZENITHAL ARC. An arc centered on the zenith and found at least 46° above the sun (or moon). It is produced by the refraction of light through the 90° prisms of ice crystals, having entered through the horizontal bases and passed out through the vertical sides. Normally, the crystals are large, oriented, hexagonal plates. The circumzenithal arc is the high sky counterpart of the circumhorizontal arc. The circumhorizontal arc is low in the sky when the sun is high (above 58° elevation); the circumzenithal arc is high in the sky when the sun is low (below 32° elevation). The majority of circumzenithal arcs are short-lived, short in length and faint or moderately bright. However, very colorful circumhorizontal arcs can occur when the refraction is close to the minimum angle of deviation, corresponding to a solar elevation angle of about 22°.

CIRQUE. Topographic feature produced by a mountain glacier. A mountain glacier usually starts in some sheltered ravine, slightly below the top of the mountain. Névé (firn) is the name of the granular ice that gradually develops from the original snow. The névé or accumulation of ice is restricted to that altitude at which the average summer temperature is 32 °F (0 °C). This line (summer isotherm) may vary from sea level, in the Polar regions, to 20,000 (6,000 meters) feet in the tropics. After the accumulation of granular ice on a slope reaches a certain thickness, the mass moves slowly downward under its own weight, by process of plastic flow. In the névé region, where the snow and ice bank rests against the sloping cliff, the ice tends to work away from the rock, forming a crevice called the bergschrund. Frost action in the region of the bergschrund causes the recession of the cliff, the broken material from which is frozen into the base of the ice and serves as tools to scour out circular basins called cirques. Small lakes and ponds that occur in cirques are called tarns. Where several cirques are developed near the summit of a mountain, the side walls of the cirques are called combs; the ridges between the cirques, cols; and the elevated terminations of the comb ridges, monuments. A triangular mountain peak, such as a Matterhorn, results from the complete cirquation of what was originally a relatively smooth-topped mountain.

CIRRIFORM. See **Clouds and Cloud Formation**.

CIRRIPEDIA. Crustaceans, of which the only commonly known representatives are the barnacles. The name applies to a subclass characterized by adaptations for sessile life; the included species are unlike other crustaceans in appearance.

Economically the barnacles are important because they attach themselves to the bottoms of ships and necessitate occasional removal. See also **Barnacle**.

Classification:

Order *Thoracica*. The common barnacles.
Order *Acrothoracica*. Small forms whose females live in cavities in the shells of mollusks.
Order *Apoda*. One simplified form, parasitic in a common barnacle.
Order *Rhizocephala*. Parasitic, usually on crabs and related crustaceans. The adult forms root-like growths in the body of the host and is otherwise degenerate in form.
Order *Ascothoracica*. Parasitic in corals; less degenerate than the preceding.

CIRRUS. 1. In protozoa, a spine-like organ of locomotion formed of aggregated cilia. 2. In annelids (worms), a slender flesh process on the parapodia. 3. In meteorology, see **Clouds and Cloud Formation**.

CIRRUS SPISSATUS. See **Clouds and Cloud Formation**.

CIRRUS UNCINUS. See **Clouds and Cloud Formation**.

CIS-COMPOUND. See **Isomerism**.

CISSOID OF DIOCLES. Draw a circle of radius a through the origin of a rectangular coordinate system with diameter $OCA = 2a$ on the X-axis (Fig. 1). Through O take any chord OR and extend it to meet, at Q, the tangent to the circle at A. On OR choose a point P so that $PQ = OR$. As P rotates about the origin its locus is the cissoid of Diocles. Its equation is $x(x^2 + y^2) = 2ay^2$ or, in polar coordinates, $r = 2a \sin^2\theta \sec\theta$.

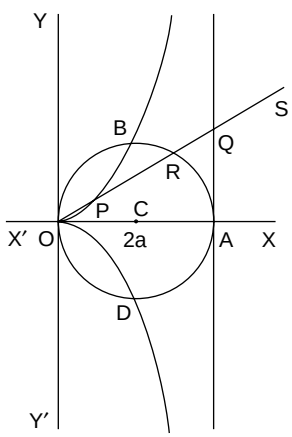

Fig. 1. Cissoid of Diocles.

The two branches of the curve are mirror images of each other with respect to the X-axis. The line $x = 2a$ is an asymptote and there is a cusp of the first kind at the origin. The name of the curve comes from a supposed resemblance to the ivy leaf (Greek, *kissoeidēs*, ivy-like) for that part of the figure bounded by the semicircle *BAD* and the part *DOPB*. Diocles was a Greek mathematician who probably lived in the second century B.C. It is said that he used the curve to solve the classical problem of the duplication of a cube.

The unqualified word cissoid is sometimes taken to mean any higher plane curve constructible by a method similar to that used for this case. Other examples are the strophoid, the folium of Descartes, and the trisectrix.

CISTERN BAROMETER. A mercury barometer in which the lower mercury surface is larger in area than the upper surface. The basic construction of a cistern barometer is as follows: A glass tube 1 meter (3.28 feet) in length, sealed at one end, is filled with mercury, and then inverted. The tube is mounted so that its mouth penetrates the upper surface of a reservoir of mercury called the cistern of the barometer. Cistern barometers are classified according to whether the cistern is fixed in volume or variable in volume.

Adjustable Cistern Barometer. A mercury barometer that is read by first bringing the free mercury surface in the cistern to a fixed level coincident with the zero of the scale.

Fortin Barometer. An adjustable cistern barometer.

Kew Barometer. A type of cistern barometer. No adjustment is made for the variation of the level of the mercury in the cistern as pressure changes occur; rather, a uniformly contracting scale is used to determine the effective height of the mercury column.

CITRIC ACID. [CAS: 77-92-9] $C_3H_4(OH)(COOH)_3$, formula weight 192.12, white crystalline solid, mp 153 °C, decomposes at higher temperatures, sp gr 1.542. Citric acid is soluble in H_2O or alcohol and slightly soluble in ether. The compound is a tribasic acid, forming mono-, di-, and tri- series of salts and esters. Citric acid may be obtained: (1) from some natural products, e.g., the free acid in the juice of citrus and acidic fruits, often in conjunction with malic or tartaric acid; the juice of unripe lemons (approximately 6% citric acid) is a commercial source; (2) by fermentation of glucose (blackstrap molasses is a major source); and (3) by synthesis.

Citric acid and sodium citrate have found use as additives in effervescent beverages and medicinal salts, although excessive quantities are considered toxic. Citric acid can be used as an effective antioxidant. Because the acid is not readily soluble in fats, it is added to formulations that improve solubility, such as propylene glycol and butylated hydroxy anisol, and this can be used as a stabilizer for tallow, fats, and greases. Citric acid also is used for adjusting pH in certain electroplating baths. It finds a number of miscellaneous uses in etching, textile dyeing and printing operations.

Citrates (like tartrates) in solution change silver of ammonio-silver nitrate into metallic silver. Calcium citrate, due to its solubility characteristics, is of importance in the separation and recovery of citric acid. Calcium citrate plus dilute H_2SO_4 yields citric acid plus calcium sulfate, and the latter may be separated by filtration. Citric acid may be obtained by evaporation of the filtrate.

In most living organisms, the citric acid cycle constitutes the final common pathway in the degradation of foodstuffs and cell constituents to carbon dioxide and water. This cycle is described in the entry on **Carbohydrates**.

CITRIC ACID CYCLE. See **Carbohydrates**.

CITRINE. The mineral citrine is a yellow variety of quartz sometimes used as a gem. It is often marketed under the name topaz and may mislead the unwary. Brazil and Madagascar have furnished material of excellent quality. See also **Quartz**.

CITRUS PSYLLA *(Insecta, Homopterau)*. This insect is a serious pest on fruit in India. The adult citrus psylla (*Diaphorina citri*) is about $\frac{1}{8}$ inch (3 millimeters) long and mottled brown. It is covered with a waxy secretion that makes it appear dusty. The nymph is light yellow and about $\frac{1}{16}$ inch (1.5 millimeters) long. These insects suck the sap from citrus leaves, usually new growth. The leaves become covered with honeydew, on which a sooty mold grows. Prolonged feeding results in lowered yields, and if left unchecked, can cause defoliation and kill the tree. The pest is also a carrier of citrus greening disease, a virus disease of citrus.

CITRUS TREES. Citriculture is an important segment of world food production and nutrition. The principal citrus fruits with their percentage of total world production are: (1) orange, 67%; tangerine (more properly called mandarin), 14.3%; lemon and lime, 9%; grapefruit and pummelo, 7.9%; and other citrus fruits, 1.8%. Citrus fruits are of the genus *Citrus*, which is of the family *Rutaceae* (rue family) and of the subfamily *Aurantoideae*. *Rutaceae* is composed of a variety of trees and thorny shrubs. In all, there are 7 subfamilies in Rutaceae, comprised of about 150 genera. The subfamily *Aurantiodeae* has about 28 genera, of which six are classified as true citrus fruit trees; that is, they have a berry fruit (hesperidium) which is characterized by a juicy pulp made of vesicles filling all of the space in the segments of the fruit not occupied by

seeds. The six genera are: *Citrus*, *Clymania*, *Eremocitrus*, *Fortunella*, *Microcitrus*, and *Poncirus*. Of these genera, only three are of commercial importance, namely, *Citrus*, *Fortunella*, and *Poncirus*.

Over the last 250 years, attempts to establish clearcut classifications of the various citrus fruits have met with exceptional difficulties. These difficulties, in turn, are reflected in the nomenclature used, both from a practical and a purely scientific viewpoint. The original efforts of Linnaeus in the mid-1700s were not favored with the knowledge of numerous citrus fruits, particularly those occurring in the Orient and other regions of the world whose flora had not been thoroughly studied at that time. Consequently the work of Linnaeus in the area of citrus fruits was far from complete and not fully accurate. Numerous attempts at classification during the intervening years have taken place, but as research continues right into present times, prior conclusions have been upset. Citrus fruits that have been growing in the Orient for many centuries were found to be much more diverse than initially assumed. Further, citrus fruits are prone to the development of diversity through both natural and artificial cross-breeding, through bud mutations, and the development of chance seedlings.

Exemplary of the status of citrus taxonomy as of an earlier date are persistent doubts concerning certain prior classifications. For example, there is no clear evidence that the grapefruit is a true species. The grapefruit is closely associated with the pummelo, probably originating in the West Indies a few centuries ago. It is not known whether the grapefruit arose purely as a bud sport,* or whether it is a hybrid between pummelo and some other entity. Thus, the practice of identifying grapefruit with a specific Latin name can be questioned. However, since 1930, assignment of grapefruit to *Citrus paradisi* Macf. has been accepted by a majority of botanists and horticulturists.

Similarly, the lemon is probably not a valid species. Research as recently as 1974 points to the lemon being neither a distinct species nor a first-generation hybrid between citron and lime. Researchers have shown that citron is most likely one of the parents of lemon, but that an unidentified genetic source (not in the citron-lime group) may have contributed to the origin of lemon. However, as early as 1766, lemon was assigned to *Citrus limon* (L) Burm. f., an identification that generally has been accepted by citrus scientists. Questions also have been raised concerning the classification of the sweet orange as *Citrus sinensis* Osbeck, a classification dating back to 1757.

6mm Y

As indicated by Tables 1 and 2, Swingle and Reece (1967) proposed 16 species of the *Citrus* genus, a classification that, at least temporarily, has been accepted by a number of citrus scientists. Eight of these species embrace the edible citrus fruits of commerce; the other species are considered inedible. However, a number of other classifications have been proposed during the last decades, including that of Tanaka (1954), who proposed as many as 159 species of *Citrus*, a scholarly classification that can be quite helpful to botanists and horticulturists, but one that is somewhat too complex for practical application by persons concerned mainly with the commercial aspects of citrus production.

Considering the many varieties of citrus fruits, there are remarkable similarities that the designers of citrus processing equipment can use to advantage. In terms of processing, the principal physical variables are size and shape of the whole fruit; internal dimensions, principally thickness of peel or rind, which embodies the epidermis, flavedo, oil glands, albedo and vascular bundles; number of sections; and relative size of core. The principal elements of a typical citrus fruit (shown in cross-section) are identified in Fig. 1. The presence or absence of seeds is also very important to the processor. Because the seeds contain materials that detract from the flavor of extracted juice, extraction machinery must be designed to avoid or at least minimize penetration of the outer skin of the seed that would free undesirable substances to mingle with the juice.

TABLE 1. SPECIES IDENTIFIED IN GENUS CITRUS[1]

Common Name	Species Name	Year Named
Citron	*C. medica* (L.)	1753
Grapefruit	*C. paradisi* Macf.	1930
Lemon	*C. limon* (L.)	1766
Lime (common)	*C. aurantifolia* Christm.	1913
Mandarin (tangerine included)	*C. reticulata* Blanco	1837
Orange:		
Sweet orange (common orange)	*C. sinensis* Osbeck	1757
Sour orange	*C. aurantium* (L.)	1753
Indian wild orange	*C. indica* Tan.	1931
Papeda:		
Papeda	*C. micrantha* Wester	1915
Celebes papeda	*C. celebica* Koord.	1898
Ichang papeda	*C. ichangensis* Swing.	1913
Khasi papeda	*C. latipes* Tan.	1928
Mauritius papeda	*C. hystrix* D.C.	1813
Melanesian papeda	*C. jacrocarpa* Mont	1860
Pummelo	*C. grandis* Osbeck	1765
Tachibana	*C. tachibana* Tan.	1924

[1]Adapted from Single/Reece (1967).

TABLE 2. OTHER NAMES AND GENERA RELATED TO CITRICULTURE

Citrange	Common orange × Trifoliate orange.
Clementine	A variety of mandarin.
Fortunella	A genus of subfamily *Aurantiodeae*. An evergreen, unifoliate with small edible fruits. Kumquat is one of these.
Limequat	A lime-kumquat hybrid.
Ponkan	A variety of mandarin.
Poncirus	A deciduous tree with trifoliate leaves and a genus of subfamily *Aurantiodeae*. Fruit contains an acrid oil and is inedible.
Poncirus trifoliata	Sometimes used as a rootstock for citrus trees.
Rough lemon	A variety of lemon sometimes used as a rootstock for citrus trees.
Satsuma	A variety of mandarin.
Tangelo	Grapefruit (*C. paradisi*) × Sweet orange (*C. sinesis*). or Grapefruit (*C. paradisi*) × Pummelo (*C. grandis*). Commercially, the tangelo is classified separately, or with grapefruit. See entry on **Grapefruit**.
Tangerine	Some varieties of mandarin are sometimes called tangerine in some regions of the world.
Tangor or Temple	Mandarin (*C. reticulata* Blanco) × Sweet orange (*C. sinensis*). Commercially, the temple is usually classified with the orange.

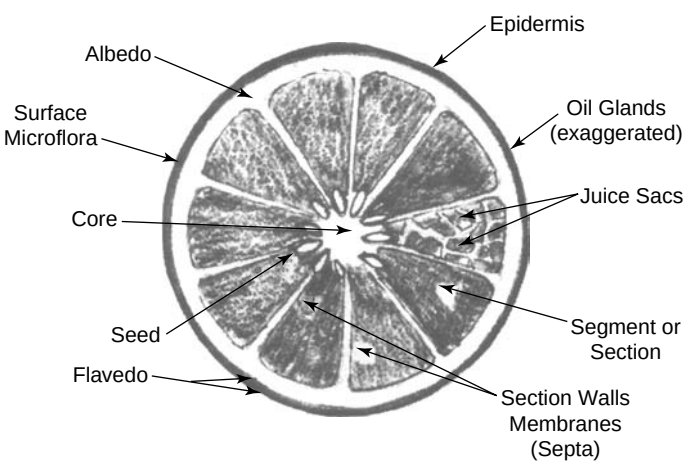

Fig. 1. Schematic diagram of typical cross section of citrus fruit.

Discovered as a constituent of citrus fruits as early as 1841 by Bernay, the knowledge of *limonin* has progressed mainly during the past 30 to

* In botany, a sport is a bud variation; in biology, a form that varies markedly from the norm.

35 years. A whole family of limonin-related compounds, called *limonoids*, have been isolated and described during this period. The structure of limonin proper was not determined until the early 1960s by several investigators using different analytical techniques. Research has shown that of the two dozen and more known limonoids, only about 30% are bitter tasting. Delayed bitterness in citrus juices has traditionally been attributed to the presence of limonin. Citrus scientists differentiate between the bitter aftertaste caused by limonin and the bitterness caused by *naringin* of grapefruit or the *neohesperidin* of the Seville orange. The aforementioned compounds are not universally present in citrus fruits, whereas findings to date indicate that limonin can be found in all citrus fruits.

Citron. A member of the subfamily *Aurantiodeae*, the citron is a lemon-like fruit with a thick peel and containing a relatively small amount of acid pulp. The citron is the most suitable of the various citrus fruits for preparing a candied peel used as a confection. The majority of citrons are grown in Italy, where the main variety is the *Diamante* or *Liscio di Diamante*.

Grapefruit. The grapefruit tree is a subtropical evergreen with dense foliage. The tree may reach a height of from 40 to 50 feet (12 to 15 meters) in its natural state without pruning. The tree is subtropical and sensitive to both high and low temperatures. The head of the tree varies from rounded to somewhat conical. Commercial growers hold the height to 15–25 feet (4.5–7.5 meters). Leaves of the grapefruit tree are larger than those of the sweet orange, but somewhat smaller than the closely related pummelo (*C. grandis*). The leaves are smooth, ovate, and bluntly tipped. The flowers are large, white, and fragrant. They are borne singly or in small clusters in the axils of the leaves. The fruits are borne in grape-like clusters (possibly accounting for the name of the fruit). Generally, the fruit is oblate (globular with flattened top and bottom), although the shape varies from one variety to the next. The skin of the fruit ranges from lemon to an orangish coloration. In some varieties, the basic lemon coloration carries a pink blush coloration. The flesh is described as slightly tan to yellow. The fruit is juicy and the juice color ranges from slightly pink to reddish of different tones, depending upon variety. Fresh juice normally has a slight bitter flavor, arising from its content of the glucoside *naringin*. The bark of the grapefruit tree is smooth and gray-brown in color.

The origin of the grapefruit is not certain and is described by some citrus scientists as remaining a puzzle. Some authorities have postulated that it may have arisen as a hybrid of the pummelo with the sweet orange. The shaddock tree, a pummelo, was observed by explorers in the very late 1600s in the West Indies, notably Jamaica.

Tangelo. This tree probably originated in China and southeastern Asia as early as 4000 years ago. It is postulated that the first tangelos resulted from insect cross-pollination of the mandarin orange and the pummelo. Possibly the first of the tangelos in Florida was the *Nocatee*, which appeared as a natural seedling in a grove located at Nocatee, Florida. Tangelo trees are vigorous growers and usually attain the size of an orange tree. They are more cold resistant then grapefruit. All are evergreen trees with unifoliolate leaves and have fragrant white flowers. Generally, tangelo fruits are about the size of the common orange, but exhibit a tendency to be slightly drawn out at the stem end (or necked). They are usually highly colored, aromatic, richly flavored, sprightly acid, with only a slightly bitter taste.

Tangelos generally are self-sterile. They produce a high percentage of nucellar embryos and thus reproduce nearly true to type by way of seed, which is not true of grapefruit.

Lemon. The lemon (*C. limon*) is probably a native of India. The trees are small and have many stout thorns. The flowers are large and purplish. The trees are considerably less hardy than orange trees. The trees require warmer winters, but less summer heat to ripen their fruit. They can survive in areas where the temperature does not drop below 44 °F (6.7 °C). The fruits are produced continuously throughout the year and are picked green. To allow them to ripen on the tree causes them to become bitter and unmarketable. As soon as they attain the size demanded by the market, they are picked and stored, often for several months. Coloring gradually develops during storage, or may be hastened by placing them in rooms heated above 90 °F (33 °C), whereupon the yellow color will develop within 4 to 5 days.

Orange. The orange (*C. sinensis*) originated in China. Some authorities believe that it was introduced into Arabia about 950 A.D. The orange tree is now widely cultivated almost wherever the climate is suitable. In the United States, there are two major growing regions. Florida produces sweet, thin-skinned juicy oranges, which ripen in early winter. They are picked before fully ripe, and mature in storage. The advent of frozen juice concentrates a number of years ago introduced a welcome element of flexibility in orange production and an effective means for matching size of crop and market demand and introduced some stability in terms of market vacillations and seasonal crop variations. California produces thick-skinned navel oranges which have a pleasing acid pulp, and ripen during the winter and spring months. The source of these navel oranges was a bud variation arising in Brazil, and later carried to California, where it was extensively propagated. Both Florida and California also produce the many-seeded Valencia oranges, which ripen from June through October, producing a crop when other varieties are not bearing. Orange trees can survive winter temperatures in the upper 40 °F (4.5 °C) range. The trees blossom in the spring, but the fruit requires several months to ripen, the time depending upon the climate.

Other Citrus Fruits. Lime plants (*C. aurantifolia*) are very thorny shrubs or small trees, which are not at all hardy, and so are grown mainly in tropical countries. In the United States, they are grown in California and the southern tip of Florida. The white flowers are small, as is the very acid thin-skinned fruit.

Related to the Citrus group is the genus *Fortunella*, with several species. These are the kumquats. They are small evergreen shrubs, often planted for ornament and because of the small yellow fruits, which are either eaten raw or used in preserve making.

The *Poncirus trifoliata*, or the trifoliate orange, has trifoliate leaves, and a hairy useless fruit. However, it is hardy and can be grown outdoors as far north as southern New York. Hence, it can be valuable for hybridizing with more desirable species.

CIVIL DAY. See **Day**.

CLAIRAUT, ALEXIS (1713–1765). Clairaut was a French mathematician who wrote a treatise about the shape of rotating solid bodies that surpassed Newton in his analysis. He is most known for calculating the effect that Saturn and Jupiter would have on the 1759 appearance of Halley's comet. With the aid of improved mathematical methods he was able to predict the comet's return to within a month.

See also **Halley's Comet**.

J. M. I.

CLAIRAUT EQUATION. A differential equation of the type $f(y - xy', y') = 0$. Its solution is $f(y - Cx, C) = 0$. It is known, however, that any equation of this general form is a family of curves and that the envelope of the family can be found in this case from the equation $\partial f/\partial C = 0$. This derivative, together with the solution to Clairaut's equation, permits the elimination of the constant of integration, C to give $y = \phi(s)$, a relation which will satisfy the differential equation. It is a singular solution because it contains no constant of integration. It is not a particular solution in the usual sense since it is not obtainable from the general solution by assigning a special value to the constant of integration. Geometrically, a singular solution is an envelope and that cannot be found from the family of curves by specifying its parameter.

Singular solutions can also occur in differential equations of higher order and in partial differential equations. Their mathematical behavior is relatively complex but they are of little interest in applied mathematics.

A simple special case is usually discussed in elementary texts and there called Clairaut's equation. It is $y = xp + p^2$, where $p = y'$, with solution $y = c_1x + c_2$.

CLAM *(Mollusca, Pelecypoda).* Any member of numerous species of bivalve mollusks; a mussel. Some species are commonly called mussels,

others clams, and in some cases the names are freely interchanged. Thus the edible mussel and other members of the same family receive this name only, the little-neck clam is always a clam, and the fresh-water species are called freely both clams and mussels (Fig. 1).

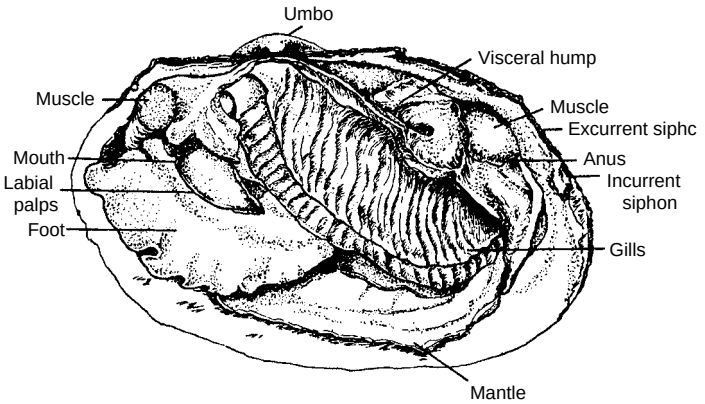

Fig. 1. A freshwater clam with the shell and mantle removed from the left side, showing the position of the body organs within the shell.

The clams are moderately important as food. Occasionally pearls are found in them. Clams of commercial importance are described in the entry on **Mollusks**.

CLAPEYRON-CLAUSIUS EQUATION. This is a widely useful differential equation involving the variables associated with the transition of a pure substance from one state to another; that is, from solid to a liquid, liquid to vapor, or solid to vapor, and vice versa.

In such a system, comprising two phases of the same substance, by adding or withdrawing heat very slowly, it is possible to change one phase reversibly into the other, the system remaining at equilibrium. For such a change, thermodynamic principles indicate that the change in Gibbs free energy is zero.

Now, since by the first law of thermodynamics,

$$dq = dE + p\,dV \tag{1}$$

and since by the definition of Gibbs free energy (G),

$$= E + pV - TS \tag{2}$$

we can differentiate this second equation and substitute dS for dq/T, obtaining

$$dG = V\,dp - S\,dt \tag{3}$$

which may be written for the phases A and B as

$$dG_A = V_A\,dp - S_A\,dT$$

$$dG_B = V_B\,dp - S_B\,dT$$

Since, as stated above, the change in Gibbs free energy is zero,

$$dG_A = dG_B \tag{4}$$

so that

$$V_A\,dp - S_A\,dt = V_B\,dp - S_B\,dt \tag{5}$$

and

$$\frac{dp}{dt} = \frac{S_B - S_A}{V_B - V_A} \tag{6}$$

Since $S_B - S_A$ is the entropy change accompanying the change of phase, we have

$$S_B - S_A = \frac{L}{T} \tag{7}$$

where L is the heat absorbed per mole in the change from A to B. Substitution of (7) in (6) gives the Clapeyron-Calusius equation:

$$\frac{dp}{dT} = \frac{L}{T(V_B - V_A)} \tag{8}$$

A similar derivation leads to another form of the equation:

$$\frac{dS}{dV} = \frac{L}{T(V_B - V_A)} \tag{9}$$

In the case of liquid $\leftrightarrow$ vapor transitions, we may neglect the volume of the liquid and assume the vapor to obey the ideal gas law, $pV = RT$ (both these simplifications do not usually introduce errors greater than 1–2%), and write Equation (8) as

$$\frac{d\log_e p}{dT} = \frac{L_{\text{vap}}}{RT^2}$$

where R is the gas constant.

For a transition taking place at some specified fixed temperature T, the common second member of these equations becomes a known constant, whose value represents the slope of either the T-p or the V-S transition curve, at the point of transition. In other words, it shows the rate at which one variable must change with respect to the other in order to maintain equilibrium between the two states at the given temperature.

For example, we may use Eq. (8) to calculate the change of the boiling point of a liquid with pressure in the vicinity of its normal boiling point.

Take the case of water near 100 °C. The absolute temperature corresponding to 100 °C is $T = 373°$. The heat of vaporization of water at this temperature is $L = 540$ cal./g. $= 2.26 \times 10^{10}$ ergs/g (see also **Mechanical Equivalent of Heat**). The specific volumes of steam and of water at this temperature are respectively $V_B = 1671$ cm^3/g and $V_A = 1$ cm^3/g. Substituting these values in (8) we obtain $dp/dT = 36{,}260$ ergs/deg cm^3 $= 36{,}260$ dynes/cm^2 deg $= 27.2$ mm Hg/deg. The reciprocal of this $dT/dp = 0.368$ deg/mm. Hg, is the quantity required. That is, near normal pressure the boiling point of water rises at the rate of 0.368° per mm of pressure. This result agrees closely with experiment.

Many other applications of the Clapeyron-Clausius equation are encountered in the thermodynamic treatment of changes of state.

CLARAIN. A term proposed by Marie Stopes in 1919 for a finely banded variety of "bright" or shiny bituminous coal. In thin sections, under the microscope clarain is seen to be composed of disintegrated plant substances including bands of spore cases, which impart a yellowish to reddish color to the substance.

CLARIFIERS. Clarification is the final step in wastewater treatment. Once the water has been thoroughly cleansed, clarifiers remove both any remaining pollutants and the chemicals added by the treatment process (such as chlorine), so water can be safely released back into the local environment. The largest user of clarifiers is probably the water-treatment industry.

The conventional one-pass clarifier uses horizontal flow in circular or rectangular vessels (Fig. 1.) with feed at one end and overflow at the other. The feed is preflocculated in an orthokinetic (paddle) flocculator which often forms an integral part of the clarifier. Settled solids are pushed to a discharge trench by paddles or blades on a chain mechanism or suspended from a traveling bridge. See also **Water**. Rectangular settling tanks are also used in liquid–liquid (such as oil-water) separation in the petroleum industry where they are known as the API (American Petroleum Institute) separators.

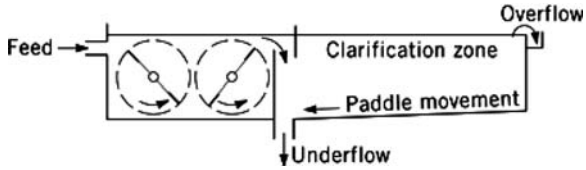

Fig. 1. Schematic diagram of a rectangular basin clarifier having an orthokinetic flocculator where the feed is mixed with a flocculant.

Where circular basin clarifiers are used, these are most commonly fed through a centrally located feed well. The overflow is led into a trough around the periphery of the basin. The bottom gently slopes to the center and the settled solids are pushed down the slope by a number of motor-driven scraper blades that revolve slowly around a vertical center shaft. This design closely resembles a conventional thickener. Like thickeners,

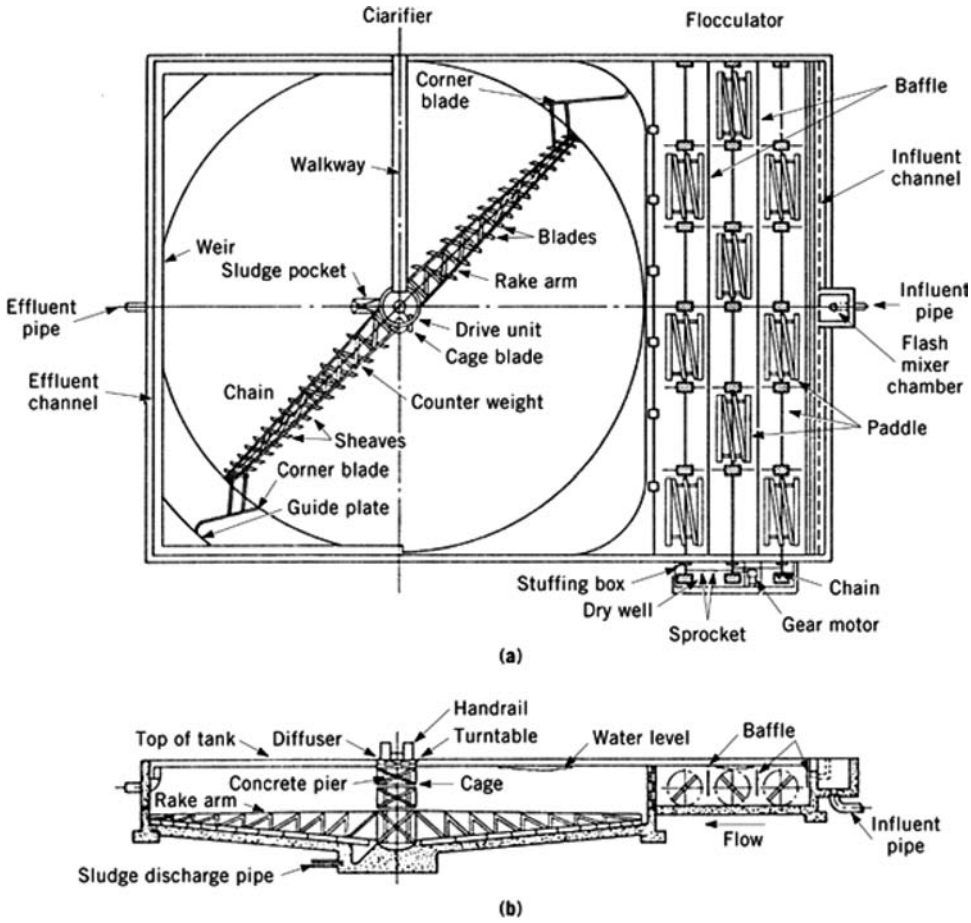

Fig. 2. The Dorrco Flocculator-Squarex clarifier combination (cross-flow arrangement): (a) plan and (b) sectional elevation. (Courtesy of Dorr-Oliver Inc.)

circular clarifiers can be stacked in multitray arrangements to save space. Some juice clarifiers are also arranged in this way.

Circular raking mechanisms are sometimes also used in square basins with horizontal flow across the basin. Such designs have to incorporate supplementary rake arms that reach into the corners of the square vessel (Fig. 2).

The conventional one-pass clarifier is designed for the lowest specific overflow rate (flow per unit area of liquid surface), which is usually 1–3 m/h depending on the degree of flocculation. These clarifiers can be started and stopped without difficulty.

Newer designs incorporate some vertical flow and combine flocculation, gravity and inertial clarification, and solids recirculation. Because such units achieve higher overflow rates, they are referred to as rapid settling or high rate clarifiers. Figure 3 gives an example in this category.

Flocculation is accelerated and higher overflow rates are achieved by external or internal recirculation of settled solids into the feed that leads to the collection of fine particles by interception. Addition of conditioned fine sand to the feed induces separation by differential sedimentation, and sometimes increases overflow rates to 6–8 m/h.

Design and operation of recirculation systems can be complicated. Problems are avoided by using a sludge-blanket clarifier, in which feed enters below a blanket of accumulated and flocculated solids that become fluidized in the zone-settling regime by the upflowing feed. Feed solids are trapped in the blanket. The solids content of the blanket continuously increases and part must be bled off in order to maintain the mass balance.

Sludge-blanket clarifiers are available in flat-, trough-, and hopper-bottom types. The hopper-bottom vertical-flow clarifier shown in Figure 4 achieves rise rates of 1–6 m/h in wastewater applications. It is a 3–4 m deep, 60° triangular or circular hopper tank, with feed introduced through a downward-pointing inlet at the bottom of the tank. The flocculated feed suspension is clarified by passage through the blanket and overflows into decanting troughs that are usually 1–1.5 m above the blanket, to allow for blanket-level variations with feed flow rate. The blanket can be continuously bled off through a submerged weir-type regulator and then thickened in a conical concentrator, or the clarifier can be periodically shut down to allow settlement bleeding.

Sludge-blanket clarifiers are difficult to start up because the first blanket must be established, and large-scale units require extensive excavation. Sizes range from 600×600 millimeters (24×24 inches) to 50×50 meters (164×164 feet). Precipitation and crystallization can be carried out in similar hopper-designed units, having overflow rates of 80 m/h (262 ft/h) or higher.

A combination of gravity settling and slow cyclonic action, first patented in 1983, is available commercially. Known as the hydrodynamic or vortex-induced separator, it is used for excess storm water treatment or for the separation of grits and sands from raw sewage and other liquids. The principle of this separator (Fig. 5) is gravity settling in a circular vessel from a slow vortex flow induced by a tangential feed. The bottom of the vessel is conical and has a large included angle from which the settled solids are swept toward the central underflow discharge. The radially inward flow at the bottom, which is responsible for the sweeping action, is often referred to as the "tea cup" effect. This is caused by rotating eddies that form in cyclonic flows in vessels having wide included angles or flat bottoms.

The vessel design features a Chinese hat-like conical core stopper above the underflow sump, which is there to prevent the vortex from reaching the latter and reentraining the settled solids. The core stopper is also believed to stabilize and locate the vortex flow in the vessel. Overflow from the vessel is through a wide cylindrical insert through the lid, similar to a vortex finder in a hydrocyclone, and an optional provision can be made for collecting any floatables in a float trap.

Units are available in stainless steel or protected mild steel, often prefabricated, up to 12.5 meters (41 feet) in diameter, capable of processing $^{3}5$ m^3/s depending on the separation efficiency required. When the separator is used for classification of granular solids, smaller diameter (£4 m) units are used, separating nearly all particles coarser than ~150 μm.

Another development of the gravity settling principle reported recently is the spiral channel separator. This is an attempt to counter some adverse

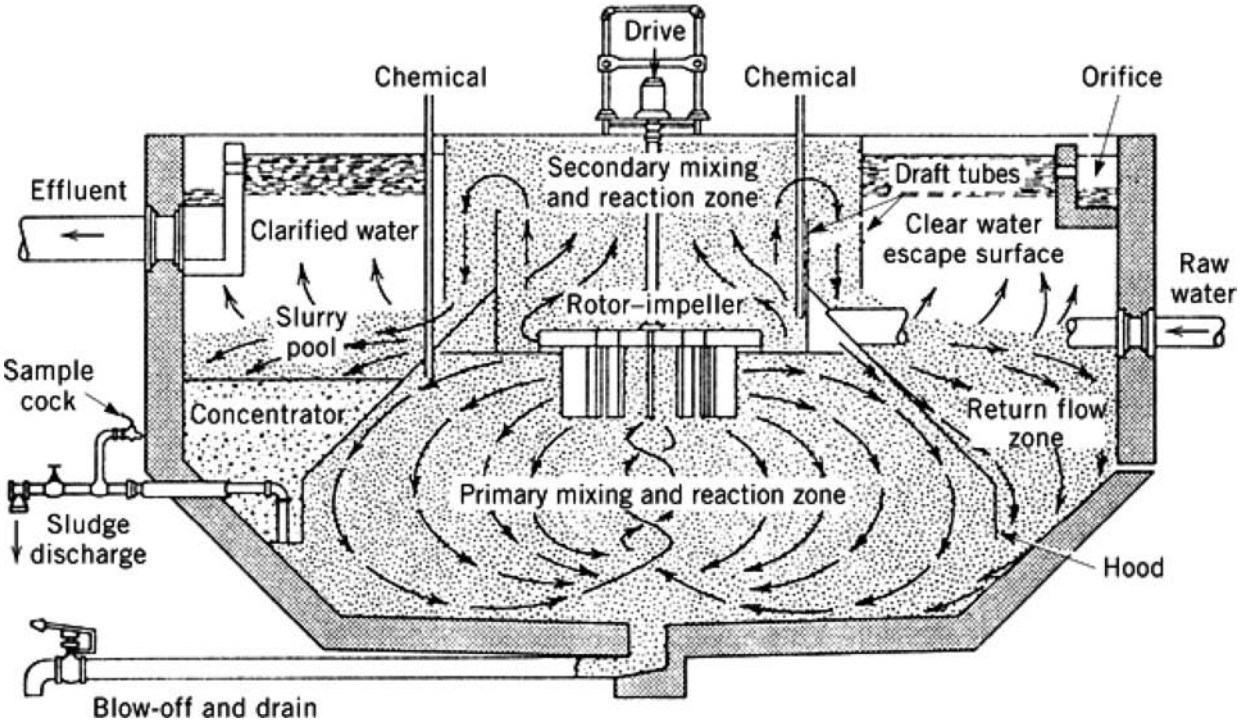

Fig. 3. Functional diagram of an accelerator where the slurry pool is indicated by shaded areas. (Courtesy of Infilco Fuller Co./General American Transportation Corp.)

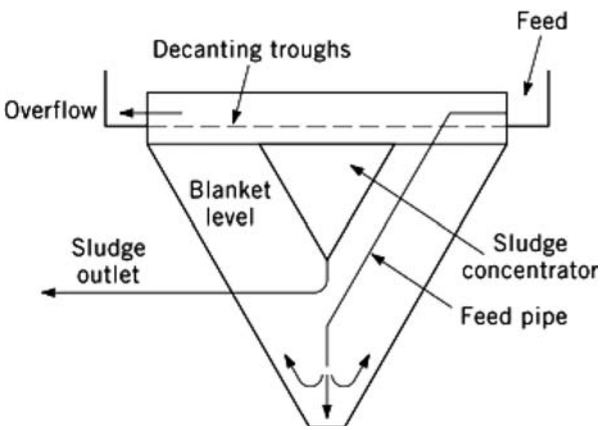

Fig. 4. Hopper-tank sludge-blanket clarifier.

hydraulic conditions encountered in both rectangular and cylindrical settling vessels. The efficiency of these conventional units is often reduced by short circuiting, recirculation, backflows, turbulence, scouring flows, and stagnant zones. These can be reduced by using a rectangular tank with a large length/width ratio (30:1) and wrapping it into a spiral-wound unit with a vertical axis. This might be simply a spiral baffle inserted into an open tank, with the baffle walls rising above the water surface and open at the bottom where the settled sludge provides the seal. This patented and tested idea has not yet found wider acceptance, but it has potential especially for sewage and water treatment works as well as for smaller installations in stand alone or retrofitted units.

Finally, when particulate clarification predominates, the most important design parameter is the pool area. The capacity per unit floor area can be substantially increased (and thus the footprint area of the settler reduced) by using the Swedish invention called the Lamella clarifier/thickener where a number of inclined plates (flat or corrugated) or tubes is stacked vertically, closely together. As the design features of these are essentially the same whether for clarification or thickening duties. The reader is referred to the article on **Thickeners** for a fuller discussion and the schematic diagram of the Lamella principle.

CLARIFYING AGENTS. Chemical substances used in connection with the purification of various solutions and liquors that occur during the processing of raw materials to final end-products. These agents operate in connection with mechanical equipment to bring about the removal of suspended particles that represent product impurities. Allowing such particles to settle by gravity alone would require very long periods. Clarification is part of the total process of sedimentation, which may be defined as the removal of solid particles from a liquid stream by gravitational force. The operation is effected by slowing the velocity of a feed stream in a large-volume tank so that gravitation settling can occur. Sedimentation is divided into two functions: (1) thickening, where the primary purpose is to increase the concentration of suspended solids of the feed stream, i.e., to remove liquids (this is largely a mechanical operation, assisted sometimes by clarifying agents); (2) clarification, where the purpose is to remove fine-sized particles and produce a clear effluent, i.e., to remove solids. Some equipment does both and the dividing line between thickening and clarification is not always sharp. See also **Classifying (Process)**. A clarifying agent to assist in this operation must possess certain properties for acting on the suspended particles — chemical precipitation, attractive via ionic forces, absorption qualities (large surface areas plus weak forces). See also **Sedimentation**.

In the sugar refining industry, for example, various soluble nonsugar compounds are present in sugar juices as the result of rupturing plant cells (either from pressing sugar cane stalks or by extraction of the sliced root of sugar beets). Lime is commonly used to precipitate impurities, followed by

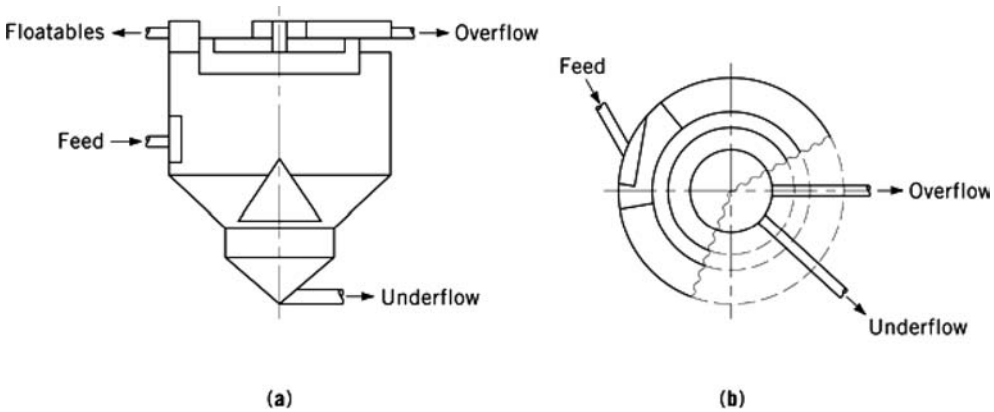

Fig. 5. Schematic diagram of the vortex-induced separator: (a) section and (b) plan. (Courtesy of Hydro Research & Development Ltd.)

carbonation of the solution with carbon dioxide [CAS: 124-38-9] to remove residual lime [CAS: 1305-78-8] as calcium carbonate [CAS: 471-34-1]. Where filtration is used, various filter aids, such as fuller's earth, may be used. See also **Fuller's Earth**. Filtering-type centrifuges also may be used. Phosphates, frequently in the form of orthophosphoric acid [CAS: 7664-38-2], may be used to precipitate the calcium. Some authorities suggest the use of polyphosphates, such as superphosphate and pyrophosphate, along with lime in the clarification operation. Phosphates assist in regulating the pH for optimal precipitation of calcium.

Tannin [CAS: 1401-55-4] is used as a clarifying agent in wine making. See also **Tannin**. Polyvinylpyrrolidone (PVP) [CAS: 25249-54-1] has been used as a clarifying agent in the food industry. Ion exchange processes are also used in various processes, along with or in lieu of conventional clarification. For example, in ion exchange, the demineralization of sugar solutions can be effected; iron can be removed from wine by substitution with hydrogen ions.

Generally, wherever practical and economical, food processors prefer to accomplish clarification without the aid of chemicals — because all or but a trace of these chemicals must be removed so that they do not reappear in the final food product. See also **Clarifiers**; and **Thickeners**.

CLARKE BELT. A belt 22,245 miles (35,800 kilometers) directly above the equator where a satellite orbits the Earth at the same speed the Earth is rotating. Science fiction writer and scientist Arthur C. Clarke wrote about this belt in 1945, hence the name.

CLASSICAL CONDENSATION THEORY. The theory that describes how vapor phase of a substance condenses into liquid and solid phases based on classical bulk thermodynamic principles.

This leads to the conclusion that water vapor will start condensing into liquid water or ice when the environment marginally surpasses saturation (100% relative humidity with respect to plain water or ice surface, respectively). In reality, it is almost always necessary to have foreign particles serving as condensation nuclei or ice nuclei for the condensation to occur even when the environment is somewhat supersaturated.

AMS

CLASSIFYING (Process). An operation or series of operations designed to separate a mixture of substances of various sizes and specific gravities into two or more categories, the cuts or divisions being made both with reference to size and to specific gravity (density). These operations find wide application in mining, metallurgical, water and sewage treatment, as well as use in other fields, such as the chemical industry.

Flotation. This is a means of separating a relatively small particle from a liquid medium. The particle may have a specific gravity greater than, less than, or the same as the liquid from which it is floated. There are two fundamental requirements: (1) a gas bubble and particle must come in contract with each other; and (2) the particle should have an *affinity* for attaching itself to the bubble.

To achieve the first objective, various methods of bubble production and particle agitation have been used. Since the invention of flotation by Haynes in 1860, two basic methods have emerged:

a. *Dissolved gas-impeller agitation*, wherein gas under pressure is sparged into the bottom of a vessel in which an impeller mixes the rising bubbles with the agitated particles.
b. *Self-induced gas-impeller agitation*, wherein the impeller is so positioned in the liquid that it inspirates ambient gas into the liquid as bubbles. These bubbles are brought into contact with the agitated particle at the impeller's most dynamic zone. This method (see Fig. 1) has become the most accepted method.

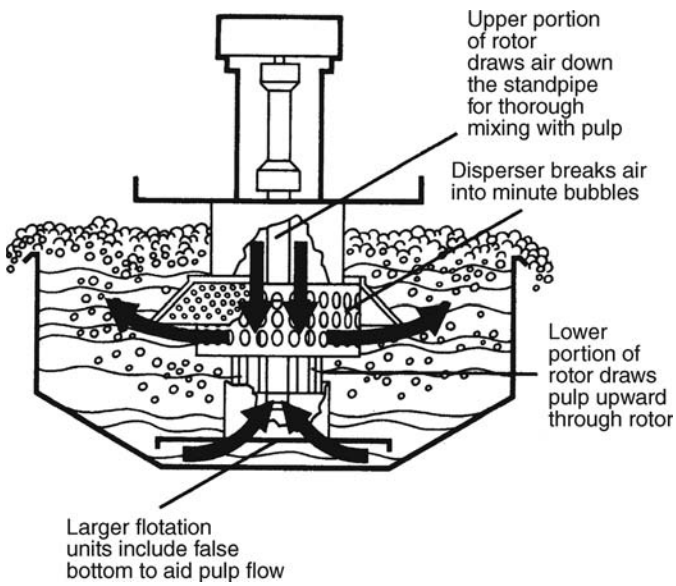

Fig. 1. Flotation cell. Upper portion of rotor draws air down the standpipe for thorough mixing with pulp. Lower portion of rotor draws pulp upward through rotor. Disperser breaks air into minute bubbles. Larger flotation units include false bottom to aid pulp flow.

The second requirement has been served by the development of a number of chemical reagents, which fall into five basic categories: (1) collection; (2) conditioning; (3) levitation; (4) frothing; and (5) depressant. See also **Flotation**.

Frothers are chemicals whose molecules contain both a polar and a nonpolar group. The purpose of a froth is to carry mineral-laden bubbles for a period of time until the froth can be removed from the flotation machine for recovery of its mineral content. Typical frothing chemicals are alcohols, cresylic acids, eucalyptus oils, camphor oils, and pine oils, all of which are slightly soluble in water. Soluble frothers in common use include alkyl ethers and phenyl ethers of propylene and polypropylene glycols.

Collectors are chemical reagents that selectively coat the particles to be floated with a water-repellant surface that will adhere to air bubbles. Collectors generally are classified as cationic, anionic, or nonionic. Examples of collectors include the xanthates, dithiophosphates, thiocarbonilides, and thionocarbonates, all of which are anionic collectors

for sulfides, a major need in ore processing. Fatty acids and soaps are anionic collectors and serve for nonsulfides. Amine salts are cationic collectors for nonsulfides.

Depressants are mainly inorganic salts, which compete with the collector for position on the sulfide surface. This permits the separation of one sulfide mineral from another. In one case, for example, in an alkaline solution, the addition of sodium cyanide prevents flotation of sphalerite and pyrite by xanthates, but not of galena, thus producing a higher grade of galena concentrates. The cyanide solution does not permanently affect the floatability of sphalerite as it can be floated by adding cupric sulfate and xanthate.

Activators are chemical reagents, which alter the surface of a sulfide so that it can absorb a collector and float. Cupric sulfate [CAS: 7758-98-7] is the most widely used activator. For example, xanthate as a collector will not readily float sphalerite, but the addition of cupric sulfate to the pulp changes the surface of the sphalerite particles to copper sulfide. Xanthates [CAS: 151-01-9] then will readily float the activated sphalerite [CAS: 1314-98-3] as it behaves similarly to copper sulfide [CAS: 1317-40-4].

Although flotation was developed as a separation process for mineral processing and applies to the sulfides of copper, lead [CAS: 1314-87-0], zinc [CAS: 1314-98-3], iron [CAS: 1317-96-0], molybdenum [CAS: 1317-33-5], cobalt [CAS: 1317-42-6], nickel [CAS: 12137-12-1], and arsenic [CAS: 1303-33-9] and to nonsulfides, such as phosphates, sodium chloride [CAS: 7647-14-5], potassium chloride [CAS: 7447-40-7], iron oxides [CAS: 1345-25-1], limestone [CAS: 1317-65-3], feldspar, fluorite [CAS: 7789-75-5], chromite, tungstates, silica [CAS: 7631-86-9], coal, and rhodochrosite, flotation also applies to nonmineral separations. Flotation is used in the water disposal field, particularly in connection with petroleum waste water cleanup.

Dense-media Separation. This operation is useful for the separation of solid particles of different densities. A liquid suspension of finely divided high-gravity solids is prepared. Ores of different densities, when exposed to such a suspension will tend to separate by rising or settling in the liquid suspension. Numerous types of solids have been used to obtain a high-gravity medium, but the magnetic solids (ferro-silicon and magnetite) are most frequently used. These solids, alone or in combination, can provide a suitable dense medium over a gravity range of 1.25 to 3.40. Dense-media separation is applicable to any ore in which the valuable component has an appreciable gravity difference from the gangue components. In coarse-ore heavy-media separation plants, the limiting bottom size of dense-medium feed is 10 mesh and the upper size limit is 12 inches (0.3 meter). The magnetic particles of the dense medium subsequently are removed by a magnetic separator.

Jigging. In this operation, a pulsating stream of liquid flows through a bed of materials of different specific gravities, causing the heavy material to work down to the bottom of the bed and the lighter material to rise to the top. This is a very old operation used for concentrating heavy mineral from the lighter gangue. Construction costs are low, but power and water consumption are high. The process is used for the concentration of coal.

Tabling. In this concentration process, a separation between two or more minerals is effected by flowing a pulp across a riffled plane surface inclined slightly from the horizontal, differentially shaken in the direction of the long axis, and washed with an even flow of water at right angles to the direction of motion. A separation between two or more minerals depends mainly on the difference in specific gravity between the effective gravity (sp gr of mineral minus sp gr of water) of the valuable and the waste material. Tables treat metallic ores effectively in size ranges from 6 to 150 mesh, but can be used to treat lighter materials, such as coal of a considerably larger size. Dry tables also are used. The shaking motion is similar except that the direction of motion is inclined upward from the horizontal and, instead of water acting as the medium of distribution, a blast of air is driven through a perforated deck. Tables also are used for selective flocculation or agglomeration of grains of one mineral in an aggregate by the addition of an agglomerating agent.

Sedimentation. This is a general term for an operation wherein suspended solids are removed from a liquid by gravitational settling. The two major forms of sedimentation equipment are (1) thickeners, and (2) clarifiers. The term *decanting* also is sometimes used to designate sedimentation. See also **Sedimentation**.

Thickeners. The primary objective of thickening is to increase the concentration of the feedstream. The mechanical continuous thickener, equipped with sludge-raking arms, is the most common type. Usually the operation is performed in cylindrical tanks. The sludge collection system and the removal system are designed to move the settled material continuously across the tank floor to a discharge point. Feed enters through a central feed well designed to distribute around the periphery. Thickened sludge, raked toward the center by a slowing revolving mechanism, enters a central collecting trough or cone and is discharged through a spigot or removed by a sludge pump. See Figs. 2 and 3.

See also **Thickeners**.

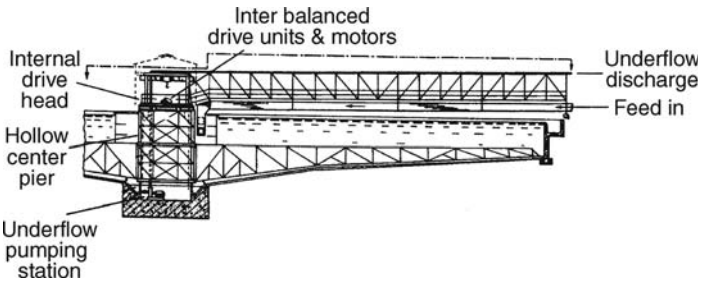

Fig. 2. Caisson-type thickener.

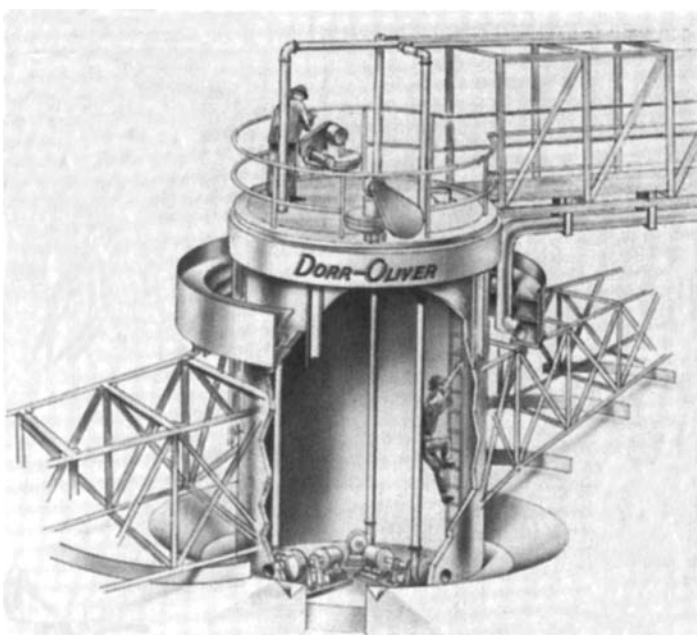

Fig. 3. Center-pier type thickener, showing pumps and access.

Clarifiers. The primary objective of clarifying is to free solids from a relatively dilute stream. These units operate on the basis of gravity sedimentation and utilize a raking mechanism, as in a thickener, Frequently, clarifiers are operated in conjunction with flocculation equipment, which employs chemical coagulants, such as alum, iron salts, lime, polyelectrolytes, activated silica sol, and other chemical reagents. Clarification essentially expedites the natural gravity settling process. An activated sludge final clarifier is shown in Fig. 4.

See also **Clarifying Agents**.

CLASTIC ROCK. A sedimentary rock that is entirely or chiefly composed of fragmental material. Sandstones and conglomerates are typical clastic rocks.

CLATHRATE. See **Compound (Chemical)**.

CLAUDE PROCESS. See **Ammonia**.

CLAUSIUS EQUATION. The Clausius equation(s) are partial differential equations (see also **Partial Differential Equation**) that give the general

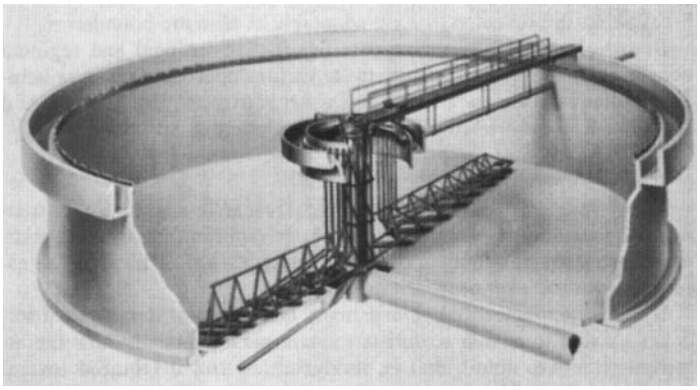

Fig. 4. Activated sludge final clarifier.

relations that exist between the thermal coefficients. For the variables T, p, and ξ (extent of reaction) they are

$$\left(\frac{\partial C_{p,\xi}}{\partial p}\right)_{T,\xi} = \left[\frac{\partial (h_{T,\xi} + V)}{\partial T}\right]_{p,\xi} \tag{1}$$

$$\left[\frac{\partial h_{h,p}}{\partial T}\right]_{T,\xi} = \left(\frac{\partial C_{p,\xi}}{\partial_\xi}\right)_{T,p} \tag{2}$$

$$\left(\frac{\partial h_{T,p}}{\partial p}\right)_{T,\xi} = \left[\frac{\partial (h_{T,\xi} + V)}{\partial \xi}\right]_{T,p} \tag{3}$$

The second equation is especially important; it relates the temperature coefficient of the heat of reaction to the heat capacities of the components that take part in the reaction. It may also be written

$$\frac{\partial}{\partial T} h_{T,p} = \sum_i v_i c_{p,i} \tag{4}$$

where $c_{p,i}$ is the partial molar specific heat at constant pressure of component i (see also **Molar Concentration**) and v_i the stoichiometric coefficient of i in the reaction.

Equations (2) and (4) are also called the *Kirchhoff equations*.

CLAUSIUS EQUATION OF STATE. A form of the equation of state, relating the pressure, volume, and temperature of a gas, and the gas constant. The Clausius equation applies a correction to the Van der Waals equation to correct the pressure-correction term a for its variation with temperature. The Clausius equation takes the form

$$\left[P + \frac{a}{T(V+c)^2}\right](V - b) = RT$$

in which P is the pressure of the gas, T is the absolute temperature, V is the volume, R is the gas constant, b is a constant, a is a temperature-dependent constant, and c is a function of a and b.

CLAUSIUS LAW. The specific heat of an ideal gas at constant volume is independent of the temperature.

CLAUSIUS, RUDOLF (1822–1888). A German mathematical physicist, Clausius reconciled the French scientist Sadi Carnot's work by insisting that in nature, heat always flows spontaneously only in one direction; from hot to cold. Its path is not reversible. Moreover, as time passes, some fraction of energy in a system is always dissipated, and is not available to work. These axioms constitute the second law of thermodynamics.

Clausius also developed kinetic-molecular theory of gases and formulated a theory of electrolysis.

See also **Kinetic Theory**; and **Thermodynamics**.

J. M. I.

CLAUSTROPHOBIA. Fear of being in a confined space.

CLAVICLE. The collar bone of humans. The ventral anterior bone of the pectoral girdle of vertebrates.

CLAWFOOT. Pes Cavus. In this disorder, the longitudinal arch of the foot is abnormally high. The name stems from the rather claw-like contraction made up of the joints between the toes and the bones behind these joints. As part of this disorder, the tendon above the heel (Achilles tendon) is shortened. Unfortunately, this results in additional weight being shifted to the forward part of the foot. Much of the discomfort of clawfoot can be relieved by wearing specially designed footwear.

CLAY ATMOMETER. An atmometer consisting of a porous porcelain container connected to a calibrated reservoir filled with distilled water. Evaporation is determined by the depletion of water in the reservoir.

See also **Atmometer**; and **Precipitation and Hydrometeors**.

CLAYDEN EFFECT. When a photographic emulsion is given a very brief exposure to light of high intensity, it is desensitized toward a subsequent longer exposure to light of moderate intensity. That is, the second exposure produces a fainter image than if the preexposure had not been given. This phenomenon was observed originally by Clayden when photographing lightning flashes, but it can be produced equally well by any type of light source, provided the intensity is sufficiently high and the duration short enough.

CLAYS. The terms *clay* or *clays* commonly refer to either rocks that are consolidated or unconsolidated sediments, or a group of minerals having unique properties. Traditionally, clays (rocks) are distinctive in at least two properties that render them technologically useful: plasticity and composition. Clays are predominantly composed of hydrous phyllosilicates, referred to as clay minerals. These are hydrous silicates of Al, Mg, K, and Fe, and other less abundant elements. Clay minerals are extremely fine crystals or particles, often colloidal in size and usually plate-like in shape. The nonclay mineral portion of clays (rocks) may consist of other minerals, portions of rocks, and organic compounds.

The very fine particles yield very large specific surface areas that are physically sorptive and chemically surface reactive. Many clay mineral crystals carry an excess negative electric charge owing to internal substitution by lower valent cations, and thereby increase internal reactivity in chemical combination and ion exchange. Clays, which may have served as substrates selectively absorbing and catalyzing amino acids in the origin of life, apparently catalyze petroleum formation in rocks. See also **Petroleum**.

A clay deposit usually contains nonclay-like minerals as impurities and these impurities may actually be essential in determining the unique and specially desired properties of the clay. Both crystalline and amorphous minerals and compounds may be present in a clay deposit.

A broad definition of clays includes the following properties: *(1)* Crystalline hydrated silicates of aluminum, iron, and magnesium comprise the majority of clay minerals; however, amorphous hydrated aluminum compounds are also included. Distinctions among clay minerals are made by chemical and structural parameters. The chemical variations range from kaolinite, which is relatively uniform in chemical composition, to smectite minerals, which vary widely in chemical composition, base exchange properties, and expanding crystal lattice. Clay minerals are excellent examples of mixed layering, both random and regular, in layer-structure silicates. These mixed-layer clays are among the most ubiquitous of the various clay minerals. The structural differences among clay minerals are related to the arrangement of tetrahedral (T) and octahedral (O) layers, and the manner in which electrostatic charge imbalances, created by chemical substitution, are neutralized. *(2)* The possible content of hydrated alumina and iron. *(3)* The extreme fineness of individual clay particles, which may be of colloidal size in at least one dimension. *(4)* The property of thixotropy in various degrees of complexity. *(5)* The possible content of quartz, SiO_2, sand and silt, feldspars, mica, chlorite, opal, volcanic dust, fossil fragments, high density so-called heavy minerals, sulfates, sulfides, carbonate minerals, zeolites, and many other rock and mineral particles ranging upward in size from colloids to pebbles.

Geology and Occurrence

Clays may originate through several processes: *(1)* hydrolysis and hydration of a silicate, i.e., alkali silicate + water → hydrated aluminosilicate

clay + alkali hydroxide; *(2)* solution of a limestone or other soluble rock containing relatively insoluble clay impurities that are left behind; *(3)* slaking and weathering of shales (clay-rich sedimentary rocks); *(4)* replacement of a preexisting host rock by invading guest clay where the constituents are carried in part or wholly by solution; *(5)* deposition of clay in cavities or veins from solution; *(6)* bacterial and other organic activity, including the extraction of metal cations as nutrients by plants; *(7)* action of acid clays, humus, and inorganic acids on primary silicates; *(8)* alteration of parent material or diagenetic processes following sedimentation in marine and freshwater environments; and *(9)* resilication of high alumina minerals.

Clays or shales that may be utilized in the manufacture of bricks, tiles, and other heavy clay products exist in every state in the United States.

Bentonite, widely distributed geographically and geologically, also varies widely in properties.

Each continent has clays of almost every type; however, certain deposits are outstanding.

The commercial value of a clay deposit depends on market trends, competitive materials, transportation facilities, new machinery and processes, and labor and fuel costs. Naturally exposed outcrops, geological area and structure maps, aerial photographs, hand and power auger drills, core drills, earth resistivity, and shallow seismic methods are used in exploration for clays. Clays are mined primarily by open-pit operation, including hydraulic extraction; however, underground mining is also practiced.

Mineralogy

The development of apparatus and techniques, such as x-ray diffraction, contributed greatly to research on clay minerals. Crystalline clay minerals are identified and classified primarily on the basis of crystal structure and the amount and locations of charge (deficit or excess) with respect to the basic lattice. Amorphous (to x-ray) clay minerals are poorly organized analogues of crystalline counterparts.

The structural variations among the clay minerals can be understood by considering various physical combinations of tetrahedral and octahedral sheets and the electrostatic effect chemical substitution has on the structural units. The tetrahedral sheets are composed primarily of Si^{4+} and oxygen, but minor amounts of Al^{3+} or Fe^{3+} may substitute for Si^{4+}. The substitution of M^{3+} for Si^{4+} leaves the tetrahedral sheet negatively charged. The cations of the octahedral sheet are composed primarily of Al^{3+}, Fe^{3+}, Mg^{2+}, and Fe^{2+}, but all other transition elements, except Sc, may be included. The anions of the octahedral sheet are O^{2-}, OH^{-}, and F^{-}. The smallest unit of the octahedral sheet contains three octahedral having an ideal net charge of negative six, i.e., three O^{2-}. If the negative charge is balanced by two trivalent cations, the layer is referred to as a dioctahedral layer; if balanced by three bivalent cations, the layer is referred to as a trioctahedral layer. Substitution of bivalent cations for trivalent cations, univalent cations (Li^{+}) for bivalent cations or unfilled octahedral sites, leaves the octahedral layer a net negative charge. The tetrahedral apical oxygen is shared with the octahedral layer to join the two types of layers.

The least complicated clay minerals are the 1:1 clay minerals composed of one tetrahedral (T) layer and one octahedral (O) layer.

Clay minerals that are composed of two tetrahedral layers and one octahedral layer are referred to as 2:1 clay minerals or TOT minerals.

The multitude of variation in clay minerals is caused by substitution in the octahedral and tetrahedral layers, resulting in charge deficits. The manner in which the charge deficit is balanced leads to many of the useful and unique properties of clay minerals.

Crystalline and Paracrystalline Groups

Kaolins. The kaolin minerals include kaolinite, dickite, and nacrite which all have composition $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$; halloysite (7 Å), $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$; and halloysite (10 Å), $Al_2O_3 \cdot 2SiO_2 \cdot 4H_2O$. The structural formulas for kaolinite and halloysite (10 Å), are $Al_4Si_4O_{10}(OH)_8$ and $Al_4Si_4O_{10}(OH)_8 \cdot 4H_2O$, respectively. The so-called fire clay mineral is a *b*-axis disordered kaolinite; halloysite (7 Å) and halloysite (10 Å) are disordered along both the *a*- and *b*-axes. Indeed, most variations in the kaolin group originate as structural polymorphs, related to variations in layer stacks.

Halloysite, a mineral in the kaolin family, has a chemical composition similar to, but physical properties that differ greatly from, kaolinite. Halloysite differs from kaolinite in tetrahedral Al content, layer stacking sequence, and configuration of the six-fold rings. Four basic morphologies of halloysite are recognized: tubular (long and short), spheroidal, platy, and prismatic.

Kaolin most commonly originates by the alteration of feldspar or other aluminum silicates via an intermediate solution phase, usually by surface weathering or by rising warm (hydrothermal) waters.

Large deposits of relatively pure kaolinite have developed from parent, feldspar-rich pegmatites, whereas others are secondarily deposited in sedimentary beds after transportation.

The textures of kaolin (rock) include varieties similar to examples observed in igneous and metamorphic as well as sedimentary rocks. Kaolin grains and crystals may be straight or curved, sheaves, flakes, face-to-face or edge-to-edge floccules, interlocking crystals, tubes, scrolls, fibers, or spheres.

Serpentines. Substituting 3 Mg^{2+} for the 2 Al^{3+} in the kaolin structure results in the serpentine minerals, $Mg_3Si_2O_5(OH)_4$. In serpentines all three possible octahedral cation sites are filled. Most serpentine minerals are tubular to fibrous in structure presumably because of misfit between Mg octahedral and tetrahedral layers.

Talc and Pyrophyllite. Talc and pyrophyllite are 2:1 layer clay minerals having no substitution in either the tetrahedral or octahedral layer. These are electrostatically neutral particles ($x = 0$) and may be considered ideal 2:1 layer hydrous phyllosilicates. Talc and pyrophyllite are found in metamorphic rocks that are rich in Mg and A1, respectively.

Smectites (Montmorillonites). Smectites are the 2:1 clay minerals that carry a lattice charge and characteristically expand when solvated with water and alcohols, notably ethylene glycol and glycerol.

Smectites are structurally similar to pyrophyllite or talc, but differ by substitutions mainly in the octahedral layers.

The minerals of the smectite group have been formed by surface weathering, low temperature hydrothermal processes, alteration of volcanic dust in stratified beds, action of circulating water of uncertain source among fractures and in veins, and laboratory synthesis.

Illite. Illite is a general term for the clay mineral constituents of argillaceous sediments that strongly resemble mica minerals. Other names that have been used for illite include bravaisite, degraded mica, hydromica, hydromuscovite, hydrous illite, hydrous mica, K-mica, micaceous clay, and sericite. Illite and the mica minerals have a 2:1 sheet structure similar to the smectite minerals except that the maximum charge deficit in mica is typically in the tetrahedral layers and contains potassium held tenaciously in the interlayer space, which contributes to a 1.0-nm basal spacing.

Illite was defined as the most abundant clay mineral in Paleozoic shale and is widespread in many other sedimentary rocks; it is common in soils, slates, certain alteration products of igneous rocks, and recent sediments. Its origin has been attributed to alteration of silicate minerals by weathering and hydrothermal solutions, reconstitution, wetting and drying of soil clays, and diagenesis involving other three-layer minerals and potassium during geologic time and pressure under deep burial. Illitization of smectite via illite–smectite mixed-layer intermediates is a very common and an important reaction in the formation of shales during burial diagenesis.

Glauconite. Glauconite is a green, dioctahedral, micaceous clay rich in ferric iron and potassium. Glauconite has many characteristics common to illite, but much glauconite contains random mixed expanding layers, and can be referred to as interstratified glauconite–smectite minerals. In addition, glauconite found in Late Cenozoic rocks tends to have less crystallographic order than older glauconite; therefore, the modifiers ordered (well crystalline) and disordered (poorly crystalline) are commonly used.

Glauconite occurs abundantly in sand-size or bigger pellets, or in pellets within fossils, notably foraminifera, giving it an organic connotation.

Celadonite is an iron-rich dioctahedral micaceous mineral that is similar to glauconite and like glauconite, has well crystalline, poorly crystalline, and interstratified varieties.

Chlorite and Vermiculite. Chlorite is a 1.4-nm (14 Å) clay mineral that cannot be expanded or collapsed by traditional laboratory procedures. Structurally, the unit layer of chloride is composed of a 2:1 layer combined with a 0.4-nm Mg or Al interlayer or hydroxide sheet.

Palygorskite and Sepiolite. Palygorskite (attapulgite) and sepiolite are clay minerals in which the 2:1 layers are linked together in chain-like or a combination of chain-sheet structures.

Palygorskite and sepiolite are different from other clay minerals in the manner in which the 2:1 layers are joined. Rather than being joined in a continuous manner, the tetrahedral sheets are joined to an adjacent inverted tetrahedral layer, making the octahedral layers noncontinuous and leaving an open channel in the mineral structure.

These clays have distinctive uses and properties not shown by platy clay minerals.

Mixed-Layer Minerals. In addition to polymorphism resulting from the disordering and proxying of one element for another, clay minerals exhibit ordered and random intercalation sandwiches with one another.

Mixed-layer clays, particularly illite–smectite, are very common minerals and illustrate the transitional nature of the 2:1 layered silicates. The transition from smectite to illite occurs when smectite, in the presence of potassium from another mineral such as potassium feldspar, or from thermal fluids, is heated and/or buried. With increasing temperature smectite plus potassium is converted to illite.

The physical structure of mixed-layer minerals is open to question. In the traditional view, the MacEwan crystallite is a combination of 1.0-nm (10-Å) nonexpandable units (illite) that forms as an epitaxial growth on 1.7-nm expandable units (smectite) that yield a coherent diffraction pattern. This view is challenged by the fundamental particle hypothesis which is based on the existence of fundamental particles of different thickness.

Amorphous and Miscellaneous Groups

Allophane and Imogolite. Allophane is an amorphous clay that is essentially an amorphous solid solution of silica, alumina, and water. Allophane has been found most abundantly in soils and altered volcanic ash. It usually occurs in spherical form but has also been observed in fibers.

Imogolite is an uncommon paracrystalline clay mineral morphology of imogolite has been reported as thread-shaped and as hollow spheres. Imogolite is generally viewed as an intermediate between allophane and kaolinite. In modern environments both allophane and imogolite are associated with volcanic material in areas of high rainfall.

High Alumina Clay Minerals. Several hydrated alumina minerals should be grouped with the clay minerals because the two types may occur so intimately associated as to be almost inseparable. Diaspore and boehmite are the chief constituents of diaspore clay, which may contain over 75 % Al_2O_3 on the raw basis. Gibbsite, and cliachite, the so-called amorphous alumina hydrate (much cliachite is probably cryptocrystalline), as well as the monohydrates, occur in bauxite, bauxitic kaolin, and bauxitic clays.

The hydrated alumina minerals usually occur in oolitic structures (small spherical to ellipsoidal bodies the size of BB shot, about 2 mm in diameter) and also in larger and smaller structures. High alumina minerals are found where intense weathering and leaching has dissolved the silica. It is generally believed that a very humid, subtropical climate is required for this (lateritic) stage of weathering.

CLEAR-AIR ECHO. A radar echo returned from a region of the atmosphere with no apparent meteorological scatterers such as clouds or precipitation. Clear-air echoes are caused by either 1) solid target returns from birds, insects, dust, or other particulate matter, or 2) spatial fluctuations of refractivity with scale sizes on the order of or smaller than the radar wavelength.

Two examples of the latter type of echo are Bragg scattering from atmospheric turbulence and Fresnel reflection or specular reflection from layers with sharp gradients in refractivity. Insects, birds, and particulates are the principal cause of clear-air echoes observed with radars having wavelengths of 3 centimeters (1.2 inch) or less, whereas high-powered radars operating at wavelengths of 10 cm (4 inches) or greater routinely detect backscattered signals from strong refractive index fluctuations.

AMS

CLEAR-AIR TURBULENCE (CAT). A higher altitude (6–15 km (3.7–9.3 miles) turbulence phenomenon occurring in cloud-free regions, associated with wind shear, particularly between the core of a jet stream and the surrounding air.

It is most common near upper air fronts and the tropopause, and can often affect an aircraft without warning. Clear-air turbulence also frequently occurs close to towering cumulus clouds (usually within 30 km (19 miles), and near mountains. Airflow disrupted by mountains and other terrain can undulate in waves of turbulence for 1,000 km (621 miles) or more. See also **Aircraft Turbulence**; and **Meteorology**.

CLEAR ICE. See **Meteorology**.

CLEAR-WINGED MOTH *(Insecta, Lepidoptera).* A moth whose wing membranes are largely free from scales and therefore transparent. A majority belongs to the families *Aegeriidae*, containing the squash-borer and other borers of economic importance, and *Sphingidae* or hawk-moths, of which the genus *Hemaris* includes such species.

CLEAVAGE (Biology). Also referred to as cytokinesis, cell cleavage is the process of segmentation and separation of two daughter cells during the process of cell division. The subdivision of the fertilized ovum, which precedes the formation of germ layers as the first stage of embryonic development. In the simplest type of cleavage the egg and each cell thereafter split completely through; this process is called holoblastic cleavage. With the accumulation of yolk in the egg its division is hampered until, in the eggs of birds and reptiles, the living matter lies on one side of the yolk and cleavage merely subdivides this small mass into a layer of cells; this is meroblastic cleavage. In still other eggs with much yolk, such as those of the insects, cleavage gives rise to a layer of cells completely enclosing the yolk. The last type is called superficial cleavage. The process of cell cleavage of plant cells is different. In these, a phragmoplast is formed which is transformed into the cell plate, which operates the two daughter cells. Within the cell plate is the secretary apparatus that produces the new primary cell wall. See also **Cell (Biology)**.

CLEAVAGE (Geology). The tendency of crystalline minerals to split more easily in certain definite directions, with the development of more or less smooth surfaces called cleavage planes. Cleavage planes can only be developed parallel to some possible crystal face. Cleavage may be described either in terms of the ease with which it is developed, or its direction. Slaty cleavage, as the term implies, is the tendency for slaty rocks to split in relatively thin, flat plates. Slaty cleavage is the result of the metamorphism (foliation) of a sedimentary rock (shale or mudstone) and is not to be confused with mineral cleavage.

CLEMENTINE MISSION. See **Space Science Missions: Solar System**.

CLICK BEETLE *(Insecta, Coleoptera).* Beetles with a peculiar junction between the first and second thoracic segments, which permits them to be moved with a convulsive snap. When laid on its back the beetle uses this method of righting itself, throwing itself into the air by these snapping movements of the body. Most members of the family *Elateridae* and some of the *Eucnemidae* are click beetles. The females of these beetles cause injury to corn (maize) plants by burrowing into the soil and laying eggs around the roots.

CLIMATE. In essence, climate is a composite of the weather that has occurred at a given location over a comparatively long period of time (decades or centuries, depending upon data available). The principal variables of weather include atmospheric pressure, temperature, humidity, precipitation, air movement, and cloud cover. Weather is the province of the meteorologist. See also **Weather Technology**.

Whereas weather fluctuations are of interest on a daily, or even minute-by-minute basis (during storms), climatic changes usually are studied over a *seasonal* time frame, thus reflecting the key climatic variable, namely, the amount of solar radiation received by a given location as determined by the tilt of Earth's axis. In fact, the word *climate* is derived from the

Greek (*klima*), which means *inclination*. Thus, the designations of the seasons — spring, summer, fall (autumn), and winter.

In analyzing climatic changes, the *climatologist* may highlight a climatic variable, such as spring floods, summer droughts, winter cloud cover, a hurricane season, and location-specific winds, such as the Chinooks and Monsoons.

A principal interest of the climatologist is that of analyzing the causes and effects of past seasonal changes on a long-term basis and of utilizing such information to forecast changes in climate that may occur decades and more into the future. Climatology is intimately associated with geology and geography.

Classification of Climates

Early geographers used climate as a base of reference for designating the principal regions of the world. As early as 624–546 B.C., Thales of Miletus, a much-traveled and knowledgeable person of the period, is known to have studied in Egypt and Babylonia. Some historians accredit the founding of Greek mathematics, astronomy, physics, and geometry to Thales. By noting that the slant of the sun's rays changed as one traveled in a northward or southward direction, Thales reasoned that Earth's surface must be curved — this observation preceding by several centuries the later postulations of the Great Explorers regarding this matter. Thales proposed the concept of the *equator* and the *plane of the ecliptic*. He recognized that the two were inclined relative to each other, tying this observation to the slanting of the sun's rays and their effect upon the climate of Earth. Thales extended the concept by suggesting that the planet could be divided by circles parallel to the equator (parallels) and by lines perpendicular to the equator (meridians). These concepts were expanded and refined by later philosophers, including Plato, Aristotle, Eratosthenes, Copernicus and numerous other visionaries of their time.

The effect on the climate of the tilting of Earth's axis by about 23.5° is delineated in Figs. 1 and Fig. 2. Ancient philosophers determined this inclination with amazing accuracy, considering the crude instruments available during their time. The length of the short shadows cast at the time of the summer solstice, when the sun is high in the sky, and of the long shadows at the time of the winter solstice, yielded a value of 23.5°. With the availability of sophisticated instrumentation in modern times, this value has been changed by only a matter of arc minutes to 23.45°.

Data-Based Climate Definitions. In the 19th century, Alexander Supan introduced a major improvement over the early geographers in the classification of climates. Supan based his climatic zoning on actual, rather than theoretical temperatures. He divided the world into 34 climatic provinces of essentially homogeneous climates, defining them mainly in terms of temperature and rainfall, and only partially by wind and orography (whether or not the climates were associated with mountainous terrain). Supan concentrated his efforts on land-based climates and, except for climates along ocean coastlines, did not have sufficient data to delineate oceanic climates.

In 1918, W. Köppen devised what became known as the *geographical system* of climates. Köppen's elaborate system was based upon annual and seasonal temperature and precipitation values. The Köppen system is empirical. Each climate is specified in accordance with fixed values of temperature and precipitation that are compiled on the basis of yearly averages or of individual months. Inasmuch as air temperature and precipitation data are among the most readily measurable surface weather conditions, it is thus relatively easy, by the Köppen system, to estimate geographical areas that are subject to one of several climate subtypes. Over the years, the Köppen classification has been updated. The most recent Köppen classifications and codes are delineated in Table 1.

In 1931, C.W. Thornthwaite devised a *bioclimatological* system that utilizes indices of *precipitation effectiveness* (for plant growth) to outline *humidity provinces*, as distinguished by the biological consequences of climate. The system also utilizes *thermal efficiency* (i.e., the effectiveness of temperature on determining rate of plant growth. As a further effort, Thornthwaite, in 1948, introduced what is termed a *rational classification*, wherein evapotranspiration (i.e., the amount of moisture that, if available, would be removed from a given land area into the atmosphere by the combined process of evaporation of liquid or solid water plus transpiration from plants) is used as a measure of thermal efficiency. These data are used to form a *moisture index* and to indicate amounts and periods of water surplus or deficiency. Definite breakpoints are revealed that are adaptable as climatic boundaries.

Because climate has an intimate bearing on national and regional economics, notably agriculture, these various approaches can be helpful for planning the use of land and water resources. See Table 2. And see Table 3, for a glossary of climate terms.

Early System Approach to Climatology

The development of early hydrological research, essentially for tracing and accounting the circulation of water vapor in the earth-ocean-atmosphere system, commenced several decades ago. This research essentially was of a semiquantitative nature.

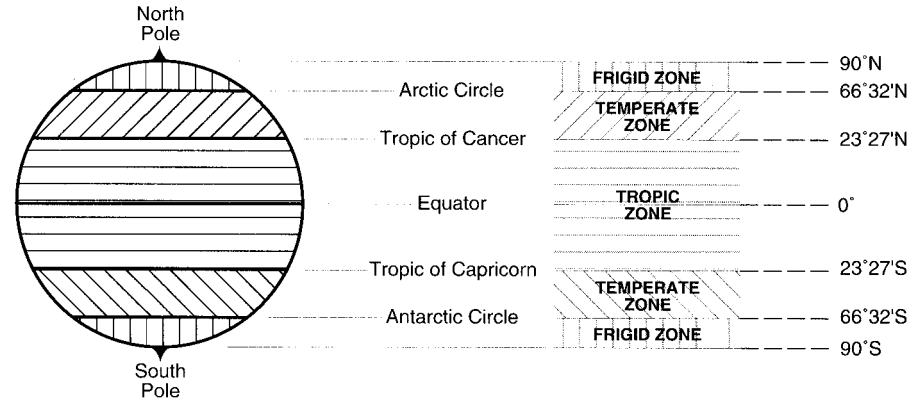
By the late nineteenth century, many basic laws of the physical sciences existed to enable scientists to state mathematically how the atmosphere moves about, that is, its dynamics. But it required several decades to formulate the necessary equations so that meteorological observations could be inserted and solutions to the equations obtained. In 1904, the Norwegian meteorologist Vilhelm Bjerknes believed that it would be possible to calculate how the atmosphere would change in the future given a set of initial conditions and using these basic laws. The number of calculations required to do so is enormous. At that time, the English scientist, Lewis Fry Richardson, estimated that it would require 64,000 people simultaneously doing weather calculations! But upon the development of modern programming methods by John von Neumann and the appearance of electronic computers, what seemed fully impossible at one time became a reasonably achievable target in the long term. However, as of the early 1990s, after a score of years of using high-power computers, the goal is not within hand. These difficulties were recognized by the National Academy of Sciences (U.S.) in 1985 when it was observed: "The atmosphere is the prototypical chaotic nonlinear system. This was shown by the simplest atmospheric model, devised by Edward Lorenz over 20 years ago, the starting point for modern mathematical studies of such systems. Because the atmosphere is chaotic, atmospheric models are sensitive to small variations in initial conditions and possess an inherent growth of error. These properties impose a theoretical limit on the range of deterministic predictions of large-scale flow patterns of about two weeks."

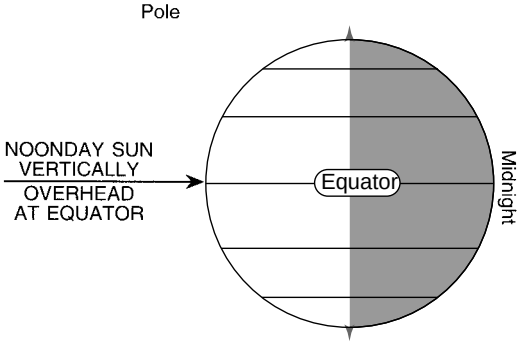
Some of the many variables that affect weather and ultimately determine climate include: (1) solar radiation, (2) distribution of land and water masses, (3) elevation and large-scale topography, (4) ocean currents, (5) wind systems, and (6) volcanic eruptions, and (7) anthropogenic pollution. A coarse diagram showing the interlocking of these and other factors and also indicating interfaces that currently are being intensely researched is given in Fig. 3. A more traditional general circulation model is shown in Fig. 4. See also **Climatology**.

Chronology of Global Dynamics Research

Although interest in global dynamics seemed to be at a peak in the early 1990s, research involving high-power computer models dates back over several decades. Since the 1960s, several climate and weather research organizations have turned to very ambitious computer programs. For example, since the formation of National Center for Atmospheric Research (NCAR) in 1960, computers have played a major role in this area of research. NCAR's first computer model of atmospheric circulation was created by Akira Kasahara and Warren Washington and consisted of a grid of thousands of points over the globe. As the model ran, it would calculate the changes at each individual point. It lacked a good data set to work with, however, and thus it was necessary to expand existing observations to cover the whole globe. Baumhefner analyzed one of the first data sets and used it as the input for a new general circulation model (GCM). Although calculating time was prohibitively long, Baumhefner found that the early GCM had some success in predicting short-term weather systems. The science had matured greatly at that stage of model development, but without a good set of global observations, the best equations and fastest computers could only achieve forecasts realistic for about three days. The time had arrived to return to the field for a more complete set of global data, one that included the sparsely observed tropics, Southern Hemisphere, and oceanic regions.

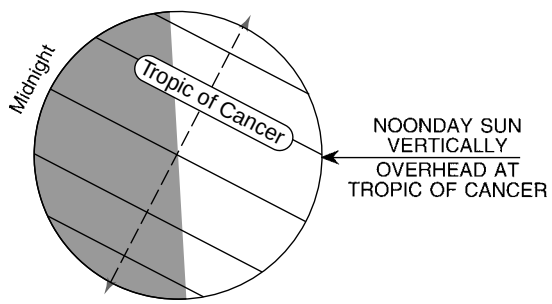
Further theoretical work by scientists, including Edward Lorenz, had suggested that the models might achieve accurate predictions of about two weeks with better information. Stimulated by this possibility, the World Meteorological Organization and the International Council of Scientific Unions in 1967 embarked on an ambitious program of international planning and experimentation, the *Global Atmospheric Research Program* (GARP) http://www.cira.colostate.edu/ramm/hillger/GARP.htm.





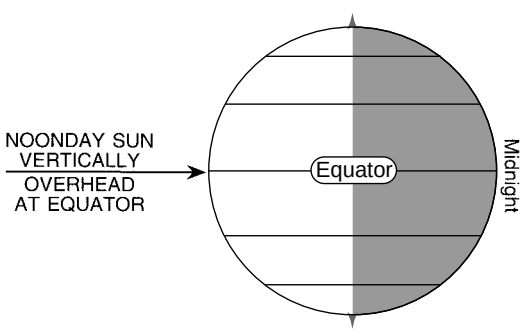
VERNAL EQUINOX
March 21st–NOON

At this time, the sun is vertically overhead at the equator. Solar radiation stretches from North to South Pole. At all places on Earth, days and nights are of equal duration.



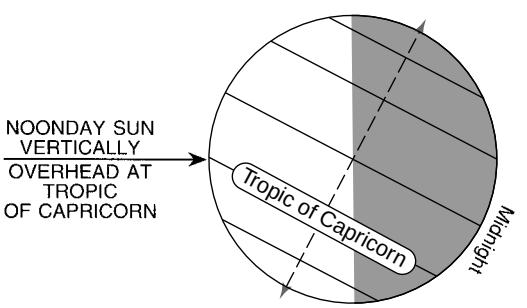
SUMMER SOLSTICE
June 21st–NOON

At this time, the sun is vertically overhead at the Tropic of Cancer. Regions north of the Arctic Circle receive 24 hours of solar radiation. Areas south of the Antarctic Circle experience 24 hours of darkness. Regions north of the equator have their longest day and shortest night of the year. The longest night and shortest day occurs south of the equator. At the equator, day and night are of equal duration.



AUTUMNAL EQUINOX
September 23rd–NOON

At this time, the sun is vertically overhead at the equator. Solar radiation stretches from North to South Pole. At all places on Earth, days and nights are of equal duration.



WINTER SOLSTICE
December 22nd–NOON

At this time, the sun is vertically overhead at the Tropic of Capricorn. Regions south of the Antarctic Circle experience 24 hours of solar radiation. Areas north of the Arctic Circle experience 24 hours of darkness. Areas south of the equator have their longest day and shortest night of the year. The longest night and shortest day occur north of the equator. At the equator, day and night are of equal duration.

Fig. 1. Earth-sun geometry and key dates of the seasons.

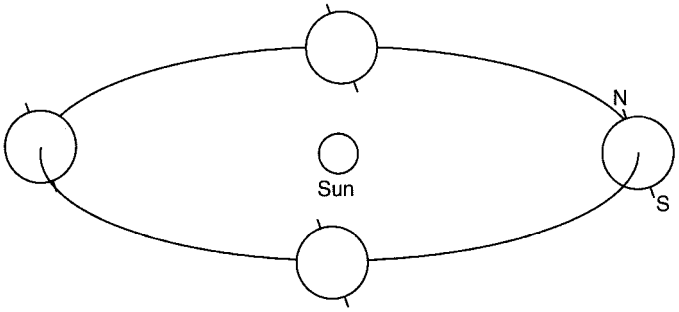


Fig. 2. Effect of Earth's titled axis on the amount of radiation the planet receives from the sun. If the axis of Earth were perpendicular to the plane of the ecliptic, the sun always would be on the celestial equator; thus, the days and nights would always be of equal length and there would be no spring, summer, autumn, and winter as we know them. Details of the effects are shown in Fig. 1. The season at any point on Earth depends upon the amount of solar radiation received; the greater the amount of sunlight received, the warmer the season. The daily amount of sunlight per unit of area depends upon: (1) the elevation of the sun above the horizon and (2) the duration of daylight.

Over nearly 15 years, GARP spawned several subprograms aimed at various large-scale meteorological features. For example, the *Monsoon Experiment* examined the annual rain and wind systems of Asia and the Indian subcontinent and culminated in a special intensive worldwide observational phase, the *Global Weather Experiment*, during 1979.

Some of the specific advancements stemming from GARP included: (1) Significant improvement in balloon technology — improved to the point that a global balloon system to collect meteorological data in connection with satellites could be conceived. (2) Invention of the spinscan camera on satellites, (by Suomi, University of Wisconsin), which enabled scientists to derive wind-flow data from watching cloud drift patterns. GARP ultimately depended on the global measurements provided by a band of geostationary satellites — three American, one European, and one Japanese. These yielded a set of tropical observations that remain useful today. (3) The concept of using radiation to infer temperatures and water vapor was proven by flying a balloon-borne spectrometer at the National Scientific Balloon Facility, operated by the University Corporation for Atmospheric Research (UCAR) in Palestine, Texas. This later formed the basis for using radiation-measuring instruments to make extensive quantitative measurements of the atmosphere from satellites.

Other new systems developed for GARP included drifting buoys that could be deployed along ship routes near Antarctica and could send ocean surface and pressure measurements via satellite. John Masterson of NCAR helped design the buoy program, working with Canadian scientists, who developed the buoys, and French scientists, who developed the tracking system.

Benefits of GARP to Weather and Climate Modeling. Computer supported mathematical modeling of complex phenomena as encountered in the earth's overall climate/weather system are, of course, no better than the information upon which they are based.

Prior to the early 1960s, models were functioning barely better than the best educated guesses (those based on weather records of average values). They were accurate up to only a day or so. Models of the early 1970s that still used deterministic equations but with inadequate data sets were accurate up to possibly 4 days. During this period, scientists developed various techniques to eliminate "noise," i.e., unwanted fluctuations in the initial conditions by accounting for the natural oscillations in the atmosphere. This technique is called *nonlinear normal-mode initialization*. Using another technique called *objective analysis*, scientists examined the initial conditions to assure that they were as realistic as possible, occasionally discarding obviously erroneous observational data. One relatively new development in atmospheric modeling was the so-called *spectral method*, which uses series of smooth mathematical functions to represent the physical features instead of the more traditional grid-point representation.

The potential of GARP to provide data sets for global forecasting encouraged the establishment of a new forecasting center called the *European Centre for Medium-Range Weather Forecasts* (ECMWF), located in Reading, England. This center uses supercomputers to run sophisticated models with the latest available data. Through extensive experience with data collected during the 1979 GARP activities, the ECMWF by 1984 had achieved significantly improved forecasts of up to 7 days. The U.S. National Meteorological Center has demonstrated similar improvements. In evaluating the usefulness of the observing systems used during the *Global Weather Experiment*, Paul Julian (NCAR scientist) concluded that the wind data taken in the tropics, combined with infrared data from satellites, were critical to these advances in analysis and model prediction.

While a better theoretical understanding of large-scale atmospheric features using numerical models remained a major target, climate research organizations such as NCAR also recognized the need by the atmospheric science community for a forecast model that everyone could use. Since 1980, scientists have developed and introduced *community climate and forecast models*. These models are accessible to all, are well documented to facilitate their use, and have surpassed and replaced prior local prediction methodologies. Scientists at universities and other institutions worldwide now can more readily run their experiments on state-of-the-art models and computers.

The first version of the community climate model was based on an Australian spectral model. In 1981, scientists decided that they could increase economy and efficiency by using the same basic computer code for both global forecast and climate studies. The community models are constantly upgraded to reflect improvements in theory and modeling techniques. They have become powerful new tools for understanding the climate and atmospheric systems. Three examples of how these tools are currently being used are described in the following paragraphs. These represent only a partial summary of their successful applications.

1. Short-Term Variations in Climate

When medium-range weather forecasts are extended over more than a few weeks, they become, in effect, short-term *climate forecasts*. One such climatic event is "blocking," when a certain type of system seems to settle in, so to speak. This could be a displacement of the jet stream that will cause an especially cold winter in one region of a country such as the United States. Blackmon (NCAR) has made considerable progress in understanding this phenomenon, using a community climate model. See Fig. 5.

NCAR scientist Harry van Loon, using a community model, has been investigating an atmospheric phenomenon called the *Southern Oscillation*. Its primary signature is a seesaw of pressures in the Southern Hemisphere. When the atmospheric pressure rises in the tropical Indian Ocean, it tends to drop in the tropical Pacific. The pressure simultaneously rises in high latitudes of the South Pacific and drops in the subtropical Pacific. At the same time the equatorial Pacific experiences weak trade winds, warm water, and heavy rains. This topic is covered in more detail in the article on **Atmosphere-Ocean Interface**, particularly in connection with the 1982–1983 El Niño event. See **El Niño**.

Scientists are also exploring other relationships between climate regimes in one region and a different climate regime somewhere else. These relationships are sometimes called "teleconnections." During the *Line Islands Experiment*, conducted in the central equatorial Pacific in 1967, scientists noticed a pattern of pressure oscillations lasting 40 to 50 days. New data obtained during the *Global Weather Experiment* in 1979 tended to verify these observations. Scientists, using community climate models, are now examining the question of how these long oscillations are related to the better understood Southern Oscillation, previously mentioned. A basic consideration of all forms of forecasting, whether short- or long-term, is what the longest or best possible forecast may be. In continuing theoretical work on predictions, scientists have recently considered the question of whether long-range (on scales of one month to two or three years) forecasts are feasible. Up to 24 years of temperature data were studied and the investigators concluded that there is some potential for skillful long-range forecasting of temperatures near the West Coast and Southeastern regions of the United States. However, it is admitted that the relatively large variability of daily temperatures throughout the interior of the continent make predictions of wider areas somewhat tenuous because of the limitations of existing technology.

2. Climate Effects of CO_2, Ozone, and Trace Gases

In addition to the great complexities of the global weather/climate system, in relatively recent years, the effects of anthropogenic activities on earth, mainly arising from the generation of atmospheric pollutants, are adding new complexities.

TABLE 1. MODIFIED KÖPPEN CLIMATIC CLASSIFICATION AND CODES

First Letter of Code	Climate Description
A	*Tropical climate*. Average temperature of every month is above 18 °C (64.4 °F). There is no winter season. Annual rainfall is heavy and exceeds annual evaporation.
B	*Dry climate*. Potential evaporation exceeds precipitation (on the average) throughout the year. There is no water surplus. Thus, no permanent streams originate in a B climate zone.
C	*Warm temperate climate*. The coldest month has an average temperature under 18 °C (64.4 °F), but above −3 °C (26.6 °F). There is both a summer and a winter season in a C climate zone.
D	*Snow climate*. The coldest month has an average temperature under −3 °C (26.6 °F). The average temperature of the warmest month is above 10 °C (50 °F). Snow climate zones coincide approximately with the poleward limit of forest growth.
E	*Ice climate*. The average temperature of the warmest month is below 10 °C (50 °F). There is no true summer in an ice climate zone.
H	*Highland climate*. A climate of high altitudes, characterized by extremes of surface temperature, low atmospheric temperature, strong winds, and rarefied air.
Second Letter of Code	
S	*Semiarid climate*. Features from 38 to 76 centimeters (15 to 30 inches) of rainfall annually at low latitudes.
W	*Arid climate*. Most regions have less than 25 centimeters (10 inches) of rainfall annually.
f	*Moist conditions*. Adequate precipitation in all months. There is no marked dry season.
w	*Dry season in winter* (of respective hemispheres).
s	*Dry season in summer* (of respective hemispheres).
m	*Rainforest climate*, but including a short dry season in monsoon type of precipitation cycle.
Examples of Code Combinations	
Af	*Tropical rainforest*.
Aw	*Tropical savanna*.
BS	*Steppe climate*.
BW	*Desert climate*.
Cw	*Temperature, rainy climate with dry winter*.
Cf	*Temperate, rainy climate, most all seasons*.
Cs	*Temperate, rainy climate with dry summer*.
Df	*Cold, snowy forest climate, moist all seasons*.
Dw	*Cold, snowy forest climate with dry winter*.
Et	*Tundra climate*.
Ef	*Climate of perpetual frost*.

Notes on Regional Precipitation: If averaged over the total surface of Earth, the yearly rainfall is about 80 centimeters (30 inches). This rainfall is distributed unevenly and, among other factors, accounts for very wide variations over Earth in terms of suitability for crop production. The equatorial zone and the monsoon area of southeast Asia receive the greatest amounts of rainfall. Middle latitude regions receive moderate quantities of precipitation, whereas the desert regions of the subtropics and the areas around the poles receive very little moisture. The pattern of precipitation distribution is also complicated by local influences, such as the pattern of global winds, the distribution of land and sea, physical barriers to moisture-laden air, such as mountain ranges, and the mechanical and thermal turbulence of air over land surfaces.

Because rainfall results from the ascent and consequent cooling of moist air, the areas of heavy rainfall indicate regions of rising air. In contrast, the desert regions occur in areas where the air is warmed and dried during descent. In the subtropics, the trade winds bring ample rain to the east coasts of the continents. The west coasts tend to be drier. In high latitudes, this trend is reversed, resulting in the west coasts being generally wetter than the east coasts.

Average amounts of precipitation for a season or a year provide little indication of the regularity with which rain may be expected. This is particularly true of regions where the average amounts of rainfall are small. Past records provide some guidance, but to date meteorology has not advanced to the point where a rather precise estimate of the maximum possible precipitation for a given locality over a specified time interval can be made. Precipitation depends upon a combination of favorable factors, such as the properties of local storms as well as the interaction between storms and local topography. At best, estimates are made on the basis of theoretical calculations, utilizing statistical analyses of the most effective combinations of weather-producing factors of historical records.

In many raegions, precipitation is not equally distributed in terms of time spans, in fact, the reverse situation is usually true. Some areas of Earth have very dry winters and rainy summers, whereas other areas may receive the majority of their annual precipitation in the fall and winter, following very dry summers. Although the engineering of water supplies and irrigation systems has done much to smooth out the variations in local precipitation, nevertheless the pattern of natural rainfall remains an extremely important factor in determining the crop make-up of a given region as well as crop yields from one season to the next.

See also **Clouds and Cloud Formation**; **Fronts and Storms**; **Hydrology**; and **Precipitation and Hydrometeors**.

The climate system remains in comparative equilibrium by balancing the incoming solar radiation with the outgoing thermal radiation. Various gases in the atmosphere, such as water vapor and carbon dioxide, partially trap the outgoing radiation, thus helping to increase surface temperatures by several tens of degrees from what they would be if there were no atmosphere. This is the well-known greenhouse effect. See Fig. 6.

In 1975, Ramanthan (NASA) showed that chlorofluorocarbons in the atmosphere, even in small concentrations, absorb radiation very strongly at certain wavelengths. Later, in a cooperative effort with Dickinson (NCAR), Ramanthan realized that ozone in the lower atmosphere could be an important greenhouse gas. The effects of methane and nitrous oxide were also explored.

TABLE 2. EFFECTS OF CLIMATE ON PRINCIPAL CLASSES OF AGRICULTURE

NOMADIC HERDING

One of the most ancient of agricultural systems. Animals, grazed on native vegetation, are the primary products. Nomadic peoples cultivate very few crops.

Locations: Herding in cold climates is found along the north and west coasts of Alaska, parts of northwestern Canada, the northern coasts of Scandinavia, including Lapland, and northwestern Russia. Herding in hot climates occurs mainly in the Sahara area of Africa, parts of southern Africa, the Arabian Peninsula, the Negev and Sinai Desert regions, parts of southwestern Asia, including Pakistan and India, as well as in the west-central portions of China and Mongolia.

Climate: Arid conditions — either very hot or very cold. Hot, arid desert and middle-latitude climates of Africa and Asia are not predisposed to production of vegetative growth. Precipitation is minimal. The northern areas may receive from 10 to 20 inches (25.4 to 50.8 centimeters) of rainfall annually. The southern areas receive under 12 inches (30.5 centimeters) annually. Desert areas may receive less than 4 inches (10.2 centimeters) of rainfall per year. In the northern regions, the frost-free growing season is only from 60 to 90 days.

Topography: Plateaus are the most prevalent landform within these regions. The plains in northern Russia and India, and the mountains in southern China and western Asia provide natural pastures for nomadic herds.

RUDIMENTARY SEDENTARY AGRICULTURE

This system of agriculture is rather primitive and is a nonmigratory practice associated with tropical and subtropical areas. Subsistence crops include maize (corn), potatoes, cacao, wheat, barley, millet, sorghum, sweet potatoes, cassava, groundnuts (peanuts), and bananas.

Locations: This system of agriculture is found in parts of Central America, the east coast of Brazil, and the Andes Mountains area of South America. Small areas of rudimentary sedentary agriculture are also found throughout central Africa and southeastern Asia, including Burma and Indonesia.

Climate: This system is often practiced in the higher elevations of the less developed countries. With increases in elevation, rather dramatic climatic changes can be encountered within a relatively small area. This type of changeable climate is commonly called *highland climate or high-altitude climate*. Precipitation is quite variable. Parts of the Andes Mountains and western Ethiopia may receive as little as 8 inches (20.3 centimeters) of rainfall annually, while in Indonesia and Myanmar (Burma), the rainfall may range from 80 to 200 inches (202 to 508 centimeters) per year. The frost-free growing season is year-long, unless modified by altitude.

Topography: Most of the regions exhibit mountainous terrain. However, the plains of Yucatan Peninsula of Mexico are cultivated in this manner.

SUBSISTENCE AGRICULTURE

This agricultural system is typical of practice in several Asian areas. A variety of food crops includes wheat, barley, maize (corn), rice, potatoes, millet, sorghum, groundnuts (peanuts), sugar cane, soybeans, and bananas. The ability of many of these densely populated regions to feed large masses of people is highly dependent upon the long growing season which permits more than 1 crop per year to be planted and harvested. Crop rotation is widespread. Large river systems in several of these areas permit extensive irrigation. With certain exceptions, varying from 1 country to the next, the crops produced are consumed by the people of the regions where grown. However, even with this land-intensive and labor-intensive system, many countries still must import large quantities of foodstuffs.

Climate: Unlike most agricultural systems, climate is not a primary factor in delineating this type of system. Over years of experience, growers have learned which crops are likely to yield reasonably well for a particular region. Climates include the tropical monsoons of India, Pakistan, and southeastern Asia, as well as the humid middle-latitude climate of northern China. Subsistence agriculture is also found in arid, semiarid, and mountainous climates. There is a large range in amount of rainfall received from one area to the next. The growing season is year-long in many of these areas, but becomes shorter in areas of higher elevation and latitude.

RICE-DOMINANT SUBSISTENCE AGRICULTURE

This is a specialized form of subsistence agriculture. Most of the produce is consumed by the local populace. Rice is so dominant that it overshadows other crops in the system. However, lesser crops include tea, sorghum, sugar cane, manioc, groundnuts (peanuts), coffee, and some fiber crops. It is not uncommon to find farms under 4 acres (2 hectares) in size. Most regions produce two to three crops on the same land per year because of the long growing season and the availability of irrigation water.

Climate and Locations: Three major climate classes are characteristic of rice-growing regions: (1) Wet and dry tropical climate of India, Vietnam, Bangladesh, Cambodia, and Thailand, which has a well-defined dry season accompanied by one or two rainy seasons; (2) rainy tropical climate of Burma, Nepal, Malaysia, Indonesia, and the Philippines where there is rainfall throughout the year and where temperatures are continuously warm to hot; and (3) humid subtropical climate of China, Japan, and Taiwan, characterized by long warm summers, cool winters, and rainfall throughout the year.

Topography: Rice-growing regions are noted for: (1) Broad, flat river flood plains (lowland rice); and (2) terraced slopes (upland rice). Frequently, because rice is so important as a local source of food, very steep hillsides, requiring laborious irrigation methods, will be intricately terraced.

PLANTATION AGRICULTURE

This system of agriculture involves large, centrally managed estates in the tropical and subtropical regions-and was once prevalent in the southeastern United States. Some plantations are essentially devoted to one crop. Major producing areas vary considerably and are scattered throughout Central America, the Caribbean, the east coast of South America, central and southern Africa, Hawaii, southern Asia, Malaysia, Indonesia, and the east coast of Australia. Plantation crops include coffee, cacao, coconut, bananas, pineapple, sugarcane, tea, manioc, and several fiber crops. Within the last several decades, plantations have become profitable subsidiaries of large corporations (usually headquartered in major importing countries). Heavy emphasis is placed upon exporting plantation crops to large consuming regions that may be located considerable distances from the plantations.

Climate: The wet and dry tropical climate is most prevalent where large plantations are located, although some areas (for certain crops) experience a rainy tropical climate. Average annual precipitation is moderate to heavy, at least 40 inches (102 centimeters) per year. The growing season is year-long. There are several exceptions to these generalities.

Topography and Soils: Because of crop specialization on plantations, it is meaningless to generalize as regards topography and soils. Trees or shrub crops can be grown on hillside plantations, while pineapple and sugarcane require level fields.

SHIFTING CULTIVATION

Today, this is an agricultural system associated mainly with the humid tropical regions, including the Amazon River basin of Brazil and portions of Bolivia, Peru, Colombia, Venezuela, and Central America. It is also widely apparent in central Africa. Shifting cultivation typically involves cutting and burning off the native vegetation, cultivating fields for a few years, and then abandoning the land for fresh clearings. There is a rotation of fields, not crops, and growers may require 5 times as much land as is cultivated in order to maintain even 75% of original soil fertility. This type of agriculture has very low productivity and is a primary cause of later water and wind erosion of soils. The Great Plains region of the United States essentially was subjected to this type of unplanned, careless form of agriculture a century or more ago and this resulted in erosion of millions of acres of soil, leading to such disasters as the Dust Bowl.

Topography: As found today, the terrain associated with shifting cultivation in South America is primarily plains and hilly lands. In Africa, hills and plateaus are cultivated. In Asia, land forms range from plains to mountains. One of the main features of shifting cultivation, as observed from reconnaissance satellites, is a patchwork pattern of small fields located on hillsides and scattered among strips of forest.

TABLE 2. (*Continued*)

TEMPERATE TO SEMITROPICAL INDUSTRIAL AGRICULTURE

This system or agriculture is distinct because of the importance of various industrial cash crops, which compete with food crops for land resources. The southern United States is a large producing region of industrial crops. Other important areas are the Nile River valley of Egypt, west central India, parts of Pakistan, and small areas in southern Russia. Cotton is the major crop. Other industrial crops (some classified broadly with foods; others identical with food crops, but used for industrial purposes) include tobacco, sunflower seeds, groundnuts (peanuts), and soybeans. Food crops, such as corn (maize), barley, rice, and wheat are frequently produced within the same regions. In some countries, industrial cash crops are raised mainly for export.

MEDITERRANEAN AGRICULTURE

This type of agricultural system is found in a zone between 30° and 45° latitude both in the Northern and Southern Hemispheres, but primarily in countries that surround the Mediterranean Sea. Other regions of the world that practice a Mediterranean agriculture include southern and west-central California, the west-central coast of Chile, the tip of South Africa, and the land adjacent to the Black and Caspian Seas in Russia and northern Iran. Major crops of this system include citrus fruits, olives and olive oil, grapes, dates, figs, subtropical fruits, tomatoes and many other vegetables. In these regions, there is a major distinction between dry land farming and irrigation agriculture. Dry land farming is common in the rougher, more mountainous areas where olives, grapes, and figs are grown on terraced slopes. The lower, more level fields and valleys are usually irrigated, producing fruits, vegetables, and cotton. Farms are usually quite small, often less than 25 acres (10 hectares) in size, except in the United States and **Russia**.

Climate: The predominant climate is commonly described as dry subtropical, with hot, dry summers and cool, moderately moist winters. The close proximity of large bodies of water has a modifying effect on climatic extremes. The average annual precipitation is between 15 and 40 inches (38 and 100 centimeters) per year. The frost-free growing season is at least 180 days, the average being 240 days or more with some areas fully frost-free.

Topography: Most regions of this type are typically hilly and/or mountainous, except for the cultivated plateaus of the Middle East and the Central Valley of California. Elevations range from about 610 to 2980 feet (186 to 908 meters).

WHEAT-DOMINANT GRAIN FARMING SYSTEM

Because of the great economic and nutritive importance of grain products to the world food supply, grain production is one of the most important of the agricultural systems. In the Western Hemisphere, wheat is the predominant crop in the central and north-central portions of the United States, the south-central part of Canada, and in the Pampas region of Argentina. In the Eastern Hemisphere, wheat is grown from the Black Sea to central Russia and in southern Australia.

Wheat is the dominant crop, with a major distinction between winter and spring wheat. Winter wheat is planted in the fall and harvested in early summer. Spring wheat is planted in the spring and harvested in late summer. Although winter wheat yields are usually higher, spring wheat is the type usually planted in the northern United States, Canada, and parts of Russia because the severe winters in some areas preclude planting winter wheat. Other major grain crops include barley, sorghum, rye, oats, and maize (corn).

Climate: Wheat can be grown successfully in areas of light precipitation. The major producing areas have a semiarid, middle-latitude climate with light precipitation, warm or hot summers, cool or very cold winters. Wheat is also grown in the drier areas of the humid middle-latitude climatic regions. Precipitation generally ranges from 12 to 20 inches (30 to 52 centimeters) per year. The growing season averages from 120 to 180 days in most regions.

Topography and Soils: Wheat and cereal grasses are grown almost totally on flat or gently rolling plains. These regions encompass primarily mollisol soils with small areas of aridisols.

LIVESTOCK RANCHING

This form of agricultural system is found in five major areas of the world: (1) The western section of North America from southern Canada to central Mexico; (2) Argentina and southern Brazil and Venezuela in South America; (3) the southern part of Africa; (4) south-central Russia; and (5) much of Australia and New Zealand. Meat products and byproducts (skins, hides, wool-not a byproduct) from cattle, sheep, and goats are of major economic importance. Some of these regions are extensive natural grasslands. Other regions require much attention to retain and reestablish native vegetation. Crops are raised to support these livestock in many of these areas and may include alfalfa, maize (corn), oats, sorghum, and millet. Livestock ranching often borders on grain-growing regions. Rainfall in these areas may show a 50% change in total precipitation from 1 year to the next. Winter feed is purchased or grown on irrigated land.

Climate: The semiarid, middle-latitude or semiarid tropical climates are conducive to livestock ranching. The hot arid climates of central Russia, parts of Argentina, Africa, and Australia are most suitable for sheep or goats, although other livestock are extensively produced. The frost-free growing season is quite variable. In the low-latitude areas, the frost-free period may be essentially continuous, whereas the period becomes progressively shorter in the higher latitudes, where winter feed for livestock is an absolute necessity.

Topography: Livestock can be raised on a variety of terrains provided that the prevailing climate is suitable for supporting grasses.

COMMERCIAL DAIRY FARMING

This type of comparatively large-scale agricultural system is found almost totally within the temperate zones in the more industrialized, developed countries. These regions include the north-central, northeastern, and the northwestern regions of the United States, as well as the south-central region of Canada and southeastern Canada. In Europe, the dairy region stretches from northern Europe through central Russia, almost to Mongolia. Dairying is practiced intensively in Switzerland, on the east coast of Australia, and in northern New Zealand. Milk and its derivatives are the major products. Forage crops which are needed to feed livestock include pasture grasses, alfalfa, clover, corn (maize) for silage, oats, and soybean meal. Commercial crops and grains are also grown and include wheat, barley, rye, potatoes, sugar beets. The size and make-up of dairy farms is quite varied and ranges from an average of about 200 acres (80 hectares) in the United States to an average of about 40 acres (16 hectares) in Denmark.

Climate: Two types of climate are best suited for dairy farming: (1) the humid middle-latitude climate of Canada, Russia, and the northeastern United States, with its hot summers, cold winters, and year-long precipitation; and (2) the temperate marine climates of the Pacific Northwest in the United States, of Europe, Australia, and New Zealand, with moderate total precipitation, characterized by many rainy days per year, warm summers, and cool winters. Precipitation is light-to-moderate, from 20 to 40 inches (51 to 102 centimeters) per year, but can be considerably higher. There is a great variation in the number of frost-free days, ranging from nearly frost-free in some areas to as few as 90 to 120 frost-free days in Canada and northern Europe.

TRUCK FARMS AND ORCHARD OPERATIONS

The crops of this type of farming include numerous vegetables and fruits. Nut crops also fall within the category. Large commercial truck farms are frequently located near major marketing centers, or as in the case of citrus growers in California or truck farms in southern Florida, for example, they ship vegetables and fruits in winter for a thousand or more miles to market. In some truck garden areas, careful scheduling of plantings during the cooler months allows for a minimum of 2 different crops per year. Some of the high yields per unit of land area are achieved in this manner. Such operations also sometimes include extensive greenhouse operations.

Note: Adapted from data furnished by the U.S. Geological Survey, Sioux Falls, South Dakota.

TABLE 3. GLOSSARY OF CLIMATE TERMS

Acclimatization — 1. (Also called acclimation.) The process by which a living organism becomes adapted to a change of climatic environment. There has been a growing amount of research on the acclimatization of man to extreme environments such as polar and tropical regions and high altitudes. These studies are directed toward 1) determination of the internal physiological changes or skin changes produced by exposure to new climates, 2) determination of criteria for preselection (i.e., selecting the most adaptable type of man for a particular climate), and 3) development of external means of aiding adaptation (e.g., preconditioning, and modification of habits, diet, and clothing). As to usage, "acclimatization" has long been considered to be equivalent to "acclimation." In some quarters, however, a fine distinction is drawn by calling "acclimation" a purely natural process (or state), and "acclimatization" a process (or state) influenced by human agency. The recent trend, at least in the United States, is to use "acclimatization" as the all-inclusive technical term, and to leave "acclimation" (which never was accepted in Great Britain) to more or less loose popular usage. 2. The state or degree of adaptation to climate.

Agricultural Climatology — In general, climatology as applied to the effect of climate on crops. It includes especially the length of the growing season, the relation of growth rate and crop yields to the various climatic factors and hence the optimal and limiting climates for any given crop, the value of irrigation, and the effect of climatic and weather conditions on the development and spread of crop diseases. This discipline is primarily concerned with the space occupied by crops, namely, the soil and the layer of air up to the tops of the plants, in which conditions are governed largely by the microclimate.

Airmass Climatology — The representation of the climate of a region by the frequency and characteristics of the air masses under which it lies; basically, a type of synoptic climatology. It is a development of the representation of the weather associated with winds of different directions (thermal wind roses, etc.) by taking account of the source and trajectory of the air, and it gives a more dynamic picture of the climate than do monthly averages.

Artificial Climate — Climate created or modified by human activity; usually used to refer to conditions in an enclosed space, not global or local external conditions.

Birainy Climate — A climate characterized by the regular recurrence of two distinct rainy seasons annually. This is found in land regions near the equator where the heaviest rains occur shortly after the equinoxes (the equinoctial rains). It may be considered a subdivision of the tropical rain forest climate.

Bolling-Allerod — A period of warm climate beginning abruptly approximately 14 700 years ago, following the end of the Pleistocene, and extending to approximately 12 700 years ago. This warm period ended with a return to cold conditions during the Younger Dryas. Traditionally, this period is divided into the Bolling (warm), Older Dryas (cold), and Allerod (warm) intervals, but recent, more detailed climatic records indicate that the entire Bolling–Allerod period was generally warm with several abrupt coolings.

Climate Analogs — Information about past climates used as a projection of future climate.

Climate analogs generally take one of the following two forms:

1. examination of climatic patterns of periods with a particular climate characteristic (e.g., warm periods) in the instrumental or paleoclimatic record;

2. studies of groups of individual years or seasons, not necessarily consecutive, selected from the instrumental record for a particular characteristic.

Climate Anomaly — Difference between the average climate over a period of several decades or more, and the climate during a particular month or season.

Climate Change Detection — The process of demonstrating that an observed change in climate is highly unusual in a statistical sense, although a reason for the change is not necessarily provided. Attribution is the process of establishing the cause of a particular change in climate, including the testing of competing hypotheses. Climate change detection and attribution studies attempt to distinguish between anthropogenic and natural influences on climate. Any anthropogenic effect will be superimposed on the background "noise" of natural climate variability.

Climate Change — Any systematic change in the long-term statistics of climate elements (such as temperature, pressure, or winds) sustained over several decades or longer. Climate change may be due to natural external forcings, such as changes in solar emission or slow changes in the earth's orbital elements; natural internal processes of the climate system; or anthropogenic forcing.

Climate Drift — The tendency for the solution of a numerical model integration to move away from its initial conditions and toward its own climate. Typically this new climate has some unrealistic features. Climate drift may be caused by various imbalances or errors in the model parameterizations.

Climate Impact Assessments — Studies that attempt to evaluate or predict the impact of climate change on physical and ecological systems, human health, and socioeconomic sectors. The potential sensitivity, adaptability, and vulnerability of these systems and sectors to climate change can be estimated.

Climate Monitoring — Long-term observations of those quantities that describe the state of the earth's surface and atmosphere (e.g., temperature, pressure, precipitation) or climate forcing functions (e.g., solar output, atmospheric carbon dioxide concentrations).

Climate Prediction — Prediction of various aspects of the climate of a region during some future period of time. Climate predictions are generally in the form of probabilities of anomalies of climate variables (e.g., temperature, precipitation), with lead times up to several seasons (*see* climate anomaly). The term "climate projection" rather than "climate prediction" is now commonly used for longer- range predictions that have a higher degree of uncertainty and a lesser degree of specificity. For example, this term is often used for "predictions" of climate change that depend on uncertain consequences of anthropogenic influences such as land use and the burning of fossil fuels.

Climate Sensitivity — 1. The magnitude of a climatic response to a perturbing influence. 2. In mathematical modeling of the climate, the difference between simulations when the magnitude of a given parameter is changed. 3. In the context of global climate change, the equilibrium change in global mean surface temperature following a unit change in radiative forcing.

Climate Signal — (Also called climatic signal.) Variations in the state of the climate system that have an identifiable and statistically discernible structure in time and/or space.

Climate Snow Line — (Also called climatic snow line.) The altitude above which a flat surface (fully exposed to sun, wind, and precipitation) would experience a net accumulation of snow over an extended period of time. Below this altitude ablation would predominate. While this concept is largely theoretical in application, it corresponds closely to the actual firn line of a glacier and to the average summer position of the snow line in mountainous terrain.

Climate System — The system, consisting of the atmosphere, hydrosphere, lithosphere, and biosphere, determining the earth's climate as the result of mutual interactions and responses to external influences (forcing). Physical, chemical, and biological processes are involved in the interactions among the components of the climate system.

Climate Variability — (Also called climatic variability.) The temporal variations of the atmosphere–ocean system around a mean state. Typically, this term is used for timescales longer than those associated with synoptic weather events (i.e., months to millennia and longer). The term "natural climate variability" is further used to identify climate variations that are not attributable to or influenced by any activity related to humans.

Climatic Classification — The division of the earth's climates into a worldwide system of contiguous regions, each one of which is defined by relative homogeneity of the climatic elements. The earliest known classification of climate, devised by the Greeks, simply divided each hemisphere into a mathematical climate of three zones, the "summerless," "intermediate," and "winterless," thus accounting only for the latitudinal differences in solar effect (the Greek word *klima* means "inclination"). More recently, these zones have been labeled the Torrid, Temperate, and Frigid Zones. Apparently, the first major improvement over this classification was introduced by Alexander Supan in the nineteenth century. He based his zones on actual rather than theoretical temperatures, and named one hot belt, two temperate belts, and two cold caps. Supan also divided the world into 34 climatic provinces, with no attempt to relate similar climates of different locations. Another basic and much used approach recognizes other climatic controls as well as the sun. The resulting climates are called (with variations) polar, temperate, tropical, continental, marine, mountain, and probably others. Of the major climatic classifications in use today, those of W. Köppen (1918) and C. W. Thornthwaite (1931) are referred to most often. Köppen's elaborate "geographical system of climates" is based upon annual and seasonal temperature and precipitation values; his climatic regions are given a letter code designation. The major categories are tropical rainy climate, dry climate, temperate rainy climate, snow forest climate, tundra climate, and perpetual frost climate. Gorczyński (1948) devised a decimal number system similar to the Köppen classification.

Thornthwaite's (1931) bioclimatological system utilizes indices of precipitation effectiveness to outline humidity provinces, and thermal efficiency for temperature provinces; and again, a letter code designates regions. Thornthwaite (1948) introduced an approach to a "rational" classification, wherein potential evapotranspiration is used as a measure of thermal efficiency, and is compared to precipitation to form a moisture index and to show amounts and periods of water surplus and deficiency. Definite break points are revealed that are adaptable as climatic boundaries. Many authors have devised modified classifications to instruct a particular audience. An excellent example is that of C. E. P. Brooks (1951) in which climatic regions are defined with respect to human activity.

Climatic Control — Any one of the relatively permanent factors that govern the general nature of the climate of a portion of the earth. These factors include 1) solar radiation, especially as it varies with latitude; 2) distribution of land and water masses; 3) elevation and large-scale topography; and 4) the atmospheric concentration of greenhouse gases. The types of climatic controls were used as the basis for early climatic classifications. All of these have been nearly constant during historical time, but most or all of them have changed during geologic time and have caused large-scale changes of climate. *See* climate control.

Climatic Cycle — (Also called climatic oscillation.) A slowly varying change of climate about a mean that recurs with some regularity but is not necessarily periodic. The term "cycle" is used in climatology more loosely than in other physical sciences. It implies quasiperiodic behavior without any real precision in the recurrence of events. It usually indicates only that the event is more probable at the peak of the cycle than at the trough. The existence of numerous cycles has been postulated, ranging from those with timescales of geological length down to a few years.

Climatic Diagram — (Also called climagram, climagraph, climatogram, climatograph, climogram, climograph.) A graph that represents climatological information. Usually two or more climatic elements are plotted to show the changes in their relationship throughout the year. Often the climatic elements are plotted on the ordinate axis and time (usually month) plotted on the abscissa. Alternatively, the 12 monthly values of one climatic element are plotted on the ordinate versus the corresponding monthly values of another climatic element plotted on the abscissa, and the resulting points are connected with a continuous line.

Climatic Discontinuity — A climate change that consists of a rather abrupt and permanent change during the period of record from one average value (for the early part of the record) to a distinctly different average value (for the later part of the record).

Climatic Divide — A boundary between regions having different types of climate. The most effective climatic divides are the crests of mountain ranges. The boundary between two well-defined ocean currents may also act as a climatic divide.

Climatic Element — Any one of the properties or conditions of the atmosphere and ocean that together define the climate of a place (e.g., temperature, humidity, precipitation).

Climatic Factor — 1. An influence that is relevant for determining the climate state in a region; much the same as climatic control, but regarded as including more local influences, such as the effects on the climate of local aerosol loading or extensive paving in or near a city. 2. An influence that has a major effect on human activities or human history. For example, it has been suggested that climate change may have been a factor in the disappearance of the Anasazi culture in the North American southwest.

Climatic Fluctuation — A climatic inconstancy that consists of any form of systematic change, whether regular or irregular, except climatic trend and climatic discontinuity. It is characterized by at least two maxima (or minima) and one minimum (or maximum) including those at the end points of the record.

Climatic Index — A numerical value, often a function of the primary climatic elements, used to characterize the climate of a location or region.

Climatic Trend — A climate change characterized by a reasonably smooth, monotonic increase or decrease of the average value of one or more climatic elements during the period of record.

Climatic Zone — A belt of the earth's surface within which the climate is generally homogeneous in some respect; an elemental region of a simple climatic classification, for example, a zone defined by the latitudinal distribution of the climatic elements. The expressions polar, temperate, subtropical, tropical, and equatorial climate are used to indicate the climatic zones that succeed each other from the pole to the equator.

Climatography — A thorough, quantitative description of climate, particularly with reference to the tables and charts that show the characteristic values of climatic elements at a station or over an area. The term often has a comparative geographic connotation. Like descriptive climatology, it is sometimes used antithetically to climatology, when the latter is narrowly used to denote only the explanation of the causes for climatic conditions. See **Physical Climate**.

Climatological Atlas — An atlas containing maps and tables of climatic data usually including distributions of highest and lowest temperatures by month, temperature means by month, diurnal ranges of temperature by month, frequency of wind direction and speed for several class values, monthly average and extreme precipitation, number of days per month with temperatures above and/or below specified values, etc., at fixed locations over land, or within geographic areas at sea. Marine climatic atlases often include frequencies of sea level pressure values, wave heights, gale-force winds, and other phenomena of significance to mariners.

Climatological Chart — A chart on which climatological information is presented, thus identifying the characteristic values of climatic elements at a station or over an area.

Climatological Network — A network of weather stations established to observe and collect climatological data, usually recording 24-hour precipitation amounts and the daily maximum and minimum temperatures at a specified time of day. At a limited number of stations in climatological networks, records are made of additional data, such as evaporation, snowfall and snow depth, and soil temperatures at several depths.

Climatological Observation — Weather observation taken at a climatological substation. It includes recording, at least once daily, one or more of the following: maximum temperature, minimum temperature, and total precipitation since the previous observation; and may also include description of the weather (cloudy, clear, etc.) and atmospheric phenomena. Such observations compose the bulk of climatological data in the United States and over much of the world. In addition, meteorological observations are, of course, "climatological" inasmuch as they are used to derive climatological data.

Climatological Substation — A weather observing station operated by a cooperative observer (unpaid volunteer) for the purpose of recording climatological observations. This is a unique category of stations in the United States (there are about 6000 of them), but it compares to the third-order climatological station as defined by the World Meteorological Organization.

Climatonomy — An approach to the study of climate based on physics and mathematics rather than the more empirical and descriptive methods of traditional climatology. This term was coined by H. Lettau (1969) to describe his one-dimensional representation of climate based on the energy and water balances at the surface.

Coastal Climate — The climate in coastal regions resulting from the modification of the macroclimate due to the discontinuity in surface roughness at the coastline and to the different thermal and moisture properties of sea and land.

Continental Climate — Characteristic of the interior of land masses of continental size. They are marked by large annual, daily, and day-to-day ranges of temperature, low relative humidity, and (generally) by a moderate or small and irregular rainfall, with the annual extremes of temperature occurring soon after the solstices. In its extreme form, a continental climate gives rise to deserts.

Continentality — The degree to which a point on the earth's surface is in all respects subject to the influence of land mass

Cooling Degree Days — The accumulation of degrees when the average daily temperature is above 75 °F (~24 °C). It is a measure of the air conditioning and/or refrigeration required to maintain a comfort level in homes, offices, public buildings, and factories. The annual cooling degree days are a measure of the tropical nature of a climate.

Degree Day — A measure of the departure of the daily average temperature from a present standard. Degree-day accumulations during a season measure the requirements of fuel and energy needed for heating or cooling.

Desert Climate — (Also called arid climate.) A climate type that is characterized by insufficient moisture to support appreciable plant life — that is, a climate of extreme aridity.

(*continued*)

Desertification — The transformation of the climate of a region toward enhanced aridity. Desertification can result from a decrease in precipitation, as well as land surface changes such as deforestation or overgrazing.

Desiccation — 1. In general, the process of drying up. 2. In climatology, a prolonged decrease or disappearance of water from a region. This may be due to 1) a decrease of rainfall; 2) a failure to maintain irrigation; or 3) deforestation or overcropping.

Dry Climate — 1. In W. Köppen's 1918 climatic classification, the major category (B climates), which includes steppe climate and desert climate. These climates, unlike the others in his work, are defined strictly by the amount of annual precipitation as a function of seasonal distribution and of annual temperature (see formulas under steppe climate). In contrast are the rainy climates. 2. In C. W. Thornthwaite's 1948 climatic classification, any climate type in which the seasonal water surplus does not counteract seasonal water deficiency; thus it has a moisture index of less than zero. These types include the dry subhumid, semiarid, and arid climates. In contrast are the moist climates. The dry climates are subdivided further according to values of humidity index into the following: little or no water surplus; moderate winter water surplus; moderate summer water surplus; large winter water surplus; large summer water surplus.

Enhanced Greenhouse Effect — The additional greenhouse effect due to an increase in the concentration of greenhouse gases. Because of the complexity of the feedback processes within the climate system, the enhanced greenhouse effect is usually referred to in terms of the radiative forcing that results at the tropopause, after the stratosphere has come into a new radiative equilibrium. For example, thus defined, the enhanced greenhouse effect due to an effective doubling of carbon dioxide concentration from its preindustrial baseline is about 4 W m^{-2}. Note the difference in meaning from the greenhouse effect, which refers to the entire natural process and which results in a climatological average counterradiation of about 330 W m^{-2} to the surface. A comparable value for the enhanced greenhouse effect at the surface will only be obtained once the new equilibrium temperature of the surface is known, since they are strongly interrelated.

Equatorial Climate — A climatic zone with a climate typical of regions along the equator. See **Tropical Climate**.

Equilibrium Climate Response — In mathematical modeling of climate, the equilibrium climate achieved after allowing the climate system sufficient time to completely adjust to a change in external forcing.

Equilibrium Climate — A statistically stationary state of climate; in mathematical modeling of climate, the nondrifting state eventually reached under some specified external "boundary" conditions (such as the trace greenhouse gas concentrations in the atmosphere, the solar constant, and, perhaps, the geographical distributions of vegetation and glacial ice).

Freeze — The condition that exists when, over a widespread area, the surface temperature of the air remains below freezing (32 °F; 0 °C) for a sufficient time to constitute the characteristic feature of the weather. This is a general term, and the time period necessary usually is considered to be two or more days; only the hardiest herbaceous crops survive, and when it cuts short a growing season, it may be termed a "killing freeze." A "hard freeze" is a freeze in which seasonal vegetation is destroyed, the ground surface is frozen solid underfoot, and heavy ice is formed on small water surfaces such as puddles and water containers. A "light freeze" is the condition that exists when the surface temperature of the air drops to below freezing for a short time period, so that only the most tender plants and vines are adversely affected. A "dry freeze" is the freezing of the soil and terrestrial objects caused by a reduction of temperature when the adjacent air does not contain sufficient moisture for the formation of hoarfrost on exposed surfaces; with respect to vegetation alone, this is termed a "black frost."

Frost Climate — The coldest temperature province in C. W. Thornthwaite's 1931 climatic classification. It is the climate of the ice cap regions of the earth, that is, those regions perennially covered with snow and ice. It is equivalent to the more commonly used term perpetual frost climate, to the colder of Köppen's 1918 polar climates, and to Nordenskjöld's 1928 high arctic climate.

Heating Degree Days — The accumulation of the degrees which the average daily temperature is below 65 °F (~18 °C). This is the usual, but not official accepted temperature base. For example, if on a given day, the mean temperature is 53 °F, this will yield 13 degree days (65 − 53 = 13). The daily accumulations of degree days provides a measure of the fuel requirements for heating various facilities. Annual degree days thus becomes a measure of the severity of a climate.

Historical Climate — The climate of the historical period, which may be taken as the past 7000 years; generally distinguished from the period of time during which regular daily observations from meteorological instruments are available, which begins generally in the seventeenth to eighteenth centuries A.D. Thus, historical climate is the climate of a period of history for which no instrumental observations exist, but its main characteristics may be reconstructed from written descriptions.

Humid Climate — (Also called forest climate) The climate of a region where the typical vegetation is forest.

Ice Day — A day during which the maximum air temperature indicated by a sheltered thermometer does not rise above 32 °F (0 °C), and ice on the surface of water does not thaw.

Interglacial — A period of warm climate during the Pleistocene (and earlier glacial epochs) during which continental glaciers retreated to minimum extent. Interglacials have been of approximately 10 000 years duration, spaced at approximately 100 000-year intervals over the last 1 000 000 years. The last 10 000 years, or postglacial, is generally considered to be an interglacial.

Macroclimate — The averaged climate of a large geographic area, as distinguished from the mesoclimate and microclimate.

Marine Climate — Also termed maritime climate, these are climates under the predominant influence of the sea. They are found where the prevailing winds blow onshore, as, of course, on oceanic islands, and on the western coasts of the continents in middle latitudes. They extend inland either until they meet a climatic divide or, in level country, until they become modified and gradually attain greater continentality. A marine climate is characterized by small diurnal and annual ranges of temperature, with retardation of the annual extremes until one or two months after each solstice.

Mathematical Climate — An elementary generalization of the earth's climatic pattern, based entirely upon the annual cycle of the sun's inclination. This early climatic classification recognized three basic latitudinal zones (summerless, intermediate, and winterless), which are now known as the Frigid, Temperate, and Torrid Zones, and which are bounded by the Arctic and Antarctic Circles and the Tropic of Cancer and Tropic of Capricorn. What we now call "mathematical climate" probably corresponds to what was classically considered to be climate (from the Greek word *klima*, meaning "inclination"). It is sometimes used synonymously with solar climate, but the latter has a more specific theoretical connotation.

Medieval Warm Period — A period of warmer climate in much of northern Europe, the North Atlantic, southern Greenland, and Iceland from about the tenth to thirteenth centuries A.D., coinciding roughly with Europe's Middle Ages. As the number of well-understood proxy records of climate covering this time period in many parts of the world has increased in recent years, it has become clear that it would be an oversimplification to view this period as uniformly warmer in all seasons, even within the relatively limited North Atlantic/northern Europe region, let alone on a global scale (Hughes and Diaz 1994).

Mediterranean Climate — (Also called etesian climate, dry-summer subtropical climate.) Characterized by mild, wet winters and warm to hot, dry summers; typically occurs on the west side of continents between about 30° and 45° latitude.

Megathermal Climate — A type of climate characterized by continuous high temperatures in combination with abundant rainfall (in excess of evapotranspiration) throughout the year. This climate is the type required to support the growth of the plant group known as megatherms. This is an (A) climate under the Köppen classification (1931) and, as defined by Thornthwaite's climatic classification scheme (1948), this is a climate with annual potential evapotranspiration in excess of 114 centimeters (49 inches).

Mesoclimate — A climate that is intermediate between a macroclimate and a microclimate. Mesoclimate may refer to a small valley, a forest clearing, a frost hollow, and open spaces in towns and villages.

Mesothermal Climate — A type of climate characterized by moderate temperatures, that is, a region lacking the constant heat of the Tropics or the constant cold of the polar caps; middle latitude climate with definite seasonal rhythm in temperature, with amplitude ranges reaching maximum for the earth in the north intermediate zone. This is a (C) climate under the Köppen classification (1931) and, as defined by Thornthwaite's climatic classification scheme (1948), this is a climate with annual potential evapotranspiration between 57 and 114 centimeters (22 and 49 inches).

Microclimate — The fine climatic structure of the air space that extends from the very surface of the earth to a height where the effects of the immediate character of the underlying surface no longer can be distinguished from the general local climate (mesoclimate or macroclimate). The microclimate varies with and in turn

is superimposed upon the larger-scale conditions. While some rigid limits have been placed on the thickness of the layer concerned, it is more realistic to consider variable thicknesses. (Observe the microclimate of a putting green versus that of a redwood forest.) Generally, four times the height of surface growth or structures defines the level where microclimatic overtones disappear. Microclimate can be subdivided into as many different classes as there are types of underlying surface. With sufficient detail, this could be almost limitless. Currently, the most studied broad types are the "urban microclimate," affected by pavement, buildings, air pollution, dense inhabitation, etc., the "vegetation microclimate," concerned with the complex nature of the air space occupied by vegetation, and its effects upon the vegetation (*see* phytocclimatology); and the microclimate of confined spaces (the cryptoclimate) of houses, greenhouses, caves, etc.

Microthermal Climate — A type of climate characterized by low annual mean temperatures (between 0° and 14 °C (32° and 57 °F), that is, a region of genuine winter emphasized by the usual snow mantle, and a true, although many times short, summer to produce a characteristic annual climate cycle. This is a (D) climate under the Köppen classification (1931) and, as defined by Thornthwaite's climatic classification scheme (1948), this is a climate with annual potential evapotranspiration between 14 and 43 centimeters (5.5 and 17 inches).

Moist Climate — In C. W. Thornthwaite's 1948 climatic classification, any type of climate in which the seasonal water surplus counteracts seasonal water deficiency; thus it has a moisture index greater than zero. Included are the moist subhumid, humid, and perhumid climates. In contrast are the dry climates. The moist climates are further subdivided according to values of aridity index into the following: little or no moisture deficiency; moderate summer water deficiency; moderate winter water deficiency; large summer water deficiency; and large winter water deficiency. See **Rainy Climate**.

Monsoon Climate — Type of climate found in regions subject to monsoons and characterized by a dry winter and a wet summer. The monsoon climate is best developed on the fringes of the Tropics (e.g., India). The Indian subcontinent has a long winter–spring dry season that includes a "cold season" followed by a short "hot season" just preceding the rains; a summer and an early autumn rainy season that is usually very wet but varies greatly from year to year; and a secondary maximum of temperature right after the rainy season.

Mountain Climate — These climates occur in relatively high elevations, distinguished by the departure of their characteristics from those of surrounding lowlands. The one common basis for this distinction is that of atmospheric rarefaction; aside from this, great variety is introduced by differences in latitude, elevation, and exposure to the sun. The most common climatic results of high elevation are those of decreased pressure, reduced oxygen availability, decreased temperature, and increased insolation. On many tropical mountains, the forest zone extends into the level of average cloud height, which causes an excessive damp climate and produces the dense, rich forest growth known as the fog forest. The purity of high-elevation air, and the therapeutic effects of greater solar radiation, has led to the establishing of many health sanatoriums in mountain regions.

Oceanacity — Characteristic of those regions (oceans, large lakes, etc.) where the climate principally is the result of large water masses.

Paleoclimate — (Or geological climate.) Climate for periods prior to the development of measuring instruments, including historic and geologic time, for which only proxy climate records are available.

Paleoclimatic Sequence — The sequence of climatic changes in geologic time. It shows a succession of oscillations between warm periods and ice ages, but superimposed on this are numerous shorter oscillations. The tendency to regard the whole of a geologic period, lasting for 20 million years and more, as having a single type of climate is a great oversimplification, as is shown by the succession of glacial and interglacial periods in the Quaternary. Even the warm periods are known to have been made up of successions of climates of different degrees of warmth; but until much more information is available, it will not be possible to set out in detail the sequence of changes of the earlier paleoclimates.

Perhumid Climate — As defined by C. W. Thornthwaite in his 1948 climatic classification, a type of climate that has humidity index values of +100 and above. This is his wettest type of climate (letter code *A*) and compares closely to the wet climate that heads his 1931 grouping of humidity provinces.

Periglacial Climate — The climate characteristic of the regions immediately bordering the outer perimeter of an ice cap or continental glacier. The principal climatic feature is the high frequency of very cold and dry winds off the ice area. These regions have been thought to create ideal conditions for the maintenance of a belt of intense cyclonic activity.

Perpetual Frost Climate — (Also called frost climate, ice-cap climate.) In general, the climate of the ice cap regions of the world; thus, it requires temperatures sufficiently cold so that the annual accumulation of snow and ice is never exceeded by ablation. The perpetual frost climate is one of the polar climates in W. Köppen's climatic classification and is characterized by a warmest-month mean temperature of less than 0 °C (32 °F). It is designated by letter code *EF* and is equivalent to the frost climate of C. W. Thornthwaite's classifications and to Nordenskjöld's (1928) high arctic climate.

Plaeoclimatology — The study of past climates throughout geologic and historic time (paleoclimates), and the causes of their variations.

Phytoclimatology — 1. The study of the microclimate in the air space occupied by plant communities within the canopy, on the surfaces of the plants themselves, and, in some cases, in air spaces within the plants. 2. The study of climatic regions defined largely by distribution of plant species.

Physical Climate — The actual climate of a place, as distinguished from a hypothetical climate, such as that simulated by a mathematical model.

Pleistocene Climate — The climate from about 2 500 000 to 10 000 years ago, differing from earlier (Pliocene) climate in being generally colder and with greater extremes of glacial (cold) to interglacial (warm) climate. Characterized in the last 875 000 years by repeated glacials, each lasting approximately 110 000 years, punctuated by interglacials lasting 10 000 to 15 000 years. Before that, the predominant periodicity was 41 000 years rather than 110 000 years. The distribution of continents and oceans has been relatively stable during the Pleistocene, but the oscillation between glacials and interglacials has been characterized by major changes in atmospheric concentrations of optically active gases such as carbon dioxide and methane (higher in interglacials), and global changes in sea level (lower in glacials) associated with changes in the volume of ice on land (lower in interglacials). Changes in the amount, and the seasonal and latitudinal distribution, of insolation resulting from the evolving characteristics of the earth's orbit around the sun play a major role as the pacemaker of these changes.

Polar Climate — These climates generally are found in those regions of the world where temperatures are sufficiently cold so that the annual accumulation of snow and ice is never exceeded by ablation (e.g. Antarctica, Greenland). Sometimes these climates are referred to as frost climates or arctic climates. They are characterized by a warmest-month mean temperature of less than 3 °F (0 °C) and include such specific divisions as tundra, snow forest, and perpetual frost climates.

Proxy Climate Record — A biologic or geologic structure of known age from which information on past climate may be extracted; may also be used with reference to climate information extracted from historical documents. Proxy climate records are of use for times and places lacking instrumental records. Examples include fossil species assemblages from rocks, geomorphic structures, the isotopic or species composition of marine or lacustrine sediments, the isotopic and other chemical composition of polar and very high elevation ice, and the structure and chemical composition of annual growth rings in trees and growth bands in corals.

Rainy Climate — In W. Köppen's 1936 climatic classification, any climate type other than the dry climates. However, it is generally understood that this refers principally to the tree climates and not the polar climates.

Second-Order Climatological Station — A station at which observations of atmospheric pressure, temperature, humidity, winds, clouds, and weather are made at least twice daily at fixed hours, and at which the daily maximum and minimum of temperature, the daily amount of precipitation, and the duration of bright sunshine are observed.

Snow Forest Climate — A major category (the *D* climates) in W. Köppen's climatic classification, defined by a coldest-month mean temperature of less than −3 °C (26.6 °F) and a warmest-month mean temperature of greater than 10 °C (50 °F). The first limit separates it from temperate rainy climates, and the second from tundra climates. It is distinguished from the dry climates by a function of annual temperature and precipitation (see formulas under steppe climate). The outstanding feature of these climates is the cold winters with at least a month of snow-covered ground. These are the coldest of the tree climates. In C. W. Thornthwaite's classifications, this general type of climate would be 1) in the 1931 system, humid or subhumid and microthermal climate, or taiga climate; and 2) in the 1948 system, humid or moist subhumid and microthermal climate.

Solar Climate — The hypothetical climate that would prevail on a uniform solid earth with no atmosphere. Thus, it is a climate of temperature alone and is determined only by the amount of solar radiation received, that is, determined by the elevation of the sun as it varies with season. Solar climatic zones, therefore,

(*continued*)

TABLE 3. (*continued*)

are parallel to lines of latitude. The solar climate and the nearly synonymous mathematical climate have both grown out of the earliest approach to climatology, as is indicated by the fact that "climate" takes its name from the inclination (Greek *klima*) of the sun's rays.

Steppe Climate — The type of climate in which precipitation is very slight but sufficient for the growth of short, sparse grass. Also called semiarid climate. This is typical of the steppe regions of south-central Eurasia. In his 1936 climatic classification, W. Köppen assigns maximum values of annual precipitation to separate this dry climate from the rainy climates as follows. For precipitation chiefly in the winter,

$$p = 0.44(t - 32)$$

For precipitation evenly distributed during the year,

$$p = 0.44(t - 19.4)$$

For precipitation chiefly in the summer,

$$p = 0.44(t - 6.8)$$

In the above, p is the mean annual precipitation in inches, and t the mean annual temperature in degrees Fahrenheit. (For minimum values of precipitation, *see* formulas under desert climate.) This scheme was modified by Bailey to

$$p = 0.41\left(T - \frac{R}{4}\right)$$

where R is the precipitation falling during the six colder months. In Köppen's system the steppe climate is designated letter code *BS*. The semiarid climate of Thornthwaite (1931) corresponds closely to the steppe climate.

Taiga Climate — (Also called subarctic climate.) In general, a climate that produces taiga vegetation; that is, one that is too cold for prolific tree growth but milder than the tundra climate and moist enough to promote appreciable vegetation. This climate type appears as a subdivision of Köppen's 1936 snow forest climate and Thornthwaite's 1931 microthermal climate.

Temperature Climate — The variable climates found in the middle latitudes, between the extremes of the tropical and polar climates. Included in this category are such specific divisions "temperate rainy," "snow forest," and portions of "dry" climates. Mesothermal climates, within this category, are characterized by "moderate" temperature; microthermal climates by "cool" temperatures.

Temperature Rainy Climate — One of the major categories (the C climate) in W. Köppen's 1936 climatic classification. These climates have a coldest-month mean temperature of less than 18 °C (64.4 °F) and greater than −3 °C (26.6 °F), with a warmest-month mean temperature of more than 10 °C (50 °F). These limits distinguish it, respectively, from tropical rainy climates, snow forest climates, and tundra climates. It is separated from the dry climates by a function of annual temperature and precipitation. In C. W. Thornthwaite's 1931 classifications, the humid or moist subhumid and mesothermal climates would very closely correspond to the above.

Thermal Equator — The belt of maximum temperature surrounding the earth, which moves north and south with (but lagging) the sun's motion. It is also spoken of as the center of the area bounded by the yearly mean isotherms of 80 °F (∼27 °C).

Tree Climate — In W. Köppen's 1936 climatic classification, any type of climate that supports the growth of trees. This includes the tropical rainy climates, temperate rainy climates, and snow- forest climates. Excluded are the dry climates and polar climates. Tree climates are separated from polar climates by the isotherm representing the warmest month mean temperature of 10 °C (50 °F). They are separated from the dry climates by a certain value of annual precipitation as a function of temperature. In this latter sense they are also known as rainy climates. See **Rainy Climate**.

Tropical Climate — Sometimes referred to as megathermal climates, these climates are typified by the equatorial and tropical regions, having continually high temperatures and high precipitation, at least during part of the year. These are the warmest types of climates, with a coldest-month mean temperature of 64.4 °F (18 °C) or higher. Included in this category are such specific divisions as "tropical rainy," "tropical rainforest," "tropical monsoon," and "tropical savannah" climates.

Tropical Monsoon Climate — One of Köppen's 1936 tropical rainy climates; it is sufficiently warm and rainy to produce tropical rain forest vegetation, but it does exhibit the monsoon climate influences in that it has a winter dry season. Some authors do not recognize this as a separate climatic type, but rather include it within the tropical rain forest climate.

Tropical Rain Forest Climate — (Also called tropical wet climate.) In general, the climate that maintains tropical rain forest vegetation; that is, a climate of unbroken warmth, high humidity, and heavy annual precipitation.

Tropical Rainy Climate — A major category (the *A* climates) in W. Köppen's 1936 climatic classification; in order to be so classified, a climate must have these two characteristics: 1) the mean temperature of the coldest month must be 18 °C (64.4 °F) or higher, separating it from temperate rainy climates; 2) the annual precipitation must be in excess of a certain amount to distinguish it from dry climates (*see* formulas under steppe climate). The three principal types of climate included in this category are the tropical rain forest climate, tropical savanna climate, and tropical monsoon climate.

Tropical Savanna Climate — In general, the type of climate that produces the vegetation of the tropical and subtropical savanna; thus, a climate with a winter dry season, a relatively short but heavy summer rainy season, and high year-round temperatures.

Tundra Climate — Generally, the climate that produces tundra vegetation; it is too cold for the growth of trees but does not have a permanent snow–ice cover. In W. Köppen's 1936 climatic classification it is one of the polar climates, defined as having a mean temperature for the warmest month of less than 10 °C (50 °F) (in contrast to snow forest and temperate rainy climates) but higher than 0 °C (32 °F) (which is the limit of perpetual frost climate). Tundra is designated *ET*. Tundra climate appears as a temperature province in C. W. Thornthwaite's 1931 classification.

Note: Weather-related terms are given under Weather Technology.

Scientists had also become so interested in the importance of CO_2 increases in the atmosphere that, in the late 1970s, a national program was established to evaluate the effects of CO_2 increases, as well as its cycles and processes. Currently, studies are underway in which a community climate model, coupled with ocean models, is used. Similar studies made by the Goddard Institute for Space Sciences are yielding similar results. Although such appraisals on the likely effects of CO_2 remain somewhat debatable, in terms of the details, most climatologists predict that increased levels of CO_2 in the atmosphere will cause a global warming trend. Debate is largely limited to the reliability of measured data and the rate at which warming will continue and, of course, how this will affect other climatic forces.

More recently, scientists have noted increases in other gases in trace concentrations that also may have an effect on the climate comparable to that of carbon dioxide. These gases include tropospheric ozone, methane, nitrous oxide, and certain chlorocarbons. The concentration of methane alone has doubled in the past 200 years.

Since a great portion of the increases in these gases is being caused by human activities, the research has taken on an urgent quality. Most scientists believe that, as these trace gases are added, the climate will become warmer. It has been estimated that the climate is now about 0.5 °C warmer than in 1900, although one cannot be fully certain that this is a significant change, because there are natural fluctuations in temperature unrelated to changes in atmospheric composition. For example, there was an unusually warm period in the 1940s. Scientists have suggested that the ocean's thermal inertia may be delaying warming by at least a decade.

3. Eddy-Resolving Ocean Models

A key element of the climate system is the oceans, a notoriously difficult region to observe. Numerical modeling in the oceanographic

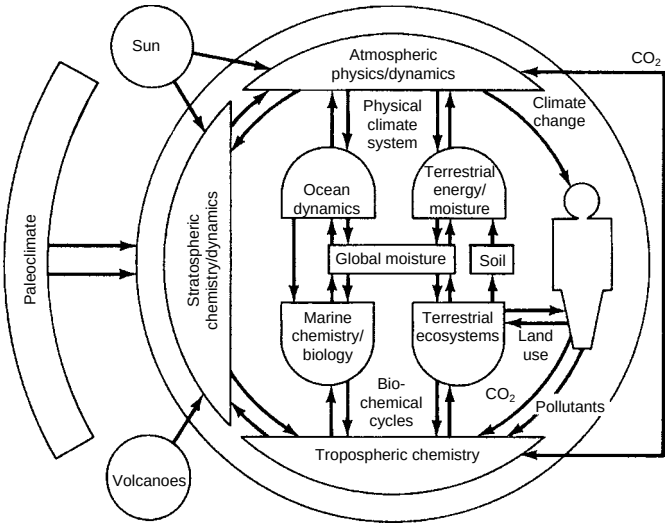

Fig. 3. Factors involved in the making of global climate. Diagram indicates areas of climatology under investigation as of the early 1990s.

sciences began in earnest only about 25 years ago. As of the late 1980s, oceanographers were beginning to model the climate of the oceans and have developed very high-resolution models that predict the flow in ocean basins quite realistically. Their simulations were now of a quality that they could begin to be coupled to the atmosphere. For example, models already predicted sea-surface temperatures in tropical regions and simulated a climatic event, such as the El Niño warming, which is described in article on **Atmosphere-Ocean Interface**.

William Holland (NCAR) observed (1985) that within 10 to 15 years, we would have a good understanding of how the ocean works, how it is driven by the atmosphere, and how other factors force its reactions. Holland estimated that by the year 2000, with still greater computer power available, it would be possible to model the entire climate system, including a sophisticated ocean. However, because of unexpected complexities and difficulties with computer modeling, the year 2000 objective was unrealistic. The particular problems of oceanographic models require that they have very high resolution in order to simulate such dynamic oceanic features as the narrow Gulf Stream, eddies, and other currents. This high resolution requires very high computational power.

Oceanographic models have matured to the point where they too need a detailed set of global observations. Data on the oceans are currently very fragmentary. The oceans, by comparison with the atmosphere, are opaque, contributing to the cost of making observations.

Contemporary Objectives of Climatology

As of 1994, climatologists, meteorologists and oceanographers were concentrating their efforts toward understanding two atmospheric phenomena. These were (1) the "Ozone Hole," which appears to be growing larger over the Antarctic region and beginning to appear over the Arctic, and (2) the "Greenhouse Theory of Climate Change." The former project is described in the article on **Polar Research**.

The Greenhouse Effect

Initial emphasis on the greenhouse effect is attributed to R.R. Revelle (Scripps Institution of Oceanography), http://www.sio.ucsd.edu/index.html who in 1957 observed that the oceans "would not soak up most of the carbon dioxide humans dump into the atmosphere." Thus, it was predicted that the buildup of CO_2 in the atmosphere would continue. Further, Revelle and a colleague, H.E. Suess, suggested that an increase in atmospheric CO_2 by a factor of 20 to 40 percent could occur over the "coming decades."

The Theory in Perspective. As of the mid-1990s, the greenhouse concept remained a theory. A greater insight pertaining to the real workability of the theory now exists, but no breakthroughs have occurred. Some scientists now are of the opinion that the sheer magnitude and complexity of the atmospheric mechanisms proposed are not amenable to breakthroughs. There remain masses of specific data to collect and other volumes of information to be correlated. Entirely new dimensions of the problem remain to be found.

In mid-1993, D.S. Chapman (University of Utah) and H.N. Pollock (University of Michigan) observed: "The proportion of carbon dioxide in the atmosphere has risen by more than 20 percent and that of methane has roughly doubled. The proposition seems reasonable that the greenhouse gases are responsible for the warming trend. Yet the case is not airtight. It is conceivable that the matching increases in temperature and greenhouse gases are a statistical coincidence and that the two variables have nothing to do with each other in the long run." (See reference listed.)

Until recently, it appeared that somewhat of a consensus had developed in the scientific community to the effect that global warming has or will occur as the result of anthropogenic causes (air pollution, deforestation, et al.). This may prove to be a gross oversimplification. There now is a growing trend among at least some meteorologists, climatologists, oceanologists, and geothermal researchers to reinventory the numerous causes and effects of a rise in global temperature; in fact, to reevaluate the short-term and long-term seriousness of the problem; and, in particular, to reassess past proposed corrective measures.

As pointed out by A.R. Solow and J.M. Broadus, "Most of our information about the possibility of climate change comes from experiments with large-scale numerical climate models run on computers and therein lies the problem. All too often, the results of these experiments are treated as if they represent a picture of future climate as accurate." (See reference listed.) The aforementioned researchers also observe, "Certainly, any response designed to cope with a rapid change of large magnitude could be a costly mistake if the world's climate changed much more slowly and modestly." One also should recall that it was only a comparatively few decades ago that some scientists and numerous lay people feared the return of the Ice Age!

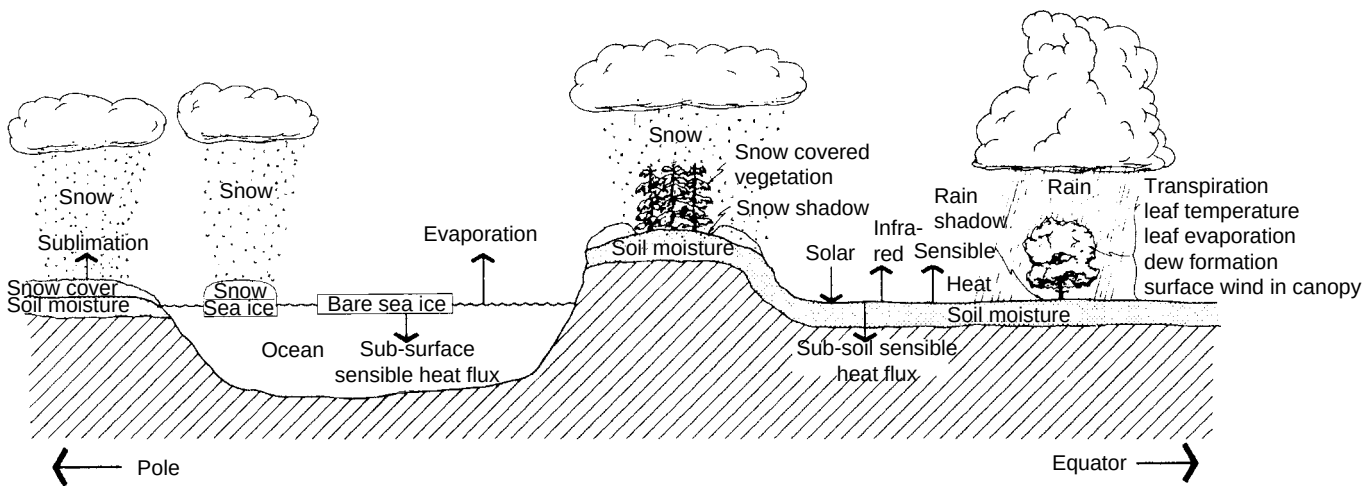

Fig. 4. Some of the many interactions that are built into advanced general circulation models (GCM) of Earth's atmosphere to simulate climate/weather systems.

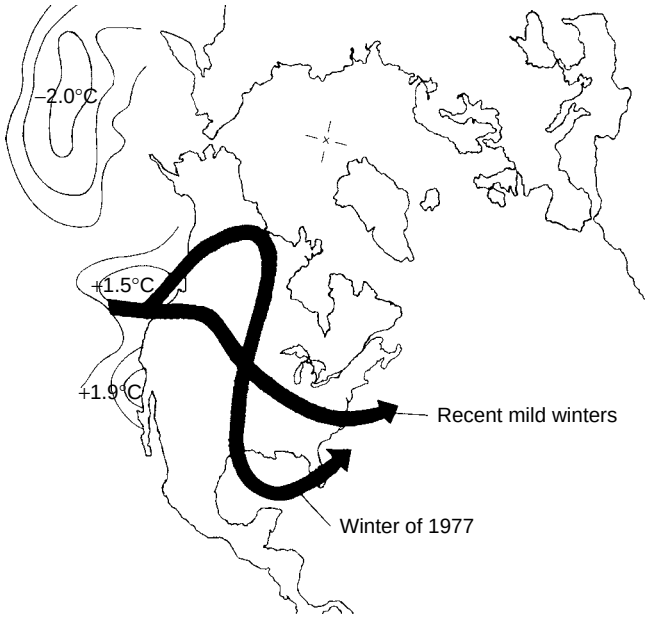

Fig. 5. Contrast of conditions that create a mild or severe winter in parts of North America. The **bold arrow** indicates the path of the jet stream.

In 1991, T.R. Karl, R.R. Helm, Jr., and R.G. Quale (National Oceanic and Atmospheric Administration, Global Climate Laboratory) reported on computerized climate models in an effort to demonstrate the effects of enhanced greenhouse gas concentrations on the climate of central North American (roughly the middle third of the United States, extending from the Canadian border to the Gulf of Mexico). As pointed out by the researchers, adequate supplies of water for crops and livestock are of critical importance to this region. The model projected a temperature increase of 2° to 4 °C (3.6° to 7.2 °F), an increase of up to 15 percent in winter precipitation, and a decrease of 5 to 10 percent in summer precipitation by the year 2030. An alarming finding but not substantiated.

In an effort to evaluate the foregoing projections, the researchers checked the climate record for the region over the past 95 years. The researchers observe, "Results indicate that temperature has increased and precipitation decreased both during winter and summer, and that the ratio of winter-to-summer precipitation had decreased. The signs of some trends are consistent with the projections whereas others are not, but none of the changes is statistically significant except for maximum and minimum temperatures, which were not among the parameters predicted by the models." The investigators further conclude, "Statistical models indicate that the greenhouse winter and summer precipitation signal could have been masked by natural climate variability, whereas the increase in the ratio of winter-to-summer precipitation and the higher rates of temperature change probably should have already been detected."

The essence of the research report concludes, "If the models are correct, it will likely take at least another 40 years before statistically significant precipitation changes are detected and another decade or two to detect the projected changes of temperature."

Fundamental Points of Greenhouse Theory. The process involves the selective transmission of short wave solar radiation by Earth's atmosphere, leading to the absorption of this energy by Earth's surface, followed by reradiation in the form of infrared radiation (IR) which is absorbed and partly radiated back to Earth's surface by carbon dioxide and water vapor in the atmosphere.

In an important 1988 paper, V. Ramanathan (University of Chicago) reported on the action of atmospheric carbon dioxide and a few other gases including methane (CH_4), nitrous oxide (N_2O), chlorofluorocarbons, and carbon tetrachloride (CCl_4).

Ramathan describes the greenhouse effect, "The gases (previously mentioned) absorb infrared (IR) radiation (also known as terrestrial or thermal radiation) emitted by the relatively warmer surface and emit radiation to space at the colder atmospheric temperatures, leading to a net trapping of IR energy within the atmosphere (the greenhouse effect). The long-term climate is governed by a balance between the absorbed solar radiation and the emitted IR. When there is enhanced IR trapping, for example, as a result of an increase in the concentrations of gases (previously mentioned), excess energy is suddenly available to drive the climate system. The result, according to the theory, is a 'vigorous' climate system, that is, a warmer globe with a more active hydrological cycle. The earth warms until the excess IR energy trapped by the greenhouse gases is radiated to space as IR emission. Because of the nonlinear interactions between the atmosphere, the cryosphere (ice and snow), the oceans, and the land, the predicted warming is not uniform but varies significantly with latitude, longitude, altitude, and season. The temperature and pressure gradients that result from the nonuniform warming patterns can alter the general circulation of the atmosphere and the oceans."

The Ramanathan paper traces the greenhouse concept back to Jean-Baptiste Fourier (1827) and to Arrhenius (1896), who studied the climatic effects of changes in atmospheric CO_2 content and forecasted that a doubling of atmospheric CO_2 would cause global warming by 5 K. These early findings are part of the incentive to tackle the warming problem en force. See also **Greenhouse Effect**; and **Greenhouse Gases**.

Deforestation. Although most scientists attribute anthropogenic pollution as the main cause of accumulating excessive quantities of carbon dioxide and other gases in Earth's atmosphere, deforestation also has been suggested as a factor, perhaps accounting for 7 to 10 percent of the accumulation. A report of the late 1980s by the World Resources Institute estimated that 80,000 square kilometers (30,888 square miles) of tropical forest (about the size of the state of Maine) were razed each year. Tropical forests are a sizable reservoir of carbon. Some researchers stress that deforestation is a major source of the increasing amount of carbon dioxide in the atmosphere. If that is the case, it may have a severe impact on

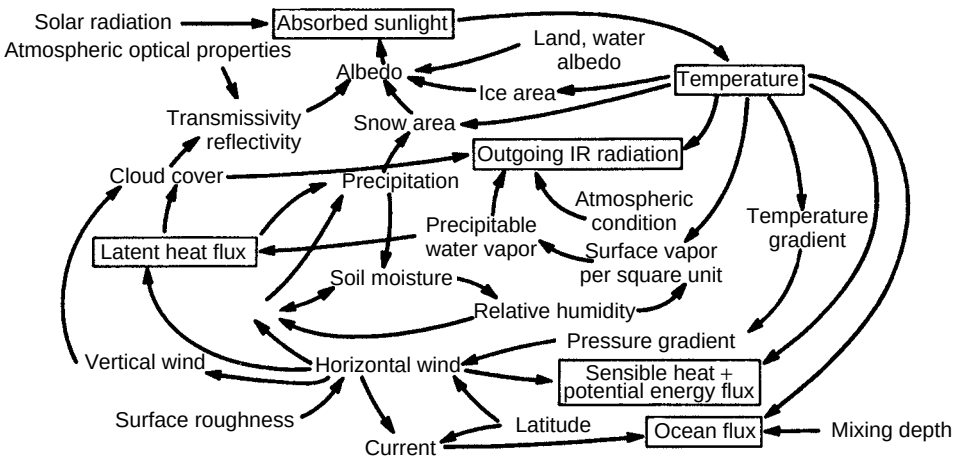

Fig. 6. Climatic cause-and-effect linkages. The complexity of climatic variables and their interactions is shown here, as prepared by W. Sellers (University of Arizona).

the earth's climate through the "greenhouse" effect. To improve the reliability of surveys, often colored politically by local governments, renewed attention is being given to satellite surveys.

In the satellite surveys (*Landsat*), healthy vegetation absorbs red light and reflects near-infrared radiation. Bare ground is brighter than vegetation in the red-spectral band and less bright in the near infrared. When a patch of forest is cut down, or when cleared land is cultivated, the change is visible in *Landsat* images. By superpositioning *Landsat* images and subtracting the later one from the earlier one, pixel by pixel, the change can be measured with considerable accuracy. Each pixel (picture element) in a *Landsat* image covers an area 59 meters (194 feet) by 70 meters (230 feet).

The technique was applied by Woodwell and colleagues (Woods Hole Research Center) to the Brazilian state of Rondônia in the southwestern Amazon basin. Before 1960, the area was essentially untouched tropical forest. In recent years of development, through the political process of giving 100 hectare (10,000 acre) plots to settlers, by 1982, the settlers had cleared at least 11,400 square kilometers (4,402 square miles) of forest.

Summer Soil Wetness. Researchers at the Geophysical Fluid Dynamics Laboratory (Princeton University) suggest that although most discussions of climatic changes due to increasing concentrations of carbon dioxide in the atmosphere center on a rise in atmospheric temperature, for agricultural planning, the change in soil wetness may be just as important. Manabe and Wetherald investigated effect on soil wetness.

Historical and Paleoclimatology

Climatologists find that looking back for many years into climatic information can be rewarding as a way of highlighting the past magnitude of climatic changes and, in some cases, revealing characteristics of their cyclic nature. Unfortunately, reliable records in many parts of the world go back only about a century. Prior to that time, there was no established network of weather observations and the instruments used were crude. There are a few exceptions of a highly qualitative nature, such as the drought years experienced in Guatemala, records of which extend back to 1563, the first recording made by the Spanish. Considerable detail on these records and their meaning to the people of Guatemala over the centuries is given by Roberts et al. (see reference). The U.S. government has made records of global temperature variations since 1870. For these records, global temperature is defined as equivalent to annual mean temperature between latitudes 0° and 80° N. The period between 1880 and 1884 is used as the zero reference base. With the general exception of the 1880s, when the annual mean temperature dropped 0.2 °C, the temperature has slowly cycled upward to a peak (+0.4 °C) in the early 1940s, after which it commenced a cyclic downturn. See Fig. 7.

From a theoretical standpoint, studying the climate of the earth back thousands and millions of years also is valuable and exceptionally interesting. The paleoclimatologist has nothing beyond permanent natural markings and phenomena that remain and that suggest a connection with prior climatic conditions.

For example, fossil evidence from the Cretaceous period (about 100 million years ago), indicates that broad-leaved tropical plants grew in the mid-latitudes (now temperate zones). Alligators lived near the Arctic Circle. Sea levels were hundreds of meters higher. Evidence indicates that the interiors of continents remained above freezing even in winter. One explanation for this climatic difference credits the much greater efficiency of oceanic currents which spread the energy received from the sun in equatorial areas much more uniformly around the earth. It is also assumed, of course, that the continents were differently shaped, thus affecting the contours and transporting speeds of the ocean currents. Some students suggest that a "greenhouse" effect may also have been present. Geochemical observations indicate that carbon dioxide and other gases escape from the earth's interior at midocean rifts. At a rift, two plates that make up the earth's surface spread apart and molten rock rises into the gap. Many investigators believe that the mid-Cretaceous was an era of rapid plate motion and thus an era of high CO_2 emissions.

Orbital Variations as Clues. Inasmuch as the tilting of the earth is so important to the existence of climatic variations on the earth in a very obvious and fundamental way, it seems logical that one could attribute changes in climate at least partially to orbital variations. This concept was put forth by Milutin Milankovitch in the 1940s. At that time, there was limited geologic evidence that climatic changes had resulted from subtle changes in the orientation of the earth's pole or of the shape of the earth's orbit. During intervening years, the reality of orbital control of climate has been evidenced, this brought about by improved geologic records and methods of analysis largely pertaining to a more reliable chronology of glaciations.

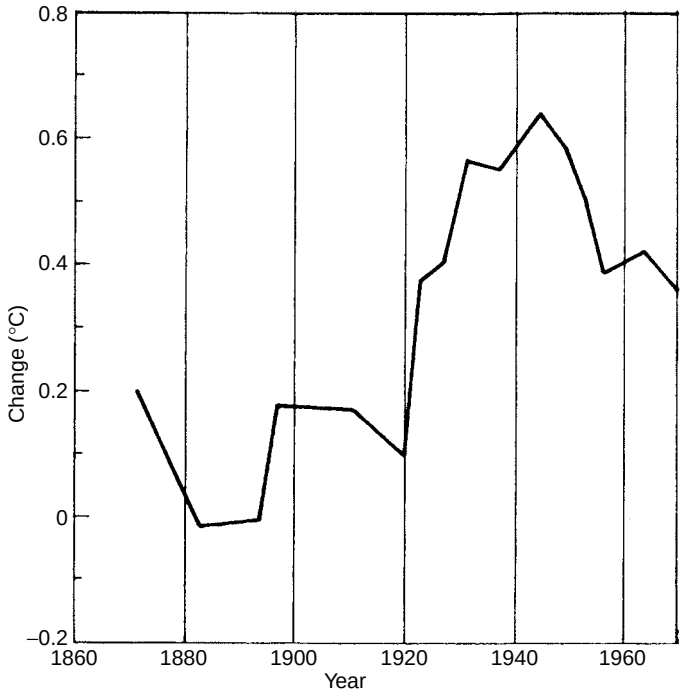

Fig. 7. Global temperature variations since 1879. The global temperature used here is equivalent to annual mean temperature between 0 and 80 °N latitude. The period of 1880–1884 is used as zero reference base.

As recently as 18,000 years ago, one-third of the earth's land surface was covered with ice. Reliable geologic marking of the glacier and particularly of the southern end of the glacier (moraine) is observable in the United States and Europe. When geologists began mapping the glaciated areas, they found a number of distinct layers, indicating that the earth had undergone many glaciations, and it was later estimated that the first extensive glaciation may have occurred in the Precambrian, some 500 or more million years ago. Thus, the Ice Age actually becomes Ice Ages. Better glaciation chronologies have been developed in relatively recent years by deducing the global volume of ice from the ratio of two isotopes of oxygen in ocean sediments deposited at the same time. As an ice age starts, the continental ice sheet grows, removing water from the ocean. The ocean water remaining becomes enriched in oxygen-18, the heavier of the two isotopes. Essentially the ratio is determined by examining shells of marine organisms that contain calcium carbonate. Since the shells fall to the ocean floor, the higher the ratio of oxygen-18 to oxygen-16 in a sediment indicates the extent of land ice when the sediment was formed. Compared with other methods, the isotope-ratio approach has two distinct advantages: (1) the record can be global, and (2) reasonably continuous records are available as contrasted with the gaps in data found from recording rocks on land.

Perhaps the oxygen-ratio data can be used to test the Milankovitch theory, a concept that has not enjoyed universal acceptance. Calculations made from the isotope data confirm prior estimates that ice-age fluctuations appear once every 100,000 years. As pointed out by Covey (see reference), the peaks in a data plot from isotope data reveal peaks that are asymmetric, sawtooth in shape, and that indicate ice was laid down over a longer period of time than was required to melt it. Smaller fluctuations are superimposed on the dominant 100,000-year cycle. Thus, to an analyst, it appears that in some way the climate has responded to some continual, what might be termed a forcing oscillation.

It would seem reasonable to assume that during an ice age the earth receives less radiation (thermal energy) from the sun. What mechanism might bring this about? Two answers become candidates: (1) oscillations in the output of the sun, concerning which we are just beginning to collect and analyze more reliable information, discussed later in this article; or (2) oscillations in the earth mass exposed to receive solar radiation. This

leads to the Milankovitch theory. Covey points out that three quantities are required to specify the earth's orbit in terms of insolation (energy received from the sun): (1) the obliquity (angle or tilt) of the earth's axis with respect to the plane of its orbit (23.5°); (2) orbital eccentricity departure of orbit from a perfect circle to an ellipse (0.017); and (3) precession (direction in which the earth's axis points slowly changes).

With the aid of several pages of text and numerous excellent illustrations, Covey concludes with the observation that it seems clear that there is a connection between the earth's orbit and the ice ages, but offers words of caution. Orbital forcing is only one of many factors that could potentially have changed the climate. An example of another possible cause would be particulates in the upper atmosphere caused by large numbers of volcanic eruptions. The advantage of the Milankovitch theory is that it can be tested. The changes in the earth's orbit and hence insolation can readily be calculated by applying Newton's law of gravity to progressively earlier configurations of the bodies in the solar system. Climatologists usually prefer to experiment with well-defined forcing factors, such as orbital variations, but the lack of information about other forcing factors does not detract from their importance.

There appears to be a growing acknowledgment of the Milankovitch theory, at least in part. The gnawing concern of some researchers relates to how orbital variations could by themselves cause such dramatic climatic changes, such as the ice ages. Some researchers believed that such major changes simply cannot be explained on the basis of insolation alone. This is where the "greenhouse" effect, previously mentioned, reenters the discussion.

By analyzing for the carbon dioxide content of polar ice cores, researchers at the University of Bern (Switzerland) developed a 40,000-year record of atmospheric CO_2. They found that ice some 20,000 years old (approximate time of last ice age) contained concentrations of CO_2 that were from 40 to 100 ppm lower than the estimated 280 ppm, the figure traditionally believed to be the concentration prior to fossil fuel burning commenced on earth. Data indicate that CO_2 began a geologically rapid rise that continued until it reached the approximate pre-industrial levels of some 10,000 years ago. The Bern measurements were confirmed by a separate group of researchers at the University of Cambridge, who used different methodologies.

If there were no interfering factors, carbon dioxide would distribute between water and air on the basis of its chemical solubility. It has been well established that the ocean's absorbance of CO_2 is much greater than by the mechanism of chemical solubility alone. In fact, of course, microorganisms and microscopic plants biochemically take up CO_2 for tissue and structure building and ultimately drop their shells, etc. in the form of carbonates. Although an oversimplification, the mechanism has been described as a "biological pump," wherein carbon from the surface and atmosphere are transferred to the sea bottom, thus becoming a key control mechanism for fixing CO_2 levels in the atmosphere.

While much further research is required, as reported by Kerr, to be a convincing agent of climate change, CO_2 must also help to amplify the minor direct effects of orbital variations on climate. Numerous theories have been proposed and it is expected that a few years will pass before such theories can be tested. As previously pointed out, until climatologists can explain why atmospheric CO^2 ranged so widely in past geologic ages, some uneasiness will persist concerning present forecasts of a destructive "greenhouse" effect in the relative near term for the global climate.

CLIMATE CHANGE. The term "climate change" is sometimes used to refer to all forms of climatic inconsistency, but because the Earth's climate is never static, the term is more properly used to imply a significant change from one climatic condition to another. In some cases, climate change has been used synonymously with the term, "global warming"; scientists,

however, tend to use the term in the wider sense to include natural changes in climate also. See also **Global Warming**.

CLIMATE MODEL. A model used to make forecasts or simulations of climate. Most climate models are closely related to NWP models. In general, the equations for the atmosphere are those for momentum, continuity, the equation of state, the law of thermodynamics, and water vapor continuity, although simplified sets of governing equations may also be used. Depending on the climate timescale of interest, the atmospheric model may be coupled to similar models for the ocean (including the deep ocean for timescales greater than a year), the land surface and biosphere, land snow and ice, and sea ice. For longer timescales, variation in external forcing factors (solar radiation) may also be important. Because climate models are generally integrated for periods of many years, they have traditionally been run at lower resolution than NWP models to reduce computational costs.

CLIMATOLOGICAL ATLAS. An atlas containing maps and tables of climatic data usually including distributions of highest and lowest temperatures by month, temperature means by month, diurnal ranges of temperature by month, frequency of wind direction and speed for several class values, monthly average and extreme precipitation, number of days per month with temperatures above and/or below specified values, etc., at fixed locations over land, or within geographic areas at sea.

Marine climatic atlases often include frequencies of sea level pressure values, wave heights, gale-force winds, and other phenomena of significance to mariners.

AMS

CLIMATOLOGY. Climatology is the study of climate, and is a branch of the atmospheric sciences. In contrast to meteorology, which studies short term weather systems lasting up to a few weeks, climatology studies the frequency with which these weather systems occur. It does not study precise instances of atmospheric phenomena (for example cloud formation, rainfall and thunder), but rather their average occurrence over years to millennia, as well as changes in long-term average weather patterns, in relation to atmospheric conditions. Climatologists, those who practice climatology, study both the nature of climates - local, regional or global - and the natural or human-induced factors that cause climates to change. Climatology considers both past and potential future climate change.

Climatology is approached in a variety of ways. Paleoclimatology seeks to reconstruct past climates by examining records such as ice cores and tree rings (dendroclimatology). The study of contemporary climates incorporates meteorological data accumulated over many years, such as records of rainfall, temperature and atmospheric composition. Knowledge of the atmosphere and its dynamics is also embodied in models, either statistical or mathematical, which help by integrating different observations and testing how they fit together. Modeling is used for understanding past, present and potential future climates.

"Climate Is What You Expect. Weather Is What You Get"

Weather is the condition of the atmosphere over a brief period of time. For example, we speak of today's weather or the weather this week. Climate represents the composite of day-to-day weather over a longer period of time.

People in Minneapolis–St. Paul expect a white Christmas, and people in New Orleans expect very warm, humid summers. And a traveler going to Orlando, Florida, in March will not pack the same kind of clothing as a traveler going to Vail, Colorado, in March. These examples show how climate influences our daily lives. Additionally:

- Our houses are designed based on the climate where we live.
- Farmers make plans based on the length of the growing season from the last killing freeze in the spring to the first freeze in the fall.
- Utility companies base power supplies on what they expect to be the maximum need for heating in the winter and the maximum need for cooling in the summer.

A climatologist attempts to discover and explain the impacts of climate so that society can plan its activities, design its buildings and infrastructure, and anticipate the effects of adverse conditions. Although climate is not weather, it is defined by the same terms, such as temperature, precipitation, wind, and solar radiation.

Climate is usually defined by what is expected or "normal", which climatologists traditionally interpret as the 30-year mean. By itself, "normal" can be misleading unless we also understand the concept of variability. For example, many people consider sunny, idyllic days normal in southern California. History and climatology tell us that this is not the full story. Although sunny weather is frequently associated with southern California, severe floods have had a significant impact there, including major floods in 1862 and 1868, shortly after California became a state. When you also factor in severe droughts, most recently those of 1987–94, a more correct statement would be that precipitation in southern California is highly variable, and that rain is most likely between October and April.

The misconception that weather is usually normal becomes a serious problem when you consider that weather, in one form or another, is the source of water for irrigation, drinking, power supply, industry, wildlife habitat, and other uses. To ensure that our water supply, livelihoods, and lives are secure, it is essential that planners anticipate variation in weather, and that they recognize that drought and flood are both inevitable parts of the normal range of weather.

Climatology provides benchmarks, such as the drought of record. The drought of record is the drought remembered as having the greatest impact on a region. Most of us are not consciously aware of how much the climate fluctuates from one decade or century to the next. One way for reservoir managers, municipal water suppliers, and other planners to check reality is to compare expectations of water supply against a region's drought of record. But caution is necessary here: although the weather conditions could recur, the impacts would likely be very different. For most of the country, the drought of record was 30 to 60 years ago, and population concentrations and water use patterns have shifted substantially since then. Planners need to consider and watch out for a variety of problems and misconceptions.

Specifically, climatology answers crucial questions such as:

- How often does drought occur in this region?
- How severe have the droughts been?
- How widespread have the droughts been?
- How long have the droughts lasted?

Examining water supplies and understanding the impact of past droughts help planners anticipate the effects of drought:

- What would happen if the drought of record occurred here now?
- Who are the major water users in the community, state, or region?
- Where does our water supply come from and how would the supplies be affected by a drought of record?
- What hydrological, agricultural, and socioeconomic impacts have been associated with the various droughts?
- How can we prepare for the next drought of record?

See also **Climate**.

CLIMAX (Ecology). The final stable stage of development that a community, species, flora, or fauna attains in a given environment. The major world climaxes correspond to formations and biomes. See also **Biome**; **Ecology**; and **Formation (Ecology)**.

CLINICAL CHEMISTRY. A subdivision of chemistry that deals with the behavior and composition of all types of body fluids, including the blood, urine, perspiration, glandular secretions, etc. It involves analysis and testing of these for content of numerous metabolic constituents, as well as foreign materials; thus it also includes toxicological factors.

CLINOMETER. Essentially a divided-circle instrument that simplifies the transfer of angles between planes. Bubbles or electronic levels frequently are used to establish the null setting principle of a precision clinometer, while less precise instruments utilize the comparison of an angle measured to a datum surface. Angular indications using a clinometer are established by placing the instrument successively on mutually inclined surfaces. The differences between the two observed readings is the angle between the surfaces. By this same principle, the clinometer may be moved to another surface, such as the face of a machine bed, and the readings compared. By adding an autocollimating telescope, a clinometer can be used as a goniometer.

For a single-sided divided-circle system, the composite errors of centering and scale dividing will approach 10 seconds of arc. Calibration may be accomplished by using autocollimators and precision polygons, or precision angle gage blocks. Calibration values also may be derived by comparing readings circle right and circle left, or by evaluating the instrument on an angle generator or sine plate. Calibration factors are furnished by the manufacturer with each instrument.

CLINOZOISITE. Clinozoisite, crystallizing in the monoclinic system, is a hydrous calcium aluminum silicate, $Ca_2Al_3Si_3O_{12}(OH)$. Crystals are usually of prismatic habit with striations parallel to the *b*-axis. May occur as granular or columnar masses. Hardness 6.5, sp gr 3.21–3.38, vitreous luster, transparent to translucent. Color gradations from gray through green to pink.

Clinozoisite occurs in crystalline schists, which are products of metamorphism from calcic feldspar-rich dark igneous rocks. Zoisite (orthorhombic) represents its dimorphous counterpart.

CLO. A unit of thermal insulation, usually applied to clothing or bedcovers. It is defined as the amount of insulation necessary to maintain comfort and a mean skin temperature of 33 °C (92 °F) for a person who is producing heat at the standard metabolic rate (50 Kcal m^{-2} of body surface per hour; one met) in an indoor environment characterized by a temperature of 21 °C (70 °F), relative humidity of less than 50%, and air motion of 6.1 m min^{-1}. If it is assumed that 76% of the metabolic heat is lost through the clothing, the unit can be defined in physical terms as the insulation that will restrict heat loss to 1 Kcal m^{-2} h^{-1} with a temperature gradient of 0.18 °C (32.32 °F) across the fabric. In the first approximation, an insulation of one clo is provided by clothing material with a total thickness of 0.64 cm (0.25 in) and air layers (between skin and clothing and between inner and outer garments) of about 0.51 cm (0.20 in).

AMS

CLOACA. A chamber at the end of the gut which receives the ducts of the reproductive and excretory systems. A cloaca occurs in the rotifers and in many vertebrates but in most mammals it is present only during embryonic life.

CLOCK (Biological). See **Circadian Clock**.

CLOCKS. A clock (from the Latin *cloca*, "bell") is an instrument for measuring time, (Usually, for measuring time of intervals less than a day — as opposed to a calendar.) Those used for technical purposes, of very high accuracy, are sometimes called chronometers. A portable clock is called a watch. The clock in its most common modern form (in use since at least the 14th century) displays the hours, minutes, and sometimes seconds that pass over a twelve or twenty-four-hour period.

The measurement of time is important in so many phases of human activity that it has long engaged the inventive genius of mankind. Far in the past people discovered that the prime requisite of time-measuring devices was a process that occurred at a uniform rate. Water clocks and hourglasses were based essentially upon the flow of a known volume of homogeneous substance through an opening. While such processes are obviously subject to errors that were difficult to avoid, such as temperature effects, they measured time periods of moderate duration with sufficient accuracy for the needs of their time. See also **Water Clocks**.

The sundial, which was also used in the earlier days, is discussed in a separate article. See **Sundial**.

The era of modern time-keeping can be said to have begun with the use of periodic processes for time measurement, and it may be traced directly to Galileo's discovery of the isochronism of the pendulum. A direct statement about the pendulum is that the period of a simple pendulum is a function of its length and not of its initial displacement. For example, if you raise the bob of a pendulum two inches, then release it and observe its period; after which you raise it four or five or six inches, and also release it and observe its period, you will find that the period remains the same. The bob merely moves more slowly over the short path than the longer one. Therefore, once men had invented a mechanism to supply the energy lost by the pendulum due to friction at its point of suspension and with the air, they were able to construct clocks as we know them today. Furthermore, when they discovered that a balance wheel turning against a spring also had a constant period they were able to produce watches as well as clocks.

The accuracy of both watches and clocks depends upon certain factors. Obviously the length of a pendulum or the dimensions of a balance wheel will change with temperature, and therefore inventors moved in the direction of greater accuracy by endeavoring to compensate for this error. One such method was the construction of these parts partly or wholly from bimetallic elements so that the overall change in dimensions with temperature would be minimized. Still another step was operation in a vacuum, to avoid the friction of the air. However, there is a practical limitation upon the extent to which the errors inherent in pendulum and balance wheel time-keepers can be minimized. See **Chronograph**; **Chronometer**; **Electric Clock**; **Pendulum Clock**; **Spring Clock**; and **Tuning Fork**.

One type of electric clock is designed to operate in synchronism with the 60-cycle current supplied by the power companies. Since their alternators must operate within a narrow frequency-range around 60 cycles per second in order to remain in synchronism, this type of electric clock is sufficiently accurate for many purposes. However, for precise scientific work a much higher degree of accuracy has been obtained from the vibrations of crystals exhibiting an electrostrictive effect. That is, any given kind of crystal, when subjected to an alternating electric field, tends to vibrate at a characteristic rate. With proper control of temperature, vibrating crystals can remain within a far smaller frequency range (i.e., inverse of period) than the devices previously mentioned in this article. Therefore, crystals are used to control oscillators, not only those which operate clocks, but those which control frequencies of broadcasting stations, and those used for other purposes.

Atomic Clock

A great advance in the accuracy of time measurement resulted from observations of various periodic processes occurring in atoms and molecules. The first atomic clock was the ammonia clock invented at the United States National Bureau of Standards in 1948. The former National Bureau of Standard (NBS) now is the National Institute of Standards and Technology (NIST), Gaithersburg, Maryland. It made use of an oscillating system in the ammonia molecule (NH_3) which may be regarded as having its three hydrogen atoms occupying positions corresponding to the three lower corners of a pyramid, while the nitrogen atom is at the apex. The periodic process in question is the vibration of the nitrogen atom up and down through the base of the pyramid, so that its limiting lower position is at the apex of another pyramid below the first one and symmetrical with it. The period of this oscillator is 23,870 megacycles. Therefore, if radiowaves of this frequency are passed through a chamber filled with ammonia, they will be strongly absorbed. The design of the first atomic clock was based upon a quartz-crystal oscillator as described above, which supplied oscillatory energy through an ammonia chamber designed to absorb energy of the correct frequency, and to permit energy to pass when it varied from the correct frequency. This "passing" energy was used in a feedback circuit to correct the original oscillatory circuit. See **Crystal Oscillator**.

This ammonia clock gave far more accurate time-keeping than had ever been known before. In fact, some models have controlled frequency within three parts per billion. Yet even more accurate time-measuring devices have been developed. The cesium clock designed at the Bureau of Standards requires the use of vaporized cesium metal obtained from an electric furnace. The atomic process here involves a transition in the precession axis (hence electromagnetic field) of the outer electron of the cesium atom. The required radio frequency is 9, 192, 631, 770 Hz (cycles per second) and the possible accuracy is to a variation of less than one part in ten billion. So unvarying, in fact, is this process that it has been made the definition of the second.

Devices using such processes have been denoted by the general term "atomic clock," which has been loosely applied to any device that depends for its constancy of rate on the frequency of a spectral line, i.e., on the energy difference of two states, for the measurement of time intervals. In

some cases they are those of an atom, e.g., the two states into which the ground state of cesium is separated in a magnetic field; in other cases they are those of a molecule, e.g., in the vibration spectrum of ammonia.

Successful atomic clocks have been built employing a beam of cesium atoms. The beam is first separated into two components by an arrangement similar to that used in the Stern-Gerlach experiment. If the component made up of atoms in the lower of the two possible states is passed into a resonant chamber fed by an oscillator, the atoms will absorb energy and be raised to the higher state if the microwave frequency of the oscillator is just that for resonance absorption. A second resolution of the beam then again gives two components with opposite spin; the relative intensities of these two may be measured and may be used to keep the oscillator in exact resonance. The period of oscillation is thus matched to the frequency of the spectral line, and the number of oscillations in a time interval may be counted by electronic and/or mechanical means.

Continuing Evolution of Atomic Clock. The world's first atomic clock was demonstrated nearly a half-century ago by NIST, but research continues toward the development of even more precise clocks. The ^{133}Cs clock, upon which the current standard *second* is defined, has an accuracy of less than 1 second in 3 million years. Scientists at NIST forecast that accuracies may approach 1 second in 10 billion years. (This, incidentally, is the estimated age of the universe.) A NIST researcher has observed that such a superclock will not require any breakthrough because the principles are well understood and that only some refinements in theory and practice are required. Such accuracy may seem unnecessary, even to some scientists, but persons in the navigation and satellite field and the designers of supercomputers do not agree.

In present atomic timekeeping, frequency changes are measured by vaporizing atoms and sorting them by use of magnets that separate the shifted from the unshifted atoms. Because of the Doppler effect, current atomic clocks are less precise than the methodologies now being studied.

In the future, by trapping and vaporizing a single atom, most of the Doppler error can be eliminated. This can be accomplished by using converging laser beams to isolate an atom that is nearly perfectly still.

In the meantime, cadmium remains a very well suited atom for the purpose, but some NIST researchers indicate that mercury may be even better for future atomic clocks. The search for better candidate atoms is large, as indeed is the number of elements in the Periodic Table that can be investigated. See also **Time**.

Specific Types of Clocks

Alarm Clock. These clocks are designed to make an alarm sound at a specific time. The primary use of these clocks is to awaken people from their sleep in order to start their days in the mornings, but they are sometimes used for other reminders as well. To stop the sound, a button or handle on the clock needs to be pressed, and some stop automatically after a few minutes if left unattended. A classical analog alarm clock has an extra "hand" that is used to specify the time at which to activate the alarm.

Traditional mechanical alarm clocks have a bell on top that rings, but digital alarm clocks can make other noises. Simple battery-powered alarm clocks make a beeping sound whereas novelty alarm clocks can speak, laugh, or sing. Some alarm clocks have radios that start playing at specified times, and are known as *clock radios*.

In a mechanical bell-style alarm clock, a spring drives a gear that propels a clacker back and forth between two bells or between the sides inside a single bell. In an electric bell-style alarm clock, the bell rings with an electromagnetic circuit and armature that turns the circuit on and off again repeatedly.

Clock Radios. Modern digital alarm clocks typically feature a radio alarm function as well as a beeping or buzzing alarm, allowing a sleeper to awaken to music or news radio rather than harsh noise. Most also offer a "snooze button", a large button on the top that stops the alarm and sets it to ring again at a short time later, typically anywhere between five and 10 minutes. Some alarm clocks also have a "sleep" button, which turns the radio on for a set amount of time (usually around one hour). This is useful for people who like to fall asleep with the radio on.

Newer digital clock radios often use a battery backup to maintain the time in the event of a power outage. Without this feature, digital clocks will reset themselves incorrectly when power is restored, causing them to fail to trigger the alarm.

Astronomical Clock. An astronomical clock is a clock with special mechanisms and dials to display the relative positions of the sun, moon, zodiacal constellations, and sometimes major planets. See also **Astronomical Clock**.

Binary Clock. A binary clock is a clock which displays traditional sexagesimal time in a binary format. More precisely it shows *each decimal digit* of sexadecimal time as a binary value. Most binary clocks are digital, although analog varieties exist. The display below uses three binary number columns, one for each of the units (hours, minutes, and seconds) of the conventional time system.

	Hours	Minutes	Seconds
32		1	1
16	0	0	1
8	1	0	0
4	0	1	0
2	1	0	0
1	0	1	1
decimal:	10:	37:	49

Bracket Clock. These clocks were developed in the last quarter of the 17th century. They are composed of two matching pieces created as an ensemble: clock and small decorative shelf. Bracket clocks are usually about one $1'H \times 9'W$. They are almost always made of wood and often ornamented with ormolu mounts, brass inlay, wood or tortoise shell veneer, or decorative varnish. Most so called bracket clocks are really spring driven table clocks. These clocks almost always had repeating work. That is to say it was possible to make the clock strike the last hour again at will. This was especially useful during the night. Many clocks which could repeat did not normally strike every hour. One did not want to awaken by the striking every hour. So they either had a strike silent lever or they didn't strike unless the repeat mechanism was pulled.

Cartel Clock. These clocks were designed to hang directly on the wall, most often used in reference to highly ornate mid-18th-century wall clocks.

Clock Network. A clock network or clock system is a set of clocks designed to always show the exact same time by communicating with each other. Clock networks usually include a central master clock kept in sync with an official time source, and one or more slave clocks which receive and display the time from the master.

The master clock in a clock network can receive accurate time in a number of ways: through the United States GPS satellite constellation, a Network Time Protocol server, the CDMA cellular phone network, a modem connection to a time source, or by listening to radio transmissions from WWV (the call sign of NIST's shortwave radio station located in Fort Collins, Colorado) or WWVH (the call sign of NIST's shortwave radio time signal station in Kekaha, on the island of Kauai in the state of Hawaii), or a special signal from an upstream broadcast network. Some master clocks don't determine the time automatically. Instead, they rely on an operator to manually set them. See also **Time and Frequency**.

Clock networks in critical applications often include a backup source to receive the time, or provisions to allow the master clock to maintain the time even if it loses access to its primary time source. For example, many master clocks can use the reliable frequency of the alternating current line they are connected to.

Applications. One of the driving factors in developing clock networks was the broadcast industry. Television, in particular, operates on a very strict schedule, where each second of airtime is planned ahead of time and must be executed precisely. A central clock system allows a television station's master control and production personnel to work within that schedule. A clock network synchronized to the standard UTC time also allows different television facilities to coordinate their activities without complicated out-of-band signaling. It also provides accurate timing to equipment in stations that are becoming increasingly automated. See also **Universal Time Coordinated (UTC)**.

Railroad Chronometer. Railroad chronometers (railroader's watches) were critical to the safe and correct operation of trains in the United

States. A system, which relied on accurate timekeeping, called Timetable and Train Order was used to ensured that two trains could not be on the same stretch of track at the same time.

After a serious train accident in 1891 in Ohio, caused by the malfunction of an engineer's watch, the North American railroad industry charged their General Time Inspector Webb C. Ball to establish unified standards for all the watches used by their personnel across the various participating Railroad Companies:

- only American-made watches may be used (depending on availability of spare parts)
- only open-faced dials, with the stem at 12 o'clock
- minimum of 17 functional jewels in the movement, 16 or 18-size only
- maximum variation of 30 seconds (approximately 4 seconds daily) per weekly check
- watch adjusted to five positions (face up, face down, crown up, crown down, or sideways)
- adjusted for severe temperature variance and isochronism (variance in spring tension)
- indication of time with bold legible Hindu-Arabic numerals, outer minute division, second dial, heavy hands,
- lever used to set the time (no risk of having the stem left out, thus inadvertently setting the watch to an erroneous time)
- Breguet balance spring
- micrometer adjustment regulator
- double roller
- steel escape wheel
- anti-magnetic protection (after the advent of diesel locomotives)
- jim-proof

The Waltham Watch Company quickly complied with the requirements of Ball's guidelines, and soon did Elgin Watch Company and most of the other American watch manufacturers, applying the American System of Watch Manufacturing. Waltham became the official timekeeper of railroads in 52 different countries.

Countdown Clock. A countdown is the backward counting to indicate the seconds, days, etc. remaining before an event occurs or a deadline expires. Typical events for which a countdown is used include the launch of a rocket or spacecraft, the explosion of a bomb, the start of a race, or the New Year.

In the context of a rocket launch, the "T minus Time" is the time before launch, e.g. "The countdown was held at T minus 5 minutes for 3 minutes and 40 seconds". The last ten seconds are usually counted down aloud "10, 9, 8, 7, 6, 5, 4, 3, 2, 1, Lift off!"

The first known use with respect to launching a rocket occurred in Fritz Lang's 1929 film *Frau im Mond*. In the film, after each number the words "seconds to go" was repeated.

Cuckoo Clock. A cuckoo clock is a clock, typically a pendulum clock, which strikes the hours using small bellows and whistles that imitate the call of the Common Cuckoo bird in addition to striking on a wire gong.

The design of a cuckoo clock is now conventional. Most are made in the shape of a rustic birdhouse or chalet. They hang on the wall, and are housed in wooden cases, frequently decorated with carved leaves; sometimes deer and other animals are added. Most now have an automaton of the bird that appears through a small trap door when the clock is striking, and vanishes behind the door after the clock is done.

The bird is often made to move while the clock strikes, typically by means of an arm that lifts the back of the carving. Some have musical movements, and play a tune on a music box before striking the hours or half-hours. Musical cuckoo clocks frequently have other automata that move when the music box plays. The clocks are almost always weight driven; a very few cuckoo clocks are spring driven.

The cuckoo clock was invented in the Black Forest town of Schönwald im Schwarzwald, Germany, by Franz Ketterer in 1738. Ketterer designed the system of small bellows and whistles that imitates the Cuckoo's call, and added them to a standard Dutch clock. Later refinements of the design changed the clock's shape to the familiar birdhouse or chalet. The centre of their production continues to be in the Black Forest region of Germany, in the area of Triberg im Schwarzwald and Neustadt.

Game Clock. A game clock consists of two adjacent clocks and buttons to stop one clock while starting the other, such that the two component clocks never run simultaneously. Game clocks are used in two-player games where the players move in turn. The purpose is to keep track of the total time each player takes for his or her own moves, and ensure that neither player overly delays the game.

Game clocks were first used extensively in tournament chess, and are often referred to as "chess clocks," but their use has since been adopted for tournament Scrabble, Shogi, Go, and nearly every competitive two-player board game.

Grandfather Clock. A grandfather clock, also floor clock or longcase clock, is a freestanding pendulum clock with the pendulum held inside its own tower, commonly around 6-8 ft (1,8-2.4 m) tall. The tower often features elaborately carved wood at the head, surrounding the clock face. The English clockmaker William Clement is credited with the development of this form in 1670. Most grandfather clocks are striking clocks. A variation of this clock is the grandmother clock, which has a smaller case.

Hourglass. An hourglass, also known as a sandglass or sand timer, is a device for the measurement of time. It consists of two glass bulbs placed one above the other which are connected by a narrow tube. One of the bulbs is usually filled with fine sand which flows through the narrow tube into the bottom bulb at a given rate. Once all the sand has run to the bottom bulb, the device is inverted in order to measure another time period.

Factors affecting the amount of time that the hourglass measures include: the volume of sand, the size and angle of the bulbs, the width of the neck, and the type and quality of the sand. Alternatives to sand that have been used are powdered eggshell and powdered marble. It is still in use, but typically only ornamentally or when a relatively approximate measurement of time is needed (for example in cooking or board games). For cooking and games the time period will be only a few minutes (for cooking eggs, a three minute timer is typical).

Pendulum Clock. A pendulum clock uses a pendulum as its time base. From their invention until about 1930, the most accurate clocks were pendulum clocks. Pendulum clocks cannot operate on vehicles, because the accelerations of the vehicle drive the pendulum, causing inaccuracies. See also **Pendulum Clock**.

Projection Clock. A projection clock (*ceiling clock*) is an analog or digital clock equipped with a projector that creates an enlarged image of the clock face on any suitable projection screen, most often the ceiling. They are not very complex, and can be built by hobbyists.

The advantage of a projection clock is that the "clock" can be placed almost anywhere, even on surfaces difficult to install traditional clocks on. They can also be moved easily, and depending on the projector used, the image can be in monochrome or color. The image generated by most projection clocks is large enough that a nearsighted person can see it from a distance without glasses or contact lenses, while an ordinary clock of similar size would be costly and impractical.

A projection clock usually needs a backlight, as most clock displays do not radiate their own light. The backlight can use different lighting technologies, from incandescent bulbs to LEDs.

Projection clocks can be divided into two groups: low-brightness and high-brightness. The image created by low-brightness projection clocks can be viewed only in a darkened room, while high-brightness ones create an image that can be viewed even in lighted rooms, but are more power-hungry.

Quartz Clock. A quartz clock is a timepiece that uses an electronic oscillator which is made up by a quartz crystal to keep precise time. This crystal oscillator creates a signal with very precise frequency. Usually some form of digital logic counts the cycles of this signal and provides a numeric time display, usually in units of hours, minutes, and seconds, which a human can read.

In modern quartz clocks, the resonator is tuning fork shaped, laser-trimmed or precision lapped to vibrate at 32,768 Hz. This frequency is exactly 2^{15}. Thus, a very simple electronic cicuit can be built with a series of 15 divide-by-2 stages to get the base time of 1 second. In most clocks, the resonator is in a small can or flat package, about 4 mm long. Standard quality resonators of this type are warranted to have a long-term accuracy of about 6 parts per million at 31°C (88°F), that is, a typical quartz wristwatch will gain or lose less than a half second per day at body temperature.

The relative stability of the resonator and its driving circuit is much better than its absolute accuracy. If a quartz wristwatch is "rated" by measuring it against an atomic clock's time broadcast, and worn on one's

body to keep its temperature constant, the corrected time can easily be as accurate as 2 seconds per month, more than good enough to perform celestial navigation.

The rest of the clock is usually a small, special-purpose computer with a program that counts the cycles, and translates them into an electrical form to drive the visible display. The use of computers in electronic timepieces has enabled a wealth of features, such as stop watches, perpetual calendars, multiple perpetual alarms that play tunes, and other features that would be impractical with simple electronic counters.

Some premium clock designs self-rate. That is, rather than just counting vibrations, their computer program takes the simple count, and scales it using a ratio calculated between an epoch set at the factory, and the most recent time the clock was set. These clocks usually have special instructions for changing the battery (the counter must not be permitted to stop), and become more accurate as they grow older.

Seiko produced the world's first quartz wristwatch, the Astron, in 1969. The inherent accuracy and low cost of production has resulted in the proliferation of quartz clocks and watches since that time. Quartz timepiece production has emerged from Asia, notably Hong Kong and Japan. Many traditional European clockmakers have continued to produce the less accurate but popular geared timepieces.

Stopwatch. A stopwatch is a timepiece designed to measure the amount of time elapsed from a particular time when activated and when the piece is deactivated.

The stopwatch is typically designed to start at the press of the top button and stop by pressing the button a second time to display the elapsed time. A press of the second button then resets the stopwatch to zero. The second button is also used to record *split times* or *lap times*. When the split time button is pressed while the watch is running, the display freezes, but the watch mechanism continues running to record total elapsed time. Pressing the split button a second time allows the watch to resume display of total time.

The stopwatch function is also present as an additional function of many digital wristwatches. If an analog wristwatch has a stopwatch function, it is called a *chronograph*. See also **Chronograph**.

A large digital version of a stopwatch designed for viewing at a distance, as in a sports stadium, is called a *stopclock*.

Striking Clock. This type of clock sounds the hours on a bell or gong. The striking feature of clocks was at one time more important than their clock faces; some early clocks struck the hours, but had no public dials to enable the time to be read. Striking clocks are the chief reason why a 12-hour clock is in general use, as opposed to a 24-hour clock; a clock that rang 24 times at midnight would be inconvenient both to build and to understand correctly. A typical striking clock will have two gear trains, because a striking clock must add a *striking train* that operates the mechanism that rings the bell in addition to the *timekeeping train* that measures the passage of time.

The most basic sort of striking clock simply sounds a bell once every hour. This sort of striking clock is called a *passing strike* clock. It is far simpler to create such a clock; all that must be done is to attach a cam to a shaft that rotates once an hour; the cam raises and then lets fall a hammer that strikes the bell. Such clocks were the earliest striking clocks; they rang once for each canonical hour, and were used as reminders to summon monks or nuns to their prayers.

Two technologies have been devised by clockmakers to enable striking clocks to correctly count out the hours. The earlier technology is called *countwheel striking*, this uses a wheel that contains notches on its side, spaced by unequal, increasing arc segments. This countwheel governs the rotation of the striking train. When the striking train is released by the timekeeping train, a lever is lifted from a notch on the countwheel; the uneven notches allow the striking train to move only far enough to sound the correct number of times, after which the lever falls back into the next notch and stops the striking train from turning further.

The countwheel has the disadvantage of being entirely independent of the timekeeping train; if the striking train winds down, or for some other reason the clock fails to strike, the countwheel will become out of synch with the time shown by the hands, and must be resynchronized by manually releasing the striking train until it moves around to the correct position. Countwheel striking was the original method of counting the hours. It has existed since the fourteenth century.

In the late seventeenth century, *rack striking* was invented. Rack striking is so called because it is regulated by a rack and pinion mechanism. The distance a lever is allowed to fall determines the number of times the bell is allowed to sound.

Rack striking attaches a snail-shaped cam to a part of the timekeeping train that revolves every twelve hours; often, the rack is attached to the part that drives the hour hand of the clock. Like the countwheel, the cam stops the striking train when the appropriate count has been reached. The diameter of the cam is largest at the one o'clock position, permitting the lever to move only a short distance, after which the striking train is stopped; it is smallest at the twelve o'clock position, which allows the lever to move the farthest.

Because it is linked to the timekeeping train, rack striking seldom becomes desynchronized from the hands. Rack striking also made possible the repeating clock, which can be made to repeat the last hour struck by pressing a button.

Specialized types of striking clocks include chiming clocks, which play fragments of a melody on the hours and quarter hours; musical clocks, which play tunes on a music box in addition to counting the time; and automaton clocks, with mechanically animated figures that periodically perform various displays, usually as a part of the clock striking the hours. The cuckoo clock is a specific type of automaton clock, which displays an animated bird and plays imitation birdcalls in addition to striking on a bell or gong.

Tide Clock. This type of clock is a novelty clock that keeps track of the moon's apparent motion around the earth. Along many coastlines the lunar part of the combined lunar and solar tides is the major component (67%).

Tidal clocks keep the average rate between high lunar tides, which occur 12 hours 24 minutes apart. The bottom of the tide clock dial is marked "low" (for "low tide") and the top of the tide clock dial is marked "high" (for "high tide"). The left side of the dial is marked "flow" or "flood" or "rising" and has a count-down of hours from 5 to 1. There is one hand on the clock face, and along the left side it points to the number of hours *until* the (lunar) high tide. The right hand side of the clock is marked "ebb" or "falling" and has a count of hours from 1 to 5. The number pointed to by the hand gives the time *since* the last (lunar) high tide. See also **Tides**.

Time Clock. This type of clock is a mechanical timepiece that was used to assist in tracking the hours an employee of a company worked. This was accomplished by inserting a heavy paper card, called a time card, into a slot on the time clock. When the time card hit a contact at the rear of the slot, the machine would print day and time information on the card. This allowed a timekeeper to have an official record of the hours an employee worked to calculate and pay an employee.

In the 1990s, time clocks started to move away from the mechanical version to computer based time tracking systems. On these systems, the employee either enters an employee number, swipes a magnetic striped card or uses some other device to identify the employee to the system. Based on the system being used, the employee then enters what should be recorded. This could be "punching in", "punching out", lunch breaks, reason for leaving early, or any other type of information the employer requires.

Watch. A watch is a small portable clock that displays the time and sometimes the day, date, month and year. In modern times they are usually wrist-watches, worn on the wrist with a watch-strap (made of e.g. leather [often synthetic], metal, or nylon), although before the 20th century and cheap miniaturization, most were pocket watches, which had covers and were carried separately, often in a pocket, and hooked to a watch chain.

Current watches are often digital watches, using a piezoelectric crystal, usually quartz, as an oscillator.

Mechanical timepieces are still used, usually powered by a spring wound regularly by the user, e.g., a stem winder. The invention of "Automatic" or "Self-Winding" watches allowed for a constant winding without special action from the wearer: it works by an eccentric weight, called a winding rotor, which rotates to the movement of the wearer's body. The back-and-forth motion of the winding rotor couples to a ratchet to automatically wind the watch.

The wristwatch was invented by Patek Philippe at the end of the 19th century. It was however considered a woman's accessory. It was not until the beginning of the 20th century that the Brazilian inventor Alberto Santos-Dumont, who had difficulty checking the time while in his first aircraft (Dumont was working on the invention of the aeroplane), asked his friend Louis Cartier for a watch he could use more easily. Cartier gave

him a leather-band wristwatch from which Dumont never separated. Being a popular figure in Paris, Cartier was soon able to sell these watches to other men. During the First World War, officers in all armies soon discovered that in battlefield situations, quickly glancing at a watch on their wrist were far more convenient than fumbling in their jacket pockets for an old-fashioned pocket watch.

The first use of electrical power in watches was as a source of energy to replace the mainspring, and therefore to remove the need for winding. The first battery-powered watch, the Hamilton Electric 500, was released in 1957 by the Hamilton Watch Company of Lancaster, PA.

The first digital watch, a Pulsar prototype in 1970, was developed jointly by Hamilton Watch Company and Electro-Data. A retail version of the Pulsar was put on sale in 1972. It had a red light-emitting diode (LED) display. LED displays were soon superseded by liquid crystal displays (LCDs), which used less battery power. The first LCD watch with a six-digit LCD was the 1973 Seiko 06LC, although various forms of early LCD watches with a four-digit display were marketed as early as 1972 including the 1972 Gruen Teletime LCD Watch.

Advanced Watches. In 1990 radio controlled wristwatches or as they are sometimes called "atomic watches" reached the market. These wristwatches normally receive a radio signal from one of the national atomic clock facilities around the world, for example the National Institute of Standards and Technology located in Boulder, Colorado in the United States. This radio signal tells the wristwatch exactly what time it is, in theory precise to a fraction of a nanosecond. It will also reset itself when daylight saving time changes.

Similarly watches with GPS time synchronisation use the satellite networks time signals. As GPS receivers are significantly more complex, very few wrist-watches integrating GPS are available and most of which are very large compared to regular watches. Early examples are the Casio PRO TREK GPS Satellite Navi and the Garmin Forerunner 201. Suunto http://www.suunto.com/suunto/main/index.jsp, is the only company offering a reasonable-sized watch integrating GPS.

A number of functionalities not directly related to time have also been inserted into watches. As miniaturized electronics become cheaper, watches have been developed containing calculators, video games, digital cameras, keydrives, GPS receivers and cellular phones. In the early 1980s Seiko marketed a watch with a television receiver in it, although at the time television receivers were too bulky to fit in a wristwatch, and the actual receiver and its power source were in a book-sized box with a cable that ran to the wristwatch. In the early 2000s, a self-contained wristwatch television receiver came on the market, with a strong enough power source to provide one hour of viewing.

In the early 2000s, the carrying of mobile telephones has become ubiquitous in many affluent countries. As these phones typically display the time on their screens when not in use, it has become common to rely on them for time-keeping, effectively making the mobile phone serve the function of a pocket watch. As a result, the wearing of wrist-watches has become less common among mobile phone users, who are now the majority of the population.

Water Clock. A water clock or clepsydra is a device for measuring time by letting water regularly flow out of a container, usually through a tiny aperture. While never reaching the level of accuracy based on today's standards of timekeeping, the water clock was the most accurate and commonly used timekeeping device for millennia, until it was replaced by the more accurate pendulum clock in the 17th century. See also **Water Clocks**.

Time Display Methods

Clocks can be classified by their method of time display, as well as by their method of timekeeping.

Analog Clocks. Analog clocks indicate time as an angle. The most common clock face uses a fixed numbered dial or dials and moving hand or hands. It usually has a circular scale of 12 hours, which also serves as a scale of 60 minutes, and often also as a scale of 60 seconds. The ultimate analog clock is the sundial, which tracks the sun continuously, registering the time by the shadow of its gnomon.

Digital Clocks. These clocks display a numeric representation of time. Two numeric display formats are commonly used on digital clocks:

- the 24-hour notation with hours ranging 00–23;
- the 12-hour notation with AM/PM indicator, with hours indicated as 12 AM, followed by 1 AM–11 AM, followed by 12PM, followed by 1PM–11PM (a notation mostly used in the United States).

Most digital clocks use an LCD or LED display; many other display technologies are used as well (cathode ray tubes, nixie tubes, etc.). After a reset, battery change, or power failure, digital clocks without a backup battery or capacitor either start counting from 00:00, or stay at 00:00, often with blinking digits indicating that time needs to be set.

Auditory Clocks. For convenience, distance, telephony or blindness, auditory clocks present the time as sounds. The form is either spoken natural language, (e.g. "The time is twelve thirty-five"), or as auditory codes (e.g. number of sequential bell rings on the hour represents the number of the hour like the clock Big Ben).

Textual Clocks. Textual clocks present the time visually in the form of natural language. For instance, in english, the time 12:35 could be represented as "Twelve thirty-five". Some versions of these clocks use a more approximate version intended to be relaxing, such as "About twelve thirty"

CLONE. The asexual formation of descendants genetically identical to the original parent. The ability to clone plants and animals demonstrated that even highly differentiated cells contain a full set of genes necessary to form every cell type found in the complete organism. Often clones of cells are functional in character, as in the "clonal selection" theory of antibody production, contact of the protein synthesizing cells with antigen brings into existence clones of cells which produce a particular protein or proteins.

Clone may also mean a group of plants produced by vegetative propagation (i.e., cutting or budding) from a single seedling. The members of a clone are identical, but cannot be grown from seed.

A recent development of great importance to many fields of science has been the production of hybridoma cells by the fusion of myeloma cells (malignant tumor cells of the immune system) with lymphocytes immunized with a particular antigen. The individual hybridoma clones can be maintained indefinitely and can be selected for the production of large amounts of identical (monoclonal) antibody against a single antigen. These highly specific monoclonal antibodies are proving to be remarkably versatile tools in many areas of biological research and clinical medicine. See also **Genetics and Gene Science (Classical)**.

CLONING *(Mammals)*. Horticulturists have been cloning their favorite plants for many years. This involves nothing more complicated than taking a piece of the plant (a cutting) and nurturing it under the proper conditions as it grows into an exact copy of its parent. Until recently such cloning has been restricted to plants and invertebrates, but recent advances in biotechnology allow scientists to clone mammals.

A **zygote**, created by the fusion of an egg and sperm cell, contains all the genetic information needed to design a complete multicellular organism. After the zygote divides, the embryo consists of two cells and the nucleus of both cells will contain identical genetic information. That is because a pair of identical nuclei was created in the mitosis that preceded the cell division. Subsequent cell divisions (each preceded by mitosis — nuclear division) create a ball of cells, all with identical nuclei and, thus, identical genetic material. Cells descendent from other cells, without themselves having been formed by the fusion of a sperm and egg, are called **clones**. The outcome of all this is a complete multicellular organism made of cells, all of which contain identical genetic information. Almost every cell in the human body is a clone from one original zygote. See Fig. 1. (The differences between the different cell types, such as the tissue they form or enzymes they produce, have to do with how certain parts of the genome are used selectively in each cell. That is the topic of gene regulation and is not discussed here.)

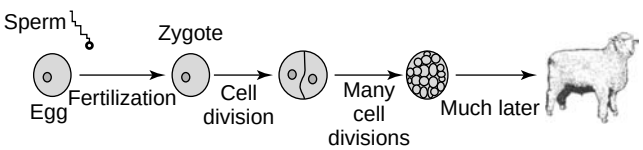

Fig. 1. Every cell is a clone of the original zygote.

If the cells of the early embryo are separated from each other, each cell behaves like a zygote. Under proper conditions (including the provision of a surrogate uterus, in the case of mammals) each "new zygote" will continue along its developmental pathway and each will eventually produce a complete organism. Notice, however, that these organisms will have identical genetic material (because they descended from the original zygote), so they will be clones. If the cells of a two-celled embryo are separated and encouraged to develop, the resulting organisms will be identical twins. Identical twins occur naturally (randomly) and the resulting identical twins are clones of each other. See Fig. 2.

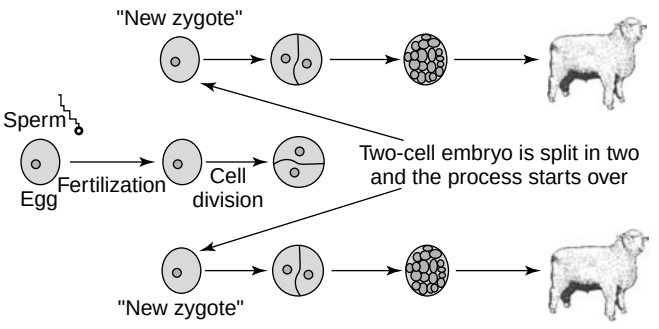

Fig. 2. Formation of identical twins.

Clones can also be produced "to order", using sophisticated laboratory procedures involving state of the art reproductive technologies. For legal reasons, this "artificial twinning technique" cannot be used on humans, but sheep and cattle breeders have adapted this technology. By splitting embryos at early stages of development and providing surrogate mothers in which the embryos can develop, an animal breeder can rapidly increase the number of individuals in a valuable herd.

This technique of "artificial twinning" can be extended. With some species (mice for example) embryos in the 4, 8, or even 16 cell stage can be dissociated into viable "new zygotes" and each one of those will grow into an entire organism. All those "twins" will be genetically identical. **Embryo cloning**, as this is known, is used by scientists to create small populations of identical mice. By using identical clones, there is no genetic variation in the experiments. Only the mice's environment can create variation, so experiments are performed more accurately and require fewer mice. Also, these cloned embryos, as "new zygotes" or having grown to the several-cell stage, can be frozen and stored for decades (perhaps centuries). See Fig. 3. This allows scientists to design better experiments, go back to repeat experiments, and to ship clones to other researchers. All these features make experimentation more useful and efficient as well as reducing the costs.

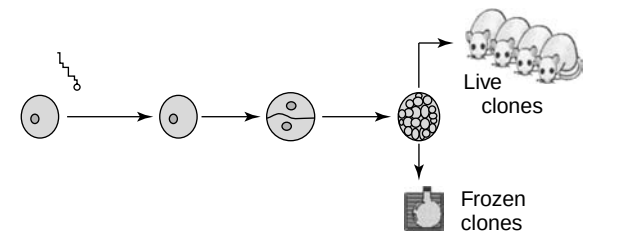

Fig. 3. Use of frozen clones.

Somatic cell cloning creates a functional zygote from the nucleus of a somatic cell. (A somatic cell is a nonreproductive cell.) This technique can be used to create clones from an animal that has already reached maturity (well past the embryo stage) using any somatic cell from its body. Dolly the sheep was the first example of a mammalian somatic clone. See also companion article on **Cloning: The Story of Dolly the Sheep**.

A host cell is prepared as the first step. A delicate needle and a good microscope are used to remove the nucleus from a zygote or egg cell. This will be the host cell and, according to some reports, need not even be from the same species. With its nucleus removed, the host cell no longer has any genetic information (except a few genes carried in the mitochondria) and is called an **enucleated** host cell.

In the second step, using a similar procedure, the nucleus is carefully collected from a different, somatic cell. This is the donor nucleus and it contains the genetic information from the somatic cell from which it was taken. When this donor nucleus is injected into the enucleated host cell, that cell and all its descendants will carry the genetic materials of the donor.

This "new zygote" can now be nurtured (usually placed in the uterus of a receptive female who acts as a surrogate mother) and allowed to develop. The resulting offspring will be a clone of the animal from which the nucleus was derived. There appears to be no limit to the number of times this can be done or the number of clones that can be created this way. See Fig. 4.

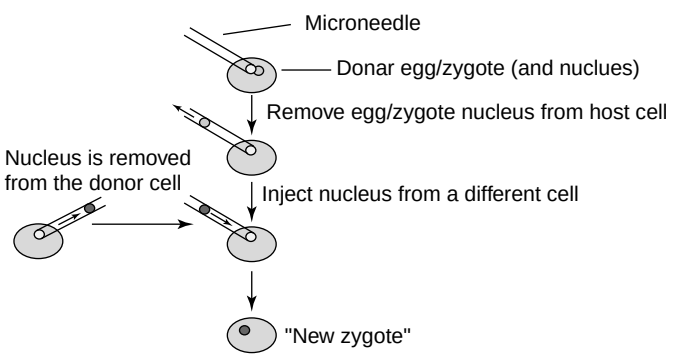

Fig. 4. Removal of nucleus from donor cell to produce new zygote.

The original procedure was not very efficient (researchers repeated this process 276 times before they successfully cloned a sheep), but new methods are under development and there is tremendous potential for the use of clones in a wide variety of areas, especially in research.

Potential Uses for Clones

Millions of transplantations (surgical transfer of an organ) are performed each year. Many of these procedures are **allografts**, where the organ or tissue is removed from one person and transplanted into another. In most cases, the donor has recently died and the family has agreed to donate useful organs for transplantation. A heart transplant is an obvious example of an allograft. Of course, the expertise of the surgeon is very important to the success of the operation, but it is the postoperative phase that is most critical. The patient's (host's) own immune system often tries to kill the transplanted organ. Organ "rejection" occurs because the patient's immune system identifies the transplanted tissue as "foreign" and tries to kill it. This is a normal and natural response by the immune system and it has evolved over millions of years as a way to reject parasites. To avoid rejection, transplantation teams try to "match" the donor tissue to that of the recipient, but there are thousands of different tissue types and getting a perfect match is rare. In most cases, the patient must settle for a less than perfect match and take immune-suppressive drugs for the rest of his or her life.

Contrast those problems with the simplicity an **autograft**, where the organ or tissue is harvested from one part of the patient and transplanted into another part of the same patient. Of course, heart transplantations are NOT autografts. A very common form of heart surgery, coronary bypass, is an example of an autograft. In this procedure (saphenous) veins are removed from the patent's leg and transplanted onto the heart to act as a conduit for blood around blocked coronary (heart) arteries. There is no organ rejection of autografts because the tissue types are identical. That makes sense because the tissue type is determined genetically, so the tissue from a vein in the leg will have the same immune type as one from the heart.

Extending that logic one step further, it is a fact that identical twins can share tissues without concerns about rejection, because they have identical tissue types (because they have identical genetic makeup). From a surgical stand point, transplantation between identical twins would be called an "allograft" (because if is between two different people), but from the immune system's point of view this would appear to be an autograft.

Cloned tissue would not be rejected by the immune system because it is tissue identical to that of the person from which it came. It could be used, either "as is" or genetically engineered to correct a biochemical defect, and then reintroduced into the person who provided the somatic cell(s).

Unfortunately, scientists can not yet grow a cloned heart in a test-tube, but that does not mean that cloning technology cannot be useful in medicine. Heart and vein transplantations are offered as examples of allografts and autografts, because they are easy to understand. However, there are other medical procedures that could benefit more immediately from the availability of cloned materials. Researchers are working on a variety of possibilities from cell therapy to organs replacement.

A zygote cloned from a patient has the potential of making a copy of any cell or organ and that new tissue would be an identical match to the patient for the same reason identical twins are perfectly matched. The clones zygote could be coaxed in the test-tube to grow into neurons (nerve cells), blood cells, and other types of cells. This has tremendous potential, and this "cloned cell technology" is working its way out of the laboratory and into the clinics.

Parkinson's disease is a neurodegenerative disease (meaning that it is a disease caused by the destruction of neurons) that occurs when a specific area of the brain dies and stops making a crucial chemical. Researchers are working to direct a patient's cloned zygote to differentiate into neurons that will produce the required chemical. Those cells, when placed in the patient from whom they were cloned, will not be rejected by the immune system and will be able to produce the required proteins. Another idea, called "cloned cell gene therapy", introduces a healthy gene into a cloned zygote that does not have a healthy gene (having inherited an unhealthy mutation of the gene). Once fixed, these cloned cells could be introduced into the patient in order to supply the chemicals she or he cannot normally produce. Examples of disease that might be cured using cloned cell gene therapy include: cystic fibrosis, haemophilia and a variety of diseases that are referred to as "storage diseases" (because they involve the storage and metabolism of fats and carbohydrates).

More complicated tissue and organs will require more sophisticated techniques to make the cloned cells useful. Skin is a relatively simple organ and is needed for transplantation in several medical problems, such as the victims of serious burns. Cloned skin cells would not be rejected and are relatively easy to grow in the lab. Therefore, cloned skin is likely to make it to the transplantation ward before cloned hearts. Cloned bone is also on the horizon. Some companies have developed "matrixes" and other supports that allow cloned bone cells to grow upon and in them. These supports can be manufactured in any shape of bone or cartilage. Advances in organ growth and *in vitro* culturing mean that it might be possible to grow complicated "spare parts", such as hearts, kidneys, etc. and thus provide an endless supply of organs (which are currently collected from dead people). Some people fear that this kind of work would lead to the cloning of entire human organisms (which is illegal) but, in fact, the opposite is true. There is no need to grow an entire person if only a part (tissue or organ) can be grown more easily in the laboratory (instead of in a womb).

Of course, somatic cloning of mammals other than human is less controversial and has other, simpler, goals. Most domestic animals are of specifically defined genetic stock. That is, they have been bred to have many of their genes "fixed" in the population. This means a pure bred collie will appear almost identical to another pure bred collie and if mated they will produce collies almost identical to each other and themselves. People who own collies might object to the notion that their dog is almost identical to another collie, but this is a relative similarity. Compared to a wolf, the genetic lineage from which all dog breeds were derived, all collies are almost identical. Indeed, it is this desire for consistency that drives the breeding programs of our domesticated animals and plants. Of course, once one has the right kind of plant, one can easily clone it (by taking cuttings), but the propagation of domestic animals is not so straight forward. It takes many generations and a great deal of work to produce pure breeds of animals. A new breed of cattle might take decades to produce, and even more decades to produce the numbers needed for the market.

The agriculture industry spends huge amounts of money to keep specific breeding programs and breeds in production. Many of these programs require the use of several "grandparent" strains in order to provide the right genetic mix in the animals sold to farmers. Also, introducing a new strain (breed), which may be nothing more different than a single gene, takes a very long time. Somatic cloning would allow animal breeders to cut costs and quickly bring to market any newly developed strains. This is particularly important in light of modern biotechnology. The genome of every domestic animal is being sequenced and the information provided will be very useful. We will be able to determine why certain strains of domestic animals are more prone to certain problems and how to correct them. Of course, once it is corrected in one animal, it will be cloned and rapidly introduced to the market. Another possibility is to introduce novel genes into domestic animals. These **transgenic animals**, as they are called, might be leaner or use their feed more efficiently. There is also the possibility that transgenic animals can produce valuable proteins for medicine or industry. (Transgenics is a large topic in its own right.) Somatic cloning will allow scientists to rapidly produce and reproduce transgenic lines.

There is also the possibility that pets could be cloned. Such clones would have all the genetic qualities of the original animal, providing a consistency impossible to produce by standard breeding. People who prefer pure breeds pay a great deal of money for the consistency of the breed and go to great lengths to assure the authenticity of the breed (by following a "paper chain" of breeding and descent). Clones are as pure a breed as one can possibly get and do not require decades to produce. The winner of a prestigious dog show could be cloned and its "twins" could be sold at whatever price the market would allow.

However, there is a less frivolous and far more useful use for cloning animals. The cloning of exotic and wild animals could be of enormous benefit to conservation. Recall that cells can be frozen and later (decades and maybe centuries later) thawed and grown in tissue culture. These cells can be used to provide the nucleus in somatic cell cloning. The enucleated host cell could come from a related but common species. If the donor individual dies (in a zoo or the wild), his/her genetic material would not be lost. Indeed, his/her clones could help to perpetuate the species

decades after the original has died! For example, a population of 50 rare individuals could be cloned into ten populations of those same individuals (10 clones of 50 individuals). Each population (of 50 individuals) could be introduced into 10 different sanctuaries in the wild or distributed to zoos for subsequent breeding. With somatic cloning a conservation biologist need not put all his/her eggs in one basket. If something goes wrong (the population is wiped out by storms, predators, or stupidity) there are plenty of copies in storage or distributed elsewhere. The San Diego Zoo already has a "frozen zoo" containing tissues and cells representing many individuals of a wide variety of endangered species. More frozen zoos are planned. Of course, these frozen zoos are meant to be a back-up to other conservation efforts, not an excuse to ignore the problems of conservation biology.

Naturally, there are many problems to be solved before cloning can be relied to help conserve endangered mammals. For example, cloning is not yet a very efficient technique and, in order to clone an endangered mammal, scientist would need to use the enucleated egg of a different, but closely related species, as the host cell. Also, a mother, of a non-endangered species, must act as the surrogate and bring the embryo to term. Would that work? The research is in progress, and there is hope.

In August 1998 scientist in New Zealand used somatic cloning techniques to pull an endangered genome from the brink of extinction. "Lady", the last remaining member of a rare breed of cattle, is too old to reproduce. Frozen semen, collected from rare bulls now long dead, is the only remaining "genome" of this breed besides Lady herself. The scientists used enucleated oocytes from a different breed of cattle as a host for Lady's nuclei. These "new Lady" embryos were implanted into surrogate Angus cows and "Lady calves" were born! Once they reach maturity, those clones will be inseminated with the sperm of that rare breed and a new herd will be created (and, one hopes, conserved).

Research is under way to clone the Northern Hairy-nosed wombat (a very rare Australian mammal) and there is even serious discussion about cloning the Giant Panda! The most extreme use of cloning technology would be to bring back an extinct species. Some scientists are trying to collect intact nuclei from frozen woolly mammoths hoping to clone that animal! Most scientists are sceptical about the idea. The hard part is to find "live" cells in a mammoth carcass after it has been frozen in the Arctic tundra for 20,000 years. However, if such cells can be collected in the field and cultured in the lab, the nuclei could be cloned into elephant eggs and elephants used to perhaps bring the mammoth to term.

In the next few years, cloning will begin to transform our lives (through medical advances), our animals (through breeding and transgenics) and even our world (as we conserve our endangered mammals).

JAMIE LOVE, Editor, Science Explained:
www.synapses.co.uk/science/index.html

CLONING (The Story of Dolly The Sheep). The first successful cloning of a mammal was done at the Roslin Institute in Scotland in 1996. The result was Dolly (named after the singer Dolly Parton), the most famous sheep in the history of the world (see Fig. 1.) The announcement in *Nature* in February 1997 [Wilmut, et al.: 1997] that scientists had cloned a sheep provided the catalyst for a wide-ranging discussion about cloning technology and its potential applications.

Dolly was born on July 5^{th} 1996 and died on February 14, 2003. What makes Dolly *different* from identical twins is that she was grown from a cell taken from an ADULT animal! Many bright, well-respected scientists said it could not be done. Dr Ian Wilmut, who is in charge of the lab that created Dolly, admits that he had his doubts. However, the hard work and imaginative thinking of his staff made it all possible. To better understand this story of the research that led to the creation of Dolly, we must consider certain basics of developmental biology.

An oocyte (pronounced "oh-oh-sight") is an unfertilized egg and it has no chance of developing into an animal unless it is fertilized. A recently fertilized egg is called a zygote (pronounced "zye-goat"). For example, a frog zygote normally divides and grows into a complete animal, a tadpole. Later that tadpole will develop into an adult frog.

A cell from a frog's gut should always remain a frog-gut-cell because it has "differentiated". Differentiation is the natural process whereby cells specialize into a certain kind of cell. See Fig. 2. As a frog embryo grows and develops, its cells differentiate into nerve cells, blood cells, fat cells and many other different kinds of cells. This is the essence of differentiation, without which an animal could never be anything but a blob

Fig. 1. Dolly (Image courtesy of Roslin Institute).

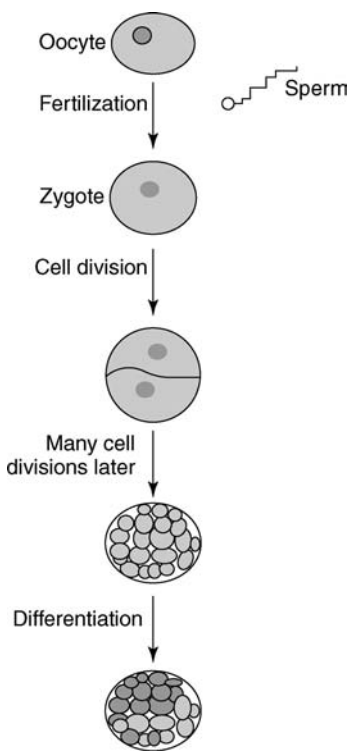

Fig. 2. Differentiation.

of unspecialized cells. As a mass of embryo cells divides and differentiates, those cells "create" the animal. This incredible process of differentiation turns zygotes into animals and it is all controlled by the genes. Although the exact process is still poorly understood, scientists agree that differentiation must have something to do with changes in the nucleus of cells. This is because the nucleus is that part of the cell containing the genetic material (the DNA all coiled up in the chromosomes).

Like most scientific "breakthroughs", the earlier work done by others provided the foundation on which to try something new.

In 1975 Gurdon developed the method of "nuclear transfer". This is a two step process.

First he used delicate needles and a good microscope to suck out the nucleus from a frog oocyte, producing an "enucleated oocyte" (an oocyte without a nucleus). With the genetic material removed, the enucleated

oocyte would not divide or differentiate even when it was fertilized. That was no surprise. (A cell is nothing without its nucleus.)

But the results from Gurdon's second step shocked many scientists. He used the same equipment and skill to transfer the nucleus from a frog's gut cell into an enucleated oocyte. This is nuclear transfer (Fig. 3), the transfer of a nucleus from one cell to another, creating a "new cell" with a different nucleus. Many of these new cells which Gurdon created behaved like a zygote. They divided and re-divided just like a normal developing embryo, producing a ball of cells. And this ball of cells differentiated. Nerve cells, skin cells, blood cells appeared just as they would in a normal embryo. After the normal length of time, Gurdon had tadpoles. Because the tadpoles had all come from the gut cells of the same adult, they all had the same genetic material. So they were all clones, identical twins of each other. But, unlike normal identical twins, they were made from differentiated cells. Gurdon had proven something that many scientists had argued about. He proved that differentiation was *reversible*. Gurdon's method of nuclear transfer turned back the hands of time, in a developmental sense, because Gurdon's method of nuclear transfer made clones from adult cells.

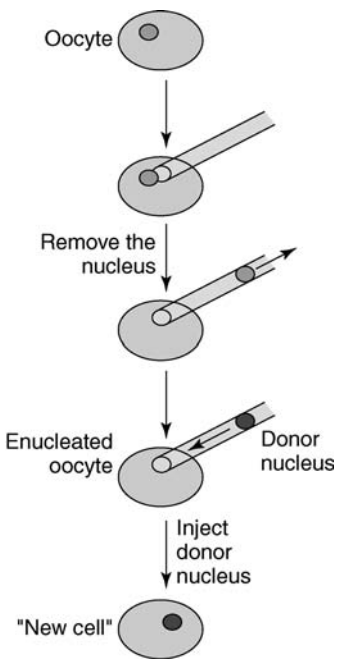

Fig. 3. Nuclear transfer.

Naturally, Gurdon's success prompted widespread consideration of cloning in the scientific community. However, there were two problems.

First, Gurdon's nuclear-transferred tadpoles never grew into frogs. Other scientists repeated his experiments and got similar results. Nuclear transfer could not clone frogs from frog cells; the result was always tadpoles. No one knew why. Even today, it is not yet understood why the tadpoles made by nuclear transfer die instead of growing into frogs.

The second problem was that Gurdon's method seemed to work only with frogs (specifically, tadpoles). When scientists tried nuclear transfer with mice, cattle or any other mammal, they were unsuccessful. The "new cells" sometimes divided a few times, but not for long, and none of them differentiated properly. At that point, one could not clone mammals. By the early 1980s, most scientists accepted the idea that something very special allows frogs to be (partially) cloned (into tadpoles). Whatever that process was, it was not found in mammals. The textbooks made it very clear: differentiation was (sort of) reversible in frogs, but not in mammals.

Keith Campbell, a scientist working for Dr Wilmut, thought that maybe the cell cycle had something to do with this cloning trouble.

The Cell Cycle

The **cell cycle** is often described as a circle of cell life and division. The governing concept of the word *cycle* is that it happens again and again. See Fig. 4.

A cell divides into two "daughter cells" and both of these cells live, "eat", grow, copy their genetic material and divide again, producing two more daughter cells. Because each daughter cell has a copy of the same genes in its nucleus, daughter cells are "clones" of each other just like identical twins. This "twining" goes on and on with each cell cycle. This is a natural process.

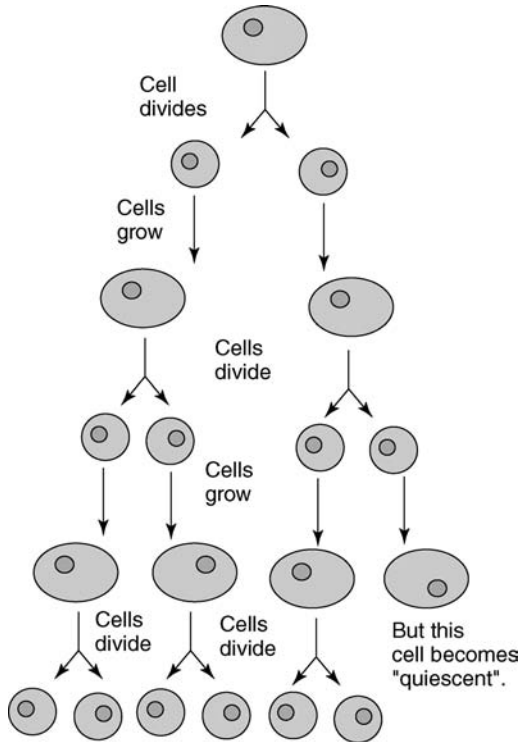

Fig. 4. Cell cycle.

The cell cycle fascinates biologists. Very fast cell cycles occur during development, causing a single cell to make many copies of itself as it grows and differentiates into an embryo. Some very fast cell cycles also occur in adult animals. Hair, skin and gut cells have very fast cell cycles to replace cells that naturally die. (Cancer is a disease caused by cells cycling out of control. — Little wonder that biologists think the cell cycle is so important.)

But there is a kind of "parking spot" in the cell cycle called "quiescence" A quiescent cell has left the cell cycle; that is, it has stopped dividing. Quiescent cells might reenter the cell cycle at some later time, or they might not. It depends on the type of cell. Most nerve cells stay quiescent forever. On the other hand, some quiescent cells may later reenter the cell cycle in order to make more cells. (For example, female breast development during puberty.)

Many biologists thought that to make a clone, one should transfer the nucleus from a fast dividing cell. It made sense, because fast cycling cells are exactly what makes an embryo grow. Besides, the gut cells used to make the tadpole clones were fast cycling cells. Many biologists tried to make clones by transferring the nucleus from fast dividing cells but all of those experiments were unsuccessful. (For instance, Dr. Jamie Love tried unsuccessfully to inject the fast growing cells from chicken feathers into hen eggs in the hope of cloning birds.)

Dr. Keith Campbell thought about it in a different way. He wondered if a quiescent nucleus would be a better donor. True, it was not cycling (the process that makes it quiescent, by definition), but Dr. Campbell theorized that, perhaps that is what the nucleus needs for it to be successfully transferred. Maybe the cell needs time to "rest" before starting to make a whole new animal. Maybe the nucleus needs time, lots of time, to get its DNA in order. Maybe quiescent cells would work! So scientists tried it with cells from sheep.

The scientists at the Roslin Institute do a lot of work with sheep as part of their partnership with a company called Pharmaceutical Proteins Limited Therapeutics (PPL Therapeutics). Earlier, they had made transgenic sheep (sheep with human genes transferred into them).

The Roslin staff used cells from an adult sheep's mammary (breast) glands for the "donor" nucleus. They grew the cells in tissue culture, an artificial medium commonly used in laboratories to grow large numbers of

cells in bottles. Tissue culture allows scientists to experiment with the cells and alter their characteristics. That is exactly what Dr Campbell did. He "starved" the cells of important nutrients, and the cells stopped growing and dividing. They became quiescent. (Dr. Campbell knew they would become quiescent when starved of nutrients because other researchers had proven that previously; but few scientists were interested because there was then no known use for quiescent cells.)

Bill Ritchie, a technician working with Dr. Campbell removed the nucleus from an oocyte that was collected from a Scottish Blackface ewe. (The Scottish Blackface breed is a common breed of sheep in Scotland, easily identified by its black face.)

Oocytes have a "shell" of proteins and fibers called the zona pellucida. Mr. Ritchie injected the nucleus from a quiescent mammary cell, through this protective coat and into the enucleated oocyte. That donor cell nucleus was from a different breed of sheep called a Finn Dorset, which happens to be a pure white breed of sheep. Next, a tiny pulse of electricity was used to cause the new nucleus to fuse with the enucleated oocyte's cytoplasm. (Cytoplasm is the solution inside the cell.) This electricity also helps "kick start" cells into "activity" so they are more likely to divide. This new, fused cell (containing the Finn Dorset mammary cell nucleus in the cytoplasm of a previously enucleated Blackface oocyte) was transferred into the reproductive "chamber" of a Blackface ewe (the same breed that provided the oocyte). The researchers then repeated this process 276 times! See Fig. 5.

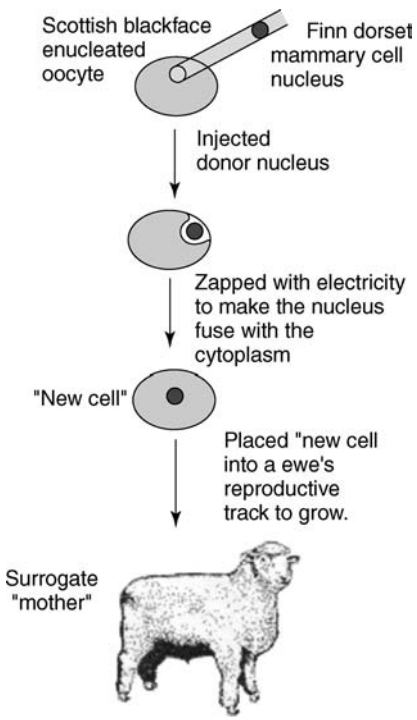

Fig. 5. The route to Dolly.

After 148 days, the normal length of gestation for the Finn Dorset breed of sheep, Dolly was born.

She was a healthy, normal looking Finn Dorset, born to a Blackface ewe. This proved that Dolly was not the product of an unscheduled mating, because, according to sheep-breeding genetics, Dolly's Blackface mother could not produce a white-faced sheep no matter who was the father. But just to be sure, the scientists DNA "fingerprinted" Dolly and her "mother" and proved that Dolly's DNA matched the cells from the tissue culture, not the cells from the ewe that gave birth to her.

(It is interesting to note that clones had been made at the Roslin Institute before, but those clones were made from the nucleus of embryo cells, not adult cells.)

Recall that a total of 277 enucelated oocytes underwent nuclear transfer but only one, Dolly, succeeded. To understand the failures, we need to know more about the way the researchers did their work. The Roslin team knew from previous research on embryo transfers (moving embryos into a different mother) that the transfers do not always work. The embryos may die for various reasons. They also knew that the nuclear transfer itself might introduce new ways for things to go wrong. One must bear in mind that they had to inject the nucleus through the enucleated oocyte's protective coat (zona pellucida), shock it with electricity, and hope that the nucleus would have become quiescent during its time in tissue culture. Any of these new steps might cause the embryo to die or never to develop.

The Early Stages of Embryology

A few days after normal fertilization, a zygote would be expected to have divided approximately four times, producing a ball of 16 cells (via the simple mathematical progression: $1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$) At this point in its development, the embryo looks like a tiny mulberry, and it is called a **morula**. ("Morula" is Latin for "mulberry".) Soon after this stage the zona pellucida (the "egg shell") starts to disappear, and as the cells continue to divide, they allow fluid to enter the center of the mass of cells. This forms a hollow ball, with cells on the outside and fluid inside. This is called a blastocyst. All mammals develop from zygote, to morula and then to blastocyst, before implanting into the wall of mother's uterus. These are critical steps in mammalian development and specifically, in that of a lamb. See Fig. 6.

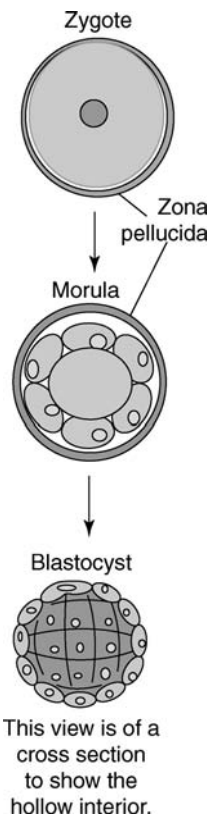

Fig. 6. Zygote to blastocyst.

A few days after placing the "new cells" into ewes' oviducts, the Roslin researchers collected them, to see how well they had developed. As one might imagine, it is not easy to find a tiny morula or blastocyst in a sheep's oviduct! Of the 277 they put into ewes, they recovered only 247. That means over 11% of the embryos were lost in the first few days. Some may have been lost because they are so difficult to find. Others may have died early and decomposed. Unfortunately, when they examined each of them under the microscope, only 29 of the 247 recovered were either a morula or a blastocyst. To put it another way, 88% of the "new cells" transferred had not developed. That was a significant loss in the experiment.

The researchers then placed the remaining 29 "good embryos" into 13 ewes. Some ewes received only one embryo, while some received two (which is the average number of lambs that ewes have at a time) and some ewes got three embryos. The exact number depended upon availability of the embryos at the time and on the availability of "receptive" ewes. Ewes, like all mammals, must have the right balance of hormones in order to

"adopt" an embryo at its particular stage of development. If the embryo and ewe are not "synchronized" (the phrase used for this balance) the embryo will not implant in the ewe's uterus. This is not an easy thing to do, and the Roslin researchers explain that not all recipients were perfectly synchronized. Perhaps that is why only one of those 13 ewes actually became pregnant. Of course, that was the one that gave birth to Dolly.

In a separate series of experiments, some of the "new cells" made with the fetal and embryo cell nuclei were grown in tissue culture up to the stage of blastocyst or morula before being placed into a ewe. Those experiments are not the ones that gave rise to Dolly, but the researchers report them because it is important to describe one's failures as well as one's successes.

The difficulty seems to have been in the ability to actually "reprogram" the "new cell" to behave like a zygote. Their success rate for this important step was 12% (29 "good embryos" from 277 "new cells"). There was also a high loss in the last stage, when only one embryo (Dolly) actually "took". This is a much higher rate of embryo loss than expected from a natural mating and it is probably due to the manipulations of the morulas and blastocysts, as well as the difficulty "synchronizing" the ewes. That means the total success rate was only 0.4% (1 lamb per 277 "new cells" made by nuclear transfer), but the result has changed the history of gene science.

Dolly is a real clone. There are two reasons why people insist she is a fake.

First, some people refuse to believe certain things that are beyond their ability to understand.

Second, Dolly's mitochondria (tiny organelles inside the cell that give it "power") are NOT cloned! This is a very specific detail, but an explanation is in order.

Mitochondria contain less that 1% of 1% of the genes in a cell. Dolly's mitochondria are from the enucleated egg from which she was created, not from the original breast cell. The scientists at the Roslin Institute injected a nucleus (not mitochondria) into the enucleated oocyte. That means all of Dolly's **nuclear** DNA is cloned, but not her mitochondria.

Mitochondria are unusual, genetically speaking. For example, we inherit half our nuclear DNA from our father and half from our mother but we get *all* our mitochondria from our mother! Those who call Dolly a "fake" could also claim that a father is less of a parent than a mother, because the child has its mother's mitochondria and not its father's. However, these arguments are specious, and they are readily refuted by the specifics of the science of developmental biology. See also **Cloning**.

Scientific Significance of Dolly

The scientific significance of Dolly, according to scientists, is that she was the first animal of any kind created from a fully differentiated cell using a process called nuclear transfer. This involves the insertion of the nucleus from an adult cell into an egg cell that has had its nucleus removed and which is then encouraged to grow by electrical stimulation [Tagliaferro and Bloom, 1999]. In the case of Dolly, researchers took a cell from the mammary gland of a 6-year-old Finn Dorset ewe, which had been pregnant for 3.5 months, and fused it with the egg cell of a Scottish blackface ewe. As the scientists Ian Wilmut and Keith Campbell, who created Dolly, explain, in their own account of the experiment, while Dolly was not the first mammal ever to be cloned, she was the first to be cloned from an adult body cell [Wilmut, et al.: 2000]. Dolly was the culmination of a long history of efforts by biologists to manipulate the process of cell differentiation and in particular to examine the genomic potential of older embryonic cells. Experiments in the late nineteenth century involving the physical separation of the cells of two-cell sea urchin embryos and of amphibians paved the way for experiments in the mid- and late-twentieth century in nuclear transplantation, involving insects, fish, mammals and eventually Dolly [McKinnell and Di Berardino, 1999]. According to the editors of *Science*, the birth of Dolly was a major scientific breakthrough, in that it made obsolete "preconceived limits" in the field of biotechnology and was seen to "profoundly change the practice or interpretation of science or its implications for society" [Bloom, 1997]. The apparent success of this experiment seemed to overturn one of the most firmly held beliefs of biology; namely that, once a cell had differentiated into its specialized form, it could not be "reprogrammed," or induced to develop into any other specialized cell.

As noted, Dolly was genetically transformed so that she would express human clotting factor IX protein in her milk. The production of transgenic animals such as sheep and pigs via the process of nuclear transfer is seen as more efficient than other methods in producing animals that may be bred as a source of human proteins used for medicines. Genetic identity achieved through nuclear transfer, scientists argue, contributes to the consistency of the medicinal product [Schnieke, et al.: 1997].

Purported Therapeutic Implications

In view of widespread concerns about the implications of the Dolly experiment, many scientists have sought to emphasize the medical benefits of cloning research and to openly reject its applications for human reproduction. Scientists have made extensive use of the media to defend and explain their work. In news articles on cloning research that were published or broadcast after the birth of Dolly, scientists who were quoted or cited often sought to distinguish therapeutic cloning–implicitly seen as "good," useful and legitimate–from reproductive cloning–seen as "bad," dangerous or illegitimate [Petersen, 2001]. Suggested therapeutic applications include the creation of human cells and tissues that can be used to repair damaged organs, and the growth of laboratory cultures of heart, skin and blood vessels on which to test new pharmaceuticals [Sexton, 2001]. Cloning is also seen to have great potential in xenotransplantation, the process of transplanting animal organs into humans. Dolly-style cloning could be used to make as many identical copies of a transgenic animal as needed within a single generation, thus creating a plentiful supply of a desired therapeutic agent [Cooper and Lanza, 2000]. In theory, a patient's own cells (e.g. skin or retinal tissue) could be cloned, providing them with grafts that would not be rejected, overcoming the immunological reaction to xenografting. In the light of Dolly, and other recent genetic developments, some scientists have begun to consider seriously the prospect of engineering the human germ line so as to eliminate the most debilitating diseases [Stock and Campbell, 2000], raising the specter of eugenics.

Social and Commercial Context of the Dolly Experiment

Amid the voluminous discussion about the Dolly experiment and its significance, there has been relatively little discussion about the context shaping cloning research and the commercial interests driving the work that led to Dolly. Scientists in this and other areas of research are increasingly dependent on private sources of funding as governments retreat from their commitment to basic research. What is clear from published accounts of Dolly and related experiments is the crucial role played by her creator's sponsor, PPL Therapeutics Limited, who see great potential in "pharming," that is, genetically altering animals so that they produce therapeutically valuable materials, usually proteins. Pharming is seen as a way of producing drugs more cheaply than is possible by other means. PPL Therapeutics provided the cells from which Dolly was made and some of the financial support, and was the principal creator of Polly [Kolata, 1997; and Wilmut et al., 2000]. As Wilmut, et al. have pointed out, PPL has survived and flourished because of its sponsored work on genetically transformed sheep, and those responsible for the sponsorship "were interested in cloning only as an adjunct to their work on genetic transformation" [Wilmut, et al.: 2000,].

The question of whether Dolly's premature death at age six and a half years old from a progressive lung disease (she was put down), in February 2003 [Meek, 2003], will lead to a wide-ranging assessment of the claims made about the technology that created her, remains to be seen. However, there is little doubt about the impact of media coverage of Dolly on public awareness of the issue of cloning and on debates about the implications and ethics of biotechnology applications, thus on these grounds alone assuring her a firm place in the history of reported scientific breakthroughs.

CLOSED LOW. See **Meteorology**.

CLOSED SYSTEM. 1. In thermodynamics, a system so chosen that no transfer of mass takes place across its boundaries; a system that can exchange energy but not matter with the outside world. 2. In mathematics, a system of differential equations and supplementary conditions such that the values of all the unknowns (dependent variables) of the system are mathematically determined for all values of the independent variables (usually space and time) to which the system applies.

CLOT. A firm mass that results from coagulation, or change from a fluid or semi-fluid state to a semisolid soft mass. This occurs in blood or lymph when it escapes from the blood or lymph vessels. For a discussion of the mechanism of blood clotting, see **Anticoagulants**; and **Blood**.

CLOTHES MOTH *(Insecta, Lepidoptera).* A moth whose larva eats dead and dry animal matter, especially fur, feathers, and wool. Three species are known. The case-bearing clothes-moth larva, *Tinea pellionella*, lives in a case made of bits of the material on which it lives, spun together with silk. The tube-building or tapestry moth, *Trichophaga tapetiella*, makes a gallery of silk and fragments as it works. The common or naked clothes-moth larva, *Tineola biselliella*, does not spin until it makes its cocoon. The adults of all three species are small, expanding to usually about $\frac{1}{2}$ inch (12 mm). As in the case of the buffalo carpet-moth good housekeeping is the best remedy for these pests. When present they may be killed by insecticides, the use of commercial sprays or in heavy infestations by fumigation.

Frequently when moths become overabundant in a house it is due to some forgotten breeding place, such as feathers or old garments in storage. A search in unexpected places is often the best cure for such attacks.

CLOUD ABSORPTION. The absorption of electromagnetic radiation within a cloud. With some exceptions, clouds typically absorb ≈10% of the (broadband) shortwave radiation and ≈95% of the longwave radiation incident on their boundaries. Thin clouds, notably thin cirrus, may absorb considerably less. The dominant absorber tends to be the water droplets or ice crystals making up the cloud, with water vapor playing a matching role only for shortwave absorption by upper tropospheric clouds.

CLOUD-AEROSOL LIDAR AND INFRARED PATHFINDER SATELLITE OBSERVATIONS (CALIPSO). The Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) satellite will provide new insight into the role that clouds and atmospheric aerosols (airborne particles) play in regulating Earth's weather, climate, and air quality.

CALIPSO combines an active lidar instrument with passive infrared and visible imagers to probe the vertical structure and properties of thin clouds and aerosols over the globe. Launch of the satellite took place April 28, 2006 at Vandenberg Air Force Bass in California. CALIPSO shared the Delta II rocket with NASA's, Ball Aerospace-built CloudSat.

CALIPSO and CloudSat are highly complementary and together provide new, never-before-seen 3-D perspectives of how clouds and aerosols form, evolve, and affect weather and climate. CALIPSO and CloudSat fly in formation with three other satellites in the A-train constellation to enable an even greater understanding of our climate system from the broad array of sensors on these other spacecraft.

CALIPSO is a joint U.S. (NASA) and French (Centre National d'Etudes Spatiales/CNES) satellite mission with an expected 3 year lifetime.

A-Train Constellation

The Afternoon or "A-Train" satellite constellation presently consists of three satellites flying in formation around the globe (NASA's Aqua and Aura satellites and CNES' PARASOL satellite). See Fig. 1. The CALIPSO and CloudSat satellite missions were inserted in orbit behind Aqua in April 2006. A sixth spacecraft, OCO, is planned for launch in 2008 and will be placed ahead of Aqua.

Each satellite within the A-Train has unique measurement capabilities that greatly complement each other. For the first time, near simultaneous measurements of aerosols, clouds, temperature, relative humidity, and radiative fluxes (the change of radiation in a layer) will be obtained over globe during all seasons. This ensemble of observations will allow one to understand how large scale aerosol and cloud properties change in response to changing environmental conditions. It will further allow one to determine how changing cloud and aerosols distributions influence our climate with greater clarity than possible before.

For much of its life, the A-Train will be maintained in orbit within 15 minutes of the leading and trailing spacecraft while traveling at over 15,000 miles per hour (24,140 kilometers per hour). CloudSat and CALIPSO will be controlled to an even finer requirement, within 15 seconds of each other, so that both instrument suites will view the same cloud area at nearly the same moment. This capability is crucial for studying clouds, which have lifetimes often less than 15 minutes.

The different instruments on each platform are described in Table 1.

CALIPSO flies as part of the Aqua satellite constellation (or A-train), which consists of the Aqua, CloudSat, CALIPSO, PARASOL, and Aura satellite missions. The constellation has a nominal orbital altitude of 705 kilometers (438 miles) and inclination of 98 degrees. Aqua will lead the constellation with an equatorial crossing time of about 1:30 PM. CloudSat and CALIPSO lag Aqua by 1 to 2 minutes and will be separated from each other by 10 to 15 seconds.

For the first 2 years of the mission, the nadir track of CALIPSO and CloudSat will be offset eastward from the Aqua nadir track by approximately 215 kilometers (134 miles) at the equator. This shift permits comparisons with MODIS aerosol products in regions that would have been otherwise masked by sun glint during the northern hemispheric summer. During the third year of the mission, the current plan is to allow CALIPSO to precess westward across the swath of MODIS and CERES to view aerosol and cloud properties at a variety of viewing angles.

The satellites in the A-train are maintained in orbit to match the World Reference System 2 (WRS-2) reference grid. This reference system was developed to facilitate regular sampling patterns by remote sensors in the Landsat program. Each satellite completes 14.55 orbits per day with a separation of 24.7 degrees longitude between each successive orbit at the equator. The orbit tracks at the equator progresses westward 10.8 degrees on succeeding days, which over a 16-day period, produces a uniform WRS grid over the globe. The WRS grid pattern consists of 233 orbits with separation between orbits at the equator of 172 kilometers (107 miles). The Aqua satellite will be controlled to the WRS grid to within +/- 10 kilometers (+/- 6 miles). Additional information on the WRS can be obtained from the Landsat 7-WRS, http://landsat.usgs.gov/project facts/project news/October 2002.php.

Table 1 lists each of the satellites in the A-Train constellation, their position within the constellation, a summary of each mission, and a description of each of their corresponding scientific instruments.

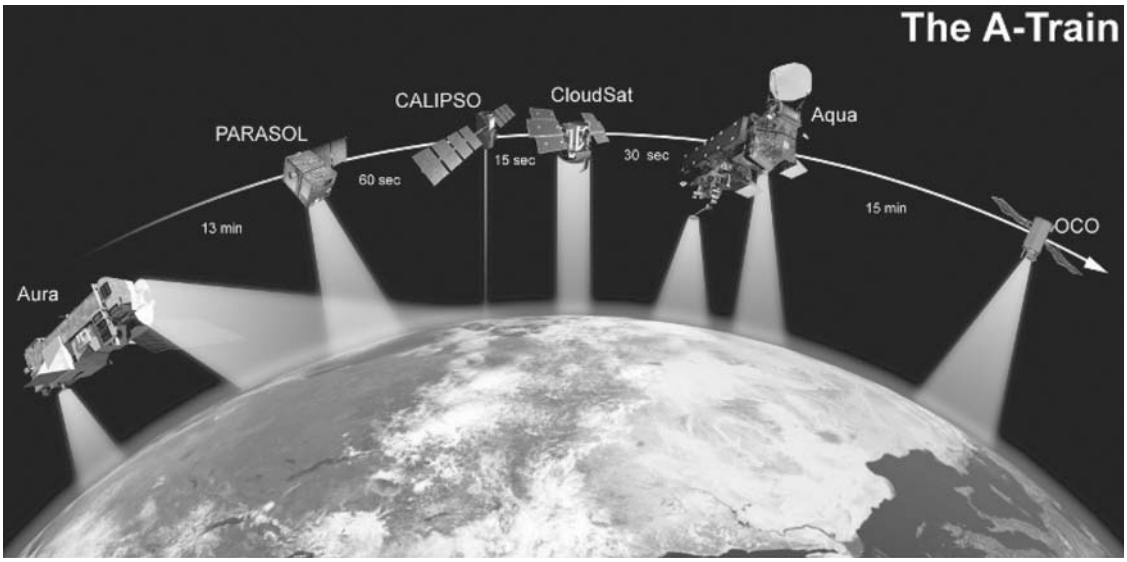

Fig. 1. A-Train Constellation of Satellites.

TABLE 1. A-TRAIN SATELLITES, POSITION, MISSION AND INSTRUMENT

Spacecraft	Position in the A-Train/Formation Requirements	Summary of Mission	Instruments Carried
Aqua	Lead spacecraft in formation until the launch of OCO.	Synergistic instrument package studies global climate with an emphasis on water in the Earth/atmosphere system, including its solid, liquid and gaseous forms.	AIRS/AMSU-A/HSB AMSR-R CERES MODIS
CloudSat	Lags Aqua by between 30 seconds and 2 minutes. Must maintain extremely precise positioning relative to both Aqua and CALIPSO to permit synergistic measurements with Aqua and CALIPSO.	Cloud Profiling Radar (CPR) will allow for most detailed study of clouds to date and should better characterize the role clouds play in regulating the Earth's climate.	CPR
CALIPSO	Lags CloudSat by no more than 15 seconds. Must maintain position relative to Aqua to permit synergistic measurements with Aqua.	Observations from spaceborne lidar, combined with passive imagery, will lead to improved understanding of the role aerosols and clouds play in regulating the Earth's climate, in particular, how the two interact with one another.	CALIOP IIR WFC
PARASOL	Lags CALIPSO by about 1 minute.	Polarized light measurements will allow better characterization of clouds and aerosols in the Earth's atmosphere, in particular, distinguishing natural and manmade aerosols.	POLDER
Aura	Lags Aqua by about 15 minutes but crosses equator 8 minutes behind Aqua due to different orbital track to allow for synergy with Aqua.	Synergistic payload will study atmospheric chemistry, focusing on the horizontal and vertical distribution of key atmospheric pollutants and greenhouse gases and how these distributions evolve and change with time.	HIRDLS MLS OMI TES
OCO	Will precede Aqua by 15 minutes when it is launched.	Will make global, space-based observations of the column integrated concentration of carbon dioxide, a critical greenhouse gas.	Three grating spectrometers

Science Objectives

Direct Aerosol Forcing and Uncertainty. Estimates of aerosol forcing can be made using models or, increasingly, directly from observations. CALIPSO two-wavelength and depolarization profiles provide vertically resolved information on aerosol distribution, extinction coefficient, hydration state, and discrimination of large and small particles. CALIPSO also offers an improved cloud-masking capability. These observations will allow improved assessments of the representation of aerosol distribution and properties in models. Use of CALIPSO observations, alone and together with other A-train observations, will allow improved observational assessments of aerosol direct forcing as well as improvements in model-based assessments.

Indirect Aerosol Forcing and Uncertainty. Changes in aerosol can potentially affect cloud reflectance and lifetime, but there are many uncertainties in how effective these mechanisms are in the real world. Regional assessments based on global datasets are needed. CALIPSO profiles will provide information on the vertical location of aerosols and whether or not they are in contact with, and therefore able to influence, clouds. CALIPSO also offers improved cloud masking of aerosol data, providing an opportunity to assess possible aerosol biases introducing uncertainties in current assessments of aerosol indirect effects.

Surface and Atmospheric Fluxes. The components of the atmospheric energy balance (in particular, SW and LW radiative fluxes) provide powerful constraints with which to test the performance of global climate models. Current global datasets of surface and atmospheric radiative fluxes contain significant uncertainties, largely due to the effects of clouds on radiation and in particular to effects of cloud multilayering. CALIPSO and Cloudsat will provide comprehensive observations of cloud height, thickness and layering. Coincident cloud observations from CALIPSO, CloudSat, and MODIS together with measurements of TOA fluxes from CERES provide an opportunity to create a greatly improved dataset of surface and atmospheric radiative fluxes, particularly in the polar regions.

Cloud-Climate Feedbacks. The fundamental problem in modeling cloud-radiation feedbacks involves the prediction of cloud properties based on atmospheric state and then using these properties to compute radiative fluxes. Testing these modeled processes requires nearly simultaneous observations of clouds, radiation, and atmospheric state. Cloud profiles from CALIPSO and CloudSat, cloud properties from MODIS/Aqua, radiative fluxes from CERES/Aqua, and measurements of atmospheric state

TABLE 2. CALIPSO SCIENCE OBJECTIVES

Science Objective	Measurement	CALIPSO	Constellation
Direct aerosol forcing	Aerosol vertical distribution and extinction profiles	CALIOP	
	Aerosol optical depth	CALIOP	Aqua-MODIS, PARASOL
	Aerosol type information	CALIOP	Aqua-MODIS, PARASOL
	Aerosol absorption		Aura-OMI
	Broadband radiances		Aqua-CERES
Indirect aerosol forcing	Aerosol and cloud vertical distributions	CALIOP	
Cloud reflectance and droplet size		Aqua-MODIS	
	Broadband radiances		Aqua-CERES
Longwave surface and atmospheric fluxes	Cloud height and thickness, multilayering	CALIOP (thin cloud)	CloudSat-CPR (thick cloud)
	Cloud ice/water phase	CALIOP (profiles)	PARASOL, Aqua-MODIS (cloud-top only)
	Cirrus emissivity and particle size	CALIOP + IIR + WFC	Aqua-MODIS, AIRS
	Other cloud properties	CloudSat, PARASOL, Aqua-MODIS, AIRS, AMSR/E	
	Broadband radiances		Aqua-CERES
Cloud radiative feedbacks	All elements of longwave surface and atmospheric fluxes plus: Cloud optical depth	CALIOP	Aqua-MODIS,
feedbacks	surface and atmospheric fluxesplus:Cloud optical depth	PARASOL	

from AIRS and AMSR (Aqua) provide the most complete closure of the cloud-radiation-atmospheric state feedback loop in the foreseeable future.

Measurement Objectives

Table 2 lists the measurements needed to address the CALIPSO science objectives and indicates a number of the synergies available from combining CALIPSO observations with the additional measurements available from the other instruments of the constellation.

CALIPSO Payload

The CALIPSO payload consists of three co-aligned nadir-viewing instruments:

- the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP)
- the Imaging Infrared Radiometer (IIR)
- the Wide Field Camera (WFC)

These instruments are designed to operate autonomously and continuously, although the WFC acquires data only under daylight conditions. Science Data are downlinked using an X-band transmitter system which is part of the payload.

The physical layout of the payload is shown Fig. 2.

Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP). CALIOP utilizes three receiver channels: one measuring the 1064 nm backscatter intensity and two channels measuring orthogonally polarized components of the 532 nm backscattered signal. Dual 14-bit digitizers on each channel provide an effective 22-bit dynamic range. The receiver telescope is 1 meter in diameter. A redundant laser transmitter is included in the payload.

An active boresight system is employed to maintain co-alignment between the transmitter and the receiver. Ball Aerospace Corporation, http://www.ballaerospace.com/calipso.html, developed the instrument.

Wide Field Camera (WFC). The WFC is a modified version of the commercial off-the-shelf Ball Aerospace CT-633 star tracker camera. It is a fixed, nadir-viewing imager with a single spectral channel covering the 620-270 nm region, selected to match band 1 of the MODIS (MODerate resolution Imaging Spectroradiometer) instrument on Aqua.

Imaging Infrared Radiometer (IIR). A three-channel IIR is provided by CNES with algorithm development performed by the Institute Pierre Simon Laplace (IPSL) in Paris.

The IIR a nadir-viewing, non-scanning imager having a 64 km by 64 km swath with a pixel size of 1 km (3,280 ft). The CALIOP beam is nominally aligned with the center of the IIR image.

The instrument uses a single microbolometer detecter array, with a rotating filter wheel providing measurements at three channels in the thermal infrared window region at 8.7 mm, 10.5 mm, and 12.0 mm.

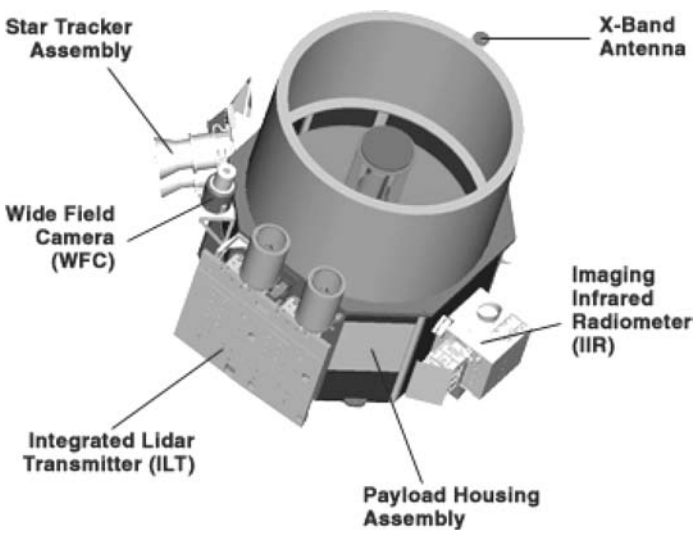

Fig. 2. CALIPSO payload configuration.

These wavelengths were selected to optimize joint CALIOP/IIR retrievals of cirrus cloud emissivity and particle size.

Partners

CALIPSO is a collaboration between NASA Langley Research Center and the French space agency Centre National d'Etudes Spatiales. Other members of the CALIPSO team are Ball Aerospace and Technologies Corporation, Hampton University, and the Institut Pierre Simon Laplace. The primary roles and contributions of the team members are.

National Aeronautics and Space Administration (NASA). NASA Langley Research Center (LaRC), http://www.nasa.gov/centers/langley/home/index.html, leads the mission and provides overall program management, systems engineering, payload mission operations, science data validation, and data processing and archival. NASA Goddard Space Flight Center (GSFC), http://www.nasa.gov/centers/goddard/home/index.html, provides program management for the CALIPSO mission.

Centre National d'Etudes Spatiales (CNES). CNES, http://www.cnes.fr/web/455-cnes-en.php, provides the PROTEUS spacecraft and the Imaging Infrared Radiometer (IIR), and performs payload-to-spacecraft integration and spacecraft mission operations.

Ball Aerospace and Technologies Corporation (BATC). BATC, http://www.ballaerospace.com/index.html, develops CALIOP and the wide-field

camera and provides payload integration, launch vehicle support, and science data downlink.

Hampton University (HU). HU http://calipsooutreach.hamptonu.edu/, an historically black university located in Hampton, Virginia, manages the CALIPSO quid pro quo validation effort, the education and public outreach program, and leads the International Science Advisory Panel.

Institut Pierre Simon Laplace (IPSL). IPSL, leads French science studies, IIR algorithm development, and contributes to science data validation.

See also **Earth Observing System (EOS)**; and **Earth System Science Pathfinder (ESSP) Program**.

CLOUD ALBEDO. Reflectivity that varies from less than 10% to more than 90% of the insolation and depends on drop sizes, liquid water content, water vapor content, thickness of the cloud, and the sun's zenith angle. The smaller the drops and the greater the liquid water content, the greater the cloud albedo, if all other factors are the same.

CLOUD ATTENUATION. Usually, the attenuation of microwave radiation by clouds.

For the centimeter wavelength band, clouds produce Rayleigh scattering. The attenuation is due largely to scattering, rather than absorption, for both ice and water clouds. The cloud attenuation for one-way transmission is

$$\text{cloud attenuation (db km}^{-1}) = 0.454\frac{6\pi}{\lambda}\frac{M}{\rho}\text{Im}(-\kappa),$$

where M (g m^{-3}) is the liquid water content, (g cm^{-3}) the density of water, λ the wavelength, and $\kappa = (m^2 - 1)(m^2 + 2)^{-1}$, where m^2 is the complex dielectric constant. The attenuation depends only on M, and in the range of wavelengths from 1 to 10 cm is approximately $(1to100) \times 10^{-2}M$ for water clouds, and $(2to20) \times 10^{-2}M$ for ice clouds.

AMS

CLOUD CAMERA. A camera system specifically designed for use in obtaining cloud photographs for the purposes of determining their locations, movement, or percent of sky coverage.

Video or motion picture cameras are operated in a manner that records a new image every second or so in order to follow cloud development (time-lapse photography). Stereographic cloud images may be obtained from cameras at separated locations. Photogrammetric analysis of images with known foreground fiducial points from cameras with known optics can yield quantitative measurements of cloud dimensions and movements. Whole-sky imaging cameras use optics or reflectors with a very wide field of view to record the position of nearly all clouds in the hemisphere of sky overhead to estimate the fractional sky coverage of cloudiness. Conversion of the photographic images to digital form allows automated analysis. Useful data are often limited to daylight periods.

CLOUD CHAMBER. An enclosure containing air or other gas saturated with water vapor, the cooling of which by a sudden expansion results in the formation of fog droplets upon particles of dust or other nuclei. That ions in the gas are capable of serving as condensation nuclei, even when no dust is present, was demonstrated by the experiments of C.T.R. Wilson. Thus the clouds produced are much more dense if the gas is traversed by some ionizing emission like x-rays or alpha rays. Sir J.J. Thomson utilized this effect in his early measurements of the electronic charge. One of the most striking phenomena of the Wilson cloud chamber is exhibited when single ionizing particles, such as alpha or beta particles, are allowed to traverse it just before the expansion. The path of each particle is marked by a visible white streak or "track" of mist, sometimes several centimeters in length, which soon diffuses and disappears. The study of photographs of such cloud tracks has afforded much information as to the nature and the movements of the particles producing them and the interactions between particles and radiations. See also **Bubble Chamber**; and **Particles (Subatomic)**.

CLOUD-DETECTION RADAR. A radar designed for detection of cloud particles as distinguished from the larger particles that constitute precipitation. Cloud radars typically employ short wavelengths of 1 cm and shorter (e.g., Ka band) and are designed for short-range, high-resolution measurements. They can also be multiwavelength or polarimetric radars capable of providing information on the shapes and sizes of the cloud particles. Radars operating at short wavelengths have increased sensitivity to all weather targets but also suffer from increased attenuation by clouds and precipitation.

CLOUD DROP. A spherical particle of liquid water, from a few micrometers to a few tens of micrometers diameter, formed by condensation of water vapor on a hygroscopic aerosol particle (cloud condensation nucleus).

Such drops, apparently suspended in the air with other drops, form a visible cloud. Clouds may also contain interstitial haze particles, smaller than a few micrometers (μm) in diameter. Activation distinguishes a cloud from a haze, which contains only or mainly unactivated droplets. Cloud drops differ in size from drizzle drops and raindrops. A diameter of 0.2 mm has been suggested as an upper limit to the size of drops that shall be regarded as cloud drops; larger drops fall rapidly enough so that only very strong updrafts can sustain them. Any such division is somewhat arbitrary, and active cumulus clouds sometimes contain cloud drops much larger than this.

AMS

CLOUD FEEDBACK. The coupling between cloudiness and surface air temperature in which a change in surface temperature could lead to a change in clouds, which could then amplify or diminish the initial temperature perturbation. For example, an increase in surface air temperature could increase the evaporation; this in turn might increase the extent of cloud cover. Increased cloud cover would reduce the solar radiation reaching the Earth's surface, thereby lowering the surface temperature. This is an example of negative feedback and does not include the effects of longwave radiation or the advection in the oceans and the atmosphere, these factors must also be considered in the overall relationship of the climate system.

CLOUD FORCING. The difference between the radiation budget components for average cloud conditions and cloud-free conditions. Roughly speaking, clouds increase the albedo from 15 to 30%, which results in a reduction of absorbed solar radiation of about 50 W/m^2. This cooling is offset somewhat by the greenhouse effect of clouds which reduces the OLR by about 30 W/m^2, so the net cloud forcing of the radiation budget is a loss of about 20 W/m^2. Were the clouds to be removed, the Earth would gain this last amount in net radiation and begin to warm up.

CLOUD-HEIGHT INDICATOR. The general term for instruments that measure the height of cloud bases. Cloud-height indicators may be classified according to their principle of operation. One class of instrument is based on height determination by means of the principle of triangulation. A beam of light projected from the ground onto the base of the cloud is observed visually or electrically from a remote point. The height of the cloud is determined trigonometrically from a measurement of the angle defined by the light projector, the observation point, and the light spot on the cloud plus the distance between the light projector and the observation point. Examples of instruments based on this principle are the ceilometer and the ceiling light. A second class of instrument is based on pulse techniques. The time required for a pulse of energy to travel from a radiator located on the ground to the cloud base and back to the ground is measured electrically. The height of the cloud is computed from this transit time and a knowledge of the propagation velocity of the pulse. Instruments based on this principle include the pulsed-light cloud-height indicator and vertically directed cloud-detection radar.

CLOUD PHYSICS. The body of knowledge concerned with physical properties of clouds in the atmosphere and the processes occurring therein. Cloud physics, broadly considered, embraces not only the study of condensation and precipitation processes in clouds, but also radiative transfer, optical phenomena, electrical phenomena, and a wide variety of hydrodynamic and thermodynamic processes peculiar to natural clouds. Cloud physics is a distinct subdivision of physical meteorology. Early interest in this subject was stimulated by the role of clouds in aircraft safety related to icing and turbulence (The Thunderstorm Project) and

the discovery of cloud modification techniques by cloud seeding. The formation of precipitation and the influence of clouds in radiative processes in the atmosphere (both solar and thermal) determine the key role of the subject in global climate.

CLOUD POINT. The temperature at which a solution becomes cloudy as it is cooled at a specified rate. The cloud point is an important property in the specification of lacquers, oils, and other industrial solutions. See also **Petroleum**.

CLOUD RADAR. A radar optimized to detect clouds. This is usually a short wavelength radar often called millimeter radar, since its wavelength is usually near 8 mm (Ka band) or 3 mm (W band). Such shorter wavelengths give radars an advantage in cloud detection because of the radar scattering cross section for small particles varying as the inverse radar wavelength to the fourth power. Because attenuation caused by atmospheric liquid and from water vapor is serious at these short wavelengths, such radars are usually operated at ranges closer than about 20 kilometers (12 miles). They can be either of the scanning type or fixed in the vertical. Their good spatial resolution allows them to depict finescale cloud features and, when used in combination with other active (e.g., lidar) and passive (microwave and IR radiometers) sensors, can, under some conditions, be used to quantitatively map cloud ice and liquid water contents, particle sizes, and concentrations.

CLOUD RADIATIVE FORCING. The difference between net irradiances measured for average atmospheric conditions and those measured in the absence of clouds for the same region and time period. Cloud radiative forcing depends jointly on the amount of cloud present and the sensitivity of radiation to cloud amount. It may be partitioned into longwave and shortwave forcing terms, the combination of which typically results in a negative net forcing when referenced to the top of the atmosphere (i.e., satellite measurements). That is, a clear region typically reflects less solar, and emits more terrestrial, radiation than does the average condition, and the difference in solar reflection is typically greater than the difference in terrestrial emission to space. While the definition of cloud radiative forcing in terms of average measured values is unambiguous, the relationship between cloud radiative forcing and the equilibrium effects of clouds on climate, especially on surface temperature, is a complicated topic.

CLOUDS AND CLOUD FORMATION. A hydrometeor; large numbers of water droplets or ice crystals virtually suspended in the atmosphere. Actually, the water or ice in a cloud occupies only a small fraction of the total space appearing as a cloud; light is well-reflected from the droplets or crystals, and the cloud body appears as an opaque drifting object. Clouds differ from fog in that the latter is, by definition, in contact with the earth's surface.

Most clouds are *convective clouds*, owing their vertical development, and possibly their origin, to the process of convection, i.e., currents of moist air ascend, and adiabatic cooling and condensation occur. In rare exceptions, such as in the case of fog, which may produce stratus, the cooling may occur as a result of other processes. The ascent of air may result from vertical instability, as in most cumulus clouds; from forced lifting at a frontal surface, as in many altostratus and other stratiform clouds; from undulatory motions at inversion surfaces; or from orographic lifting.

Condensation at the point of saturation or at a low degree of supersaturation is dependent upon the presence of many condensation nuclei for water clouds, or ice nuclei for ice-crystal clouds. The size of cloud drops varies from one cloud type to another, and within any given cloud there always exists a finite range of sizes. Generally speaking, cloud drops range from between 1 and 100 micrometers in diameter, though they may be as large or larger than 200 micrometers in diameter. Larger drops within a cloud fall rapidly enough so that only very strong updrafts can sustain them. As cloud drops increase in size, they may form virga or precipitation.

Cloud Formation

Cloud formation results from the simultaneous presence in the atmosphere of several contributing factors. Because cloud particles are primarily liquid or crystalline water, the first requirement is for water substance. In fact, from a meteorological viewpoint, water vapor is the most important substance found in air. It is not only important as the raw material for clouds and rain, but also as a vehicle for the transport of energy (latent heat) and as a regulator of planetary temperatures via the greenhouse effect. Water vapor in the atmosphere has a varied distribution, ranging from zero to a volume percentage of about 4%. The water vapor content of natural air over Pittsburgh, Pennsylvania, as an example, is given on a month-to-month basis in the accompanying Table 1.

TABLE 1. WATER VAPOR CONTENT OF NATURAL AIR (MONTHLY AVERAGES AT PITTSBURGH, PENNSYLVANIA)

Month	Average Temperature		Concentration of Water in Air		Volume of Water, Gallons per Hour (At air rate of 20,000 cubic feet per minute)
	°F	°C	Grains per Cubic Foot	Parts per Million	
January	37.0	2.8	2.18	5	87
February	31.7	−0.2	1.83	4.2	73
March	47.0	8.3	3.40	7.8	136
April	51.0	10.6	3.00	6.9	120
May	61.6	16.6	4.80	11	192
June	71.6	21.4	5.94	13.6	238
July	76.2	24.4	5.60	12.8	224
August	73.6	23.1	5.16	11.8	206
September	70.4	21.3	5.68	13	227
October	56.4	13.5	4.00	9.2	160
November	40.4	4.7	2.35	5.4	94
December	36.6	2.5	2.25	5.1	90

Water vapor is concentrated in greatest quantity in the lower part of the atmosphere, with only a minute fraction occurring above the tropopause. See **Atmospheric (Earth)**. The principal sources of water vapor are oceans, large lakes, and vegetation-covered land areas, especially those of the tropics and subtropics. The winds carry water vapor from the source regions elsewhere over the entire globe. Transportation of water vapor is sufficiently localized in character so that tongues and islands of moist and dry air are present everywhere in the lower hemisphere. In the Northern Hemisphere, moist tongues usually flow from south or west, and dry tongues from some northerly direction, except that, particularly during summer, very dry air originating in the subtropical anticyclones often flows from the south and west. In the Temperate Zone, moist tongues normally appear on the west side of anticyclones and on the east side of cyclones; and dry tongues appear on the east side of anticyclones and the west side of cyclones.

The amount of water vapor contained in the air may be expressed as the relative humidity, which is simply the fraction actually present of the amount of water required to completely saturate the air.

A second requirement is the presence of particles of solid, semisolid, or semiliquid matter that have an affinity for water. These particles act as microscopic nuclei upon which water vapor can collect and thereby permit particle growth to the necessary size for cloud droplets and crystals. Condensation nuclei present in the atmosphere include industrial combustion and other products, exhaust products from engines, and notably sea salt. Sublimation nuclei, also called freezing nuclei, in the free atmosphere consist almost entirely of ice crystals.

A third requirement for cloud formation is a refrigeration mechanism to lower the temperature of the air and thereby raise the relative humidity to saturation. Cooling mechanisms in the atmosphere are mainly thermodynamic in which ascending air is cooled very nearly 2 °C (35.6 °F) for each 1,000 feet (304.8 meters) of elevation. See Fig. 1. Other cooling mechanisms of lesser importance include (1) radiation, (2) contact cooling, and (3) mixing. Cooling beyond the initial saturation temperature forces water vapor onto growing cloud particles.

The number of condensation nuclei available to act as cores for cloud droplet growth varies from as few as one thousand to several hundred thousand per cubic centimeter. Among the available nuclei with affinity for water, some have a greater affinity than others which, therefore, causes selective growth. Clouds of liquid droplets always result when the relative humidity approaches or equals 100% when the temperature is above freezing. The relationship of cloud droplet growth with humidity is shown in Fig. 2.

Sublimation nuclei are not always present and liquid cloud droplets do form in their absence in temperatures down to at least −40 °C (−40 °F). When sublimation nuclei are present, cloud particles consist primarily of ice crystals. See also **Precipitation and Hydrometeors**

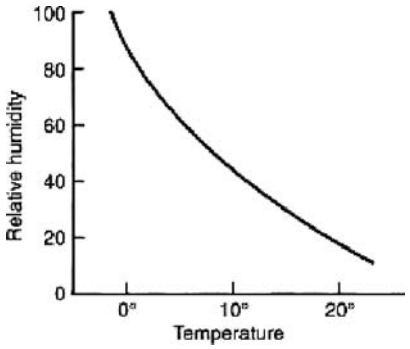

Fig. 1. Increase in relative humidity with decreasing temperature for a situation at 5,000 feet (1,524 meters), starting with a given water vapor content at 20 °C (68 °F).

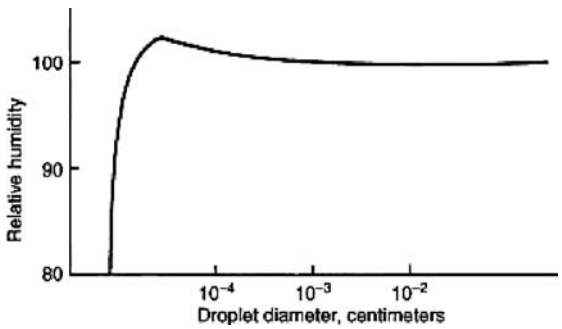

Fig. 2. Typical growth of cloud droplet in relation to relative humidity. The size of the oversaturation in particles is related to their affinity for water.

Cloud Seeding. During the 1940s, a discovery was made by Dr. Vincent J. Schaefer that the introduction of solid carbon dioxide into water droplet clouds having temperatures lower than 0 °C (32 °F) caused the cloud particles to transform from liquid droplets to ice crystals. The terminology "cloud seeding" was thereby introduced. Solid carbon dioxide (dry ice) has a temperature close to −70 °C (−94 °F) and its presence in saturated air below freezing temperatures causes a multitude of micro ice crystals to be generated (sometimes called diamond dust). Water substance is transferred rapidly from the liquid droplets to the tiny ice crystals, causing the ice crystals to grow and to fall as snow. The cloud is thereby cleared away by dry ice seeding.

Later, Dr. B. Vonnegut discovered that certain other crystalline forms whose structure is very similar to water crystals cause water to collect onto these nonwater crystals. The effect was similar to that achieved by dry ice seeding. Silver iodide was the most prominent of the nonwater crystals considered in this manner. Silver iodide initiates ice crystal formation (glaciation) at about −7 °C (19.4 °F). As of the late 1980s, the viability and reliability of cloud seeding is seriously questioned and much of the research once devoted to the topic has waned. See also **Cloud Seeding**.

Glaciation of Clouds. Water droplet clouds usually have distinct, clearly delineated and sharply bordered edges. Ice crystal clouds have "soft" fuzzy edges.

When ice crystal particles are introduced into liquid droplet clouds at temperatures below freezing, the water in the liquid droplets migrates rapidly to the crystals, which then grow rapidly. The transformation of a liquid droplet cloud to an ice crystal cloud is known as *glaciation*. To the observer watching this transformation, there is a rather rapid change from "hard" edged clouds to "fuzzy and milky" edged clouds. The anvil head of a thunderstorm is made of ice crystals that were glaciated in the growing cumulonimbus.

Cloud Evaporation. Any downward motion of air results in compressive heating of the air. Cloud particles in downward-moving air are in an environment of relative humidity less than 100% and lose their liquid or solid water, shrink in size quite rapidly, and assume the dimensions of nuclei. In essence, the cloud so affected disappears. This phenomenon can be observed on the lee slopes of mountains that are cloud covered on the windward side.

Cloud Classification

There are three classification schemes whereby clouds are distinguished and grouped: (1) by appearance; (2) by usual altitudes where found; and (3) by particulate composition. The scheme in general use, based on a classification system introduced by Luke Howard in 1803, is the one adopted by the World Meteorological Organization http://www.wmo.ch/index-en.html, and published in the *International Cloud Atlas* (1987). This classification is based upon the determination of:

a. Genera, the main characteristic forms of clouds. The ten cloud genera are cirrus, cirrocumulus, cirrostratus, altocumulus, altostratus, nimbostratus, stratocumulus, stratus, cumulus, and cumulonimbus. Descriptions are given later.

b. Species, the peculiarities in shape and differences in internal structure of clouds. The fourteen cloud species are fibratus, uncinus, spissatus (false cirrus), castellanus, floccus, stratiformus, nebulosus, lenticularis, fractus, humilis, mediocris, congestus, calvus, and capillatus.

c. Varieties, special characteristics of arrangement and transparency of clouds. The nine cloud varieties are intortus, vertebratus, undulatus, radiatus, lacunosis, duplicatus, translucidus, perlucidus, and opacus.

d. Supplementary features and accessory clouds, appended and associated minor cloud-forms. The nine supplementary features and accessory clouds are incus, mamma, virga, praecipitatio, arcus, tuba, pileus, velum, and pannus.

e. Mother-clouds, the clouds from which other clouds have formed.

Classification by Altitude. The three classes by altitude are distinguished as *high clouds* (cirrus, cirrocumulus, cirrostratus, occasionally altostratus, and the tops of cumulonimbus); *middle clouds* (altocumulus, altostratus, nimbostratus, and portions of cumulus and cumulonimbus); and *low clouds* (stratocumulus, stratus, most cumulus, and cumulonimbus bases, and sometimes nimbostratus).

Classification by Particulate Composition. Included are *water clouds*, composed entirely of ordinary and/or supercooled water droplets (altocumulus, nimbostratus, stratocumulus, stratus, and cumulus); *ice-crystal clouds*, composed entirely of ice crystals (cirrostratus, cirrus, occasionally altostratus, and cirrocumulus); and *mixed clouds*, a combination of water and ice crystals (cumulonimbus, usually altostratus, occasionally cirrocumulus and the water clouds).

Nimbus. A name formerly used for any rain-producing cloud, but it is not now recognized in the international cloud classification.

Popular Names. Aside from the foregoing classifications, there are various popularly recognized cloud forms or conditions, which are apt to be colorfully descriptive of the cloud's appearance or portent. *Mare's tail*, for example, describes long, detached, well-defined wisps of fibrous cirrus cloud, with feather-like tufts at one end. *Mackerel sky* is a sky with considerable cirrocumulus or, especially, small-element altocumulus clouds arranged in uniform bands similar in appearance to the scales on a mackerel. *Emissary sky* describes a sky that is often one of the first indications of the approach of a cyclonic storm, composed of isolated or small, separated groups of cirrus clouds. *Scud* is a term most often applied to low, ragged, wind-torn stratus clouds moving rapidly beneath a layer of nimbostratus. The terms "incus," "anvil cloud," or "thunderhead" are described in the definition of the genus cumulonimbus, below. "Abraham's tree" is a name given to the cloud variety radiatus. Certain clouds that form over mountain peaks or ridges are described as cap clouds, banner clouds, and crest clouds.

The Ten Cloud Genera

Some of the major cloud formations are illustrated in Fig. 3. The ten genera are defined briefly in the following paragraphs.

Full discussion of all the species, varieties, supplementary features and accessory clouds would involve details beyond the scope of this article. The species *stratoformis*, for example, is the most common form of the genera altocumulus and stratocumulus, consisting of a very extensive, not necessarily continuous, horizontal layer or layers. *Translucidus*, as a variety of stratiformis, denotes the greater part of the layer, patch, or sheet as being sufficiently translucent to reveal the position of the sun or of higher clouds. The variety *perlucidus*, on the other hand, denotes distinct spaces in stratiforms, which permit the sun, moon, blue sky, or higher clouds to be seen. Similarly, distinction is made between the

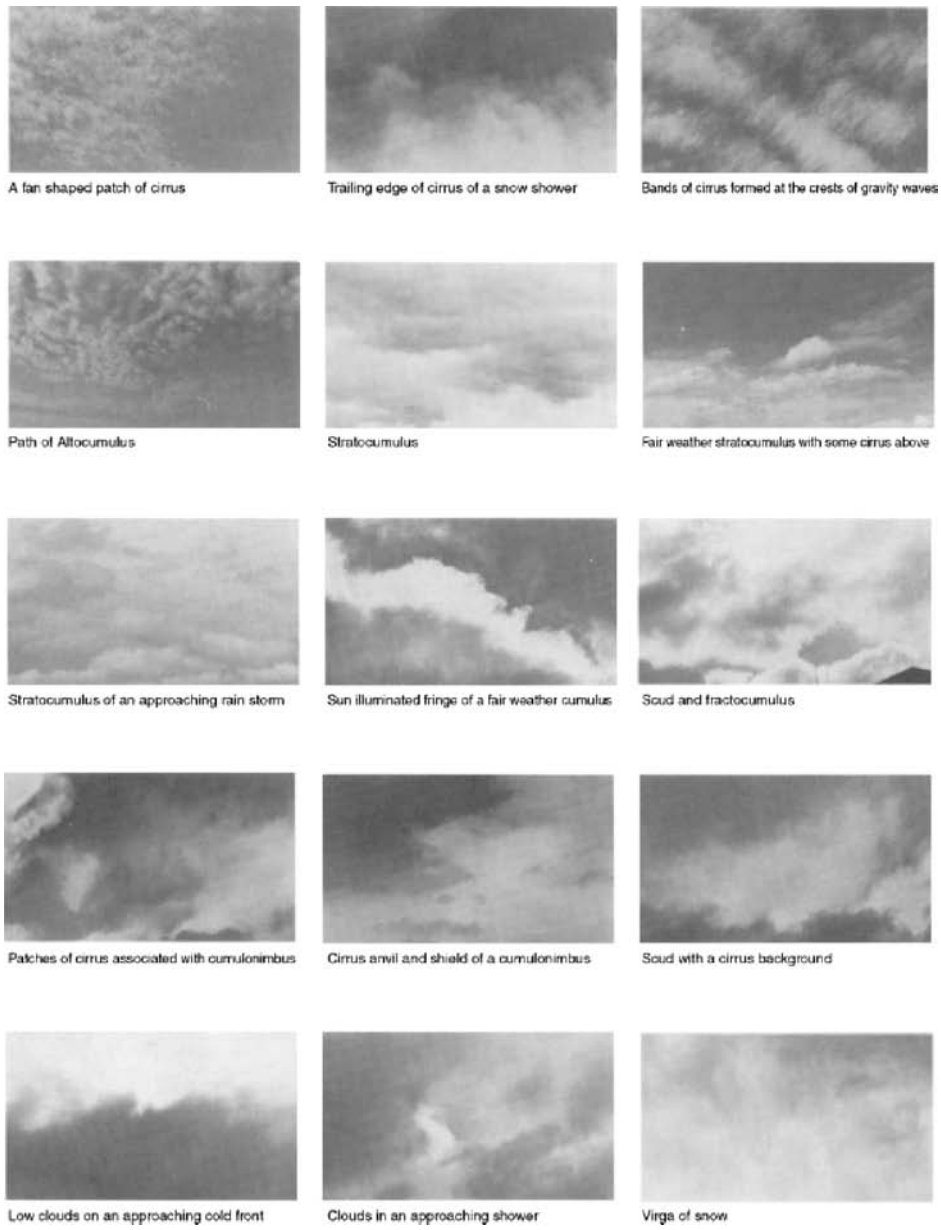

Fig. 3. Various cloud formations.

characteristics of cloud precipitation. *Praecipitatio* is a supplementary feature denoting precipitation that reaches the earth's surface, while *virga* refers to precipitation that evaporates before reaching the earth's surface. Through such fine distinctions, clouds can be minutely defined and classified.

Following are descriptions of the ten cloud genera:

Cirrus is a high-altitude, ice-crystal cloud in the form of white, delicate filaments, patches, or narrow bands. It is usually thin, wispy, often in streaks, and is always whitish without shadows. The term "cirrus" is frequently used for all types of cirriform clouds, i.e., cirrus, cirrocumulus, cirrostratus, and all their species and varieties.

These clouds have a fibrous aspect and/or a silky sheen. Many of the ice crystal particles of cirrus are sufficiently large to acquire an appreciable speed of fall; therefore, the cloud elements have a considerable vertical extent. Wind shear and variations in particle size usually cause these fibrous trails to be slanted or irregularly curved. For this reason, cirrus does not usually tend, as do other clouds, to appear horizontal when near the horizon. Because cirrus elements are too narrow, they do not produce a complete circular halo. Cirrus often evolves from virga of cirrocumulus or altocumulus (Ci cirrocumulogenitus or Ci altocumulogenitus), or from the upper part of cumulonimbus (Ci cumulonimbogenitus). Cirrus may also result from the transformation of cirrostratus of uneven optical thickness, the thinner parts of which dissipate (Ci cirrostratomutatus). It may be difficult at times to distinguish cirrus from cirrostratus (often impossible when near the horizon); cirrostratus has a much more continuous structure, and if subdivided, its bands are wider. Thick cirrus (usually cirrus spissatus) is differentiated from patches of altostratus by its lesser extension and white color. The term "cirrus" is frequently used for all types of cirriform clouds.

Cirrocumulus is a small, billowed, high-altitude cloud appearing as a thick, white patch without shadows, composed of very small elements in the form of grains, ripples, etc. It may be composed of highly supercooled water droplets, as well as small ice crystals, or a mixture of both; usually, the droplets are rapidly replaced by ice crystals. Sometimes corona or irisation may be observed; mamma may appear; and small virga may fall. Cirrocumulus is most often confused with altocumulus, but differs primarily in that its constituent elements are very small and are without shadows. A cirrocumulus cloud formation indicates some instability in the layer at and above the cloud level, which permits rising currents to form the cloud parcels and descending currents to create clear spaces between them. Cirrocumulus frequently occurs in advance of a cyclonic storm.

Cirrostratus is a high-altitude, ice-crystal cloud appearing as a whitish veil, usually fibrous, but sometimes smooth, which may totally cover the sky. It is usually translucent, often produces halo phenomena, i.e., mock suns and mock moons, which are images of the real celestial bodies. Sometimes a banded aspect may appear, but the intervals between the bands are filled with thinner cloud veil. The edge of a veil of cirrostratus

may be straight and clear-cut, but more often it is irregular and fringed with cirrus. Some of the ice crystals that compose the cloud are large enough to fall and thereby produce a fibrous aspect. Cirrostratus occasionally may be so thin and transparent as to render it nearly indiscernible, especially through haze or at night. At such times, the existence of a halo may be the only revealing feature. The angle of incidence of illumination upon a cirrostratus layer is an important consideration in evaluating the identifying characteristics. When the sun is high (generally above 50° elevation), cirrostratus never prevents the casting of shadows by terrestrial objects; and a halo might be completely circular. At progressively lower angles of the sun, halos become fragmentary and light intensity noticeably decreases. Cirrostratus may be produced by the merging of elements of cirrus (Cs cirromutatus); from cirrocumulus (Cs cirrocumulogenitus); from the thinning of altostratus (Cs altostratomutatus); or from the anvil of cumulonimbus (Cs cumulonimbogenitus). Since cirrostratus and altostratus form from each other, it is frequently difficult to delineate between the two. In general, altostratus does not cause halo phenomena, is thicker than cirrostratus, appears to move more rapidly, and has a more even optical thickness. When near the horizon, cirrostratus may be impossible to distinguish from cirrus.

Altocumulus (abbreviated Ac). A middle-altitude water or mixed cloud, white and/or gray in color, that occurs as a layer or patch with a waved aspect, the elements of which appear as laminae, rounded masses, rolls, etc. These elements usually are sharply outlined, but they may become partly fibrous or diffuse; they may or may not be merged; they generally have shadowed parts; and, by convention, when observed at an angle of more than 30° above the horizon, an altocumulus element subtends an angle between 1° and 5°. Small liquid water droplets invariably compose the major part of the composition of altocumulus. This results in sharpness of outline, small internal visibility (both common cumuliform characteristics) and in the occurrence of coronae and irisation (colored diffraction phenomena). With sufficiently low temperatures, ice crystals may appear in all forms of altocumulus, but mainly in the species castellanus or floccus, each unit of which may produce an individual snow shower. The crystals that fall from altocumulus sometimes produce parhelia (*sundogs*), or a moon or sun pillar, any of which indicates the presence of tabular crystals. See also **Sundogs** and **Sun Pillars**. Should the composition become entirely ice crystals, the cloud would lose its characteristic sharpness of outline. Altocumulus often forms directly in clear air. It may be produced by an increase in size or thickening of the elements of an entire layer or patch of cirrocumulus (Ac cirrocumulomutatus); by subdivision of a layer of stratocumulus (Ac stratocumulomutatus); by transformation of altostratus (Ac altostratomutatus) or nimbostratus (Ac nimbostratomutatus); or by the spreading of cumulus or cumulonimbus (Ac cumulogenitus or Ac cumulonimbogenitus). Altocumulus frequently occurs in a given sky at different levels; also, it often is associated with clouds of other genera. Virga may appear with most of the species of altocumulus. This supplementary feature, however, should not be confused with the very white trails of ice crystals that frequently are formed with the dissipation of altocumulus floccus. When detached, the ice crystal trails are cirrus. Sometimes mamma occur with altocumulus. Cirrocumulus and stratocumulus are the clouds most easily confused with altocumulus. The elements of cirrocumulus never have shadows of their own, and nearly always are smaller. Stratocumulus elements are larger than those of altocumulus. The rolls or cells that are associated with altocumulus are thought to be a result of the absorption of terrestrial radiation and/or the presence of wind shear, which drives Rayleigh–Bénard convection or Kelvin–Helmholtz shear instability. See also **Wind Shear**.

Altostratus is a translucent to opaque cloud composed of water droplets. It appears in the form of a dull, drab, gray or bluish (never white) sheet, through which the sun or moon might appear as seen on a ground-glass screen. It is a middle-level cloud. Altostratus very often totally covers the sky and may, in fact, cover an area of several thousand square miles. The layer has parts thin enough to reveal the position of the sun, and if gaps and rifts appear, they are irregularly shaped and spaced. Within the rather large vertical extent of altostratus (from several hundred to thousands of feet) a very heterogeneous particulate composition may exist. In this most complete case, there may be distinguished 1) an upper part, mostly or entirely ice crystals; 2) a middle part, a mixture of ice crystals and/or snowflakes and supercooled water droplets; and 3) a lower part, mostly or entirely supercooled or ordinary water droplets. A number of partial combinations of these composition types may occur, but never an entire cloud like 3) above. The particles are widely enough dispersed so as not to obscure the sun except by its thickest parts, but rather to impose a "ground-glass" effect upon the sun's image, and to prevent sharply outlined shadows from being cast by terrestrial objects. Halo phenomena do not occur. Altostratus is a precipitating cloud (*praecipitatio*) and therefore often is accompanied by virga and mamma. Rain, snow, ice pellets, etc., are present in the cloud and under its base, frequently rendering the base quite indistinct, particularly when the precipitation does not reach the ground. When precipitation reaches the ground, it is usually very light and of a relatively continuous nature. Altostratus may be formed by the thickening of cirrostratus (As cirrostratomutatus), or by the thinning of nimbostratus (As nimbostratomutatus). If widespread precipitation develops in altocumulus, altostratus may result (As altocumulogenitus). Sometimes, particularly in the tropics, altostratus may be produced by the spreading of the middle or upper portion of cumulonimbus (As cumulonimbogenitus). Cirrostratus and nimbostratus are the two other forms most easily confused with altostratus. In the first case, it should be remembered that cirrostratus does allow terrestrial shadows and frequently produces halo phenomena. See also **Atmospheric Optical Phenomena**. Nimbostratus is darker colored, hides the sun, is more uniform in optical thickness, and always produces precipitation. At night, if precipitation does not reach the ground, it is conventional to call the doubtful layer altostratus. Any stratiform (layered) cloud necessarily forms because further vertical development is inhibited by the presence of a temperature inversion. Rolls and cells in altostratus are thought to be of similar origin to those in altocumulus.

Nimbostratus is a large middle-altitude water cloud, gray-colored, often dark and dull, and usually ragged. It is rendered diffuse by more-or-less continuously-falling rain, snow, sleet, etc., of the ordinary varieties, and is not accompanied by lightning, thunder, or hail. In most cases the precipitation reaches the ground, but not necessarily. Nimbostratus is composed of suspended water droplets, sometimes supercooled, and of falling raindrops and/or snow crystals or snowflakes. It occupies a layer of large horizontal and vertical extent. The great density and thickness (usually many thousands of feet) of this cloud prevent observation of the sun; this, plus the absence of small droplets in its lower portion, gives nimbostratus the appearance of dim and uniform lighting from within. It also follows that nimbostratus has no well-defined base, but rather a deep zone of visibility attenuation. Frequently a false base may appear at the level where snow melts into rain. Nimbostratus usually results from the thickening of altostratus to the point where the sun becomes totally indiscernible (Ns altostratomutatus); this point in time usually coincides with the beginning of relatively continuous precipitation. Rarely, it may evolve in like manner from stratocumulus or altocumulus (Ns stratocumulomutatus or Ns altocumulomutatus). Nimbostratus sometimes forms by the spreading of cumulonimbus or cumulus congestus when these clouds produce rainfall (Ns cumulonimbogenitus or Ns cumulogenitus). By definition, nimbostratus is always accompanied by the complementary features praecipitatio or virga. The accessory cloud, pannus, also is a common feature. At first the pannus consists of separate units, but later they may merge into a continuous layer and extend upward into the nimbostratus. Nimbostratus is most easily confused, in identification, with thick masses of altostratus, stratus, or stratocumulus. Altostratus, however, is lighter in color, appears less uniform from below, and does not completely hide the sun. In case of further doubt, a cloud is called nimbostratus if precipitation from it reaches the ground. Stratus also may have precipitation, but only of very small-sized particles. Stratocumulus shows clear relief and a well-defined limit of its base.

Stratocumulus is a low-altitude water or mixed cloud, whose tessellated, rounded, or roll-shaped elements are usually in orderly groups, giving the appearance of a simple wave system. These elements are generally flat-topped, smooth, and large; observed at an angle of more than 30° above the horizon, the individual stratocumulus element subtends an angle of greater than 5°. When a layer is continuous, the elemental structure is revealed in true relief on its under surface. Stratocumulus is composed of small water droplets, sometimes accompanied by larger droplets, soft hail, and (rarely) by snowflakes. When the cloud is not very thick, the diffraction phenomena corona and irisation appear. Under ordinary conditions, ice crystals are too sparse even to give the cloud a fibrous aspect; however, in extremely cold weather, ice crystals may be numerous enough to produce abundant virga, and sometimes even halo phenomena. Mamma may be a supplementary feature of stratocumulus, in which case the mammiform protuberances may develop to the point where they seem about to

detach themselves from the main cloud. Virga may form under the cloud, particularly at very low temperatures. Precipitation rarely occurs with stratocumulus. Stratocumulus frequently forms in clear air. It may also form from the rising of stratus, and by the convective or undulatory transformation of stratus, or nimbostratus, with or without change of height (Sc stratomutatus or Sc nimbostratomutatus). Stratocumulus is analogous to altocumulus and forms directly from the latter when the elements grow to a sufficient size (Sc altocumulomutatus). The further humidification, accompanied by turbulence and/or convection, of an already humid layer of air near the base of nimbostratus or even altostratus can form stratocumulus (Sc nimbostratogenitus or Sc altostratogenitus). If the ascending currents that produce cumulus or cumulonimbus approach an upper layer of stable air, they slow down, and all or a portion of the mother-cloud tends to diverge gradually and spread horizontally, often producing stratocumulus (Sc cumulogenitus or Sc cumulonimbogenitus). A particular form of Sc cumulogenitus, previously called stratocumulus vesperalis, often occurs in the evening when convection decreases, resulting in the gradual dissipation of both bases and tops of cumuliform clouds. Since stratocumulus may be transformed directly from or into altocumulus, stratus, and nimbostratus, all transitional stages may be observed. By convention, altocumulus is composed of apparently smaller elements (often simply because of its higher altitude); stratus and nimbostratus do not show regular subdivisions or wave form, and they have a more fibrous aspect. When the base of stratocumulus is rendered diffuse by precipitation, the cloud becomes nimbostratus.

Stratus is a low-altitude water cloud in the form of a gray layer, having a rather uniform base. Stratus does not usually produce precipitation, but when it does occur it is in the form of minute particles, such as drizzle, ice crystals, or snow grains. Stratus often occurs in the form of ragged patches, or cloud fragments (stratus fractus), in which case rapid transformation is a common characteristic. Stratus clouds have characteristically low vertical velocities, usually less than 1 m s^{-1}. When the sun is seen through the cloud, its outline is clearly discernible, and it may be accompanied by corona phenomena. In the immediate area of the solar disk, stratus may appear very white; away from the sun, or when the cloud is thick enough to obscure it, stratus gives off a weak, uniform luminescence. The particulate composition of stratus is quite uniform, usually of fairly widely dispersed water droplets and, at lower temperatures, of ice crystals (although this is much less common). Halo phenomena may occur with this latter composition. Dense stratus often contains particles of precipitation. The prior existence of any other cloud in the low or middle levels is seldom required for the formation of stratus. A common mode of stratus development is the transformation of fog, the lower part of which evaporates while the upper part may rise (St nebulomutatus). As can be expected by its close relationship to fog, stratus follows a diurnal cycle with a maximum (over land) in the night and early morning. Insolation tends to dissipate this cloud rapidly, and often brings about the transformation of stratus fragments to cumulus clouds. Fog arriving from the sea frequently becomes stratus over the adjacent land. Coastal regions also provide the low-level moisture and frequently the lapse-rate stability conducive to its formation, and therefore these areas have the greatest stratus status. Stratus also develops from stratocumulus when the undersurface of the latter descends or for any reason loses its relief or apparent subdivisions (St stratocumulomutatus). Nimbostratus and cumulonimbus often produce stratus fractus, as precipitation from these clouds causes low-level condensation (St fractus-nimbostratogenitus or St fractus cumulonimbogenitus). Stratus fractus in this form constitutes the accessory feature pannus of these mother-clouds. Stratocumulus and nimbostratus are the clouds most difficult to distinguish from stratus. Stratus is lower and lacks the uniform undulations or relief of stratocumulus. More difficulty is encountered when differentiating it from nimbostratus. Their modes of formation are different, nimbostratus usually having been formed from a preexisting mid- or low-level cloud; nimbostratus is more dense and has a wetter aspect, and its precipitation is of the ordinary varieties. As a final distinction, the wind accompanying nimbostratus is usually stronger than that with stratus.

Cumulus is a low-altitude, water or mixed cloud in the form of billowed heaps of individual, detached elements, with flat bases and tufted tops. The cloud is a low type, but can be found with bases from 500 to 1000 feet (152.4 to 304.8 meters) and tops as high as 20,000 feet (6096 meters).

The cumulus clouds develop vertically, appearing as rising mounds, domes, or towers, the upper parts of which often resemble a cauliflower. The sunlit parts of these clouds are mostly brilliant white; their bases are relatively dark and nearly horizontal. Near the horizon the vertical development of cumulus often causes the individual clouds to appear merged. If precipitation occurs, it is usually of a showery nature. Various effects of wind, illumination, etc., may modify many of the above characteristics. Strong winds may shred the clouds, often tearing away the cumulus tops to form the species fractus. Under certain conditions cumulus clouds may be arranged in files, cloud streets, oriented approximately parallel to the wind direction. Changes in direction of illumination and in background cause modification of color and of apparent surface relief. Cumulus is composed of a great density of small water droplets, frequently supercooled. Within the cloud larger water drops are formed that may, as the cloud develops, fall from the base as rain or virga. Ice crystal formation will occur within the cloud at sufficiently low temperatures, particularly in upper portions as the cloud grows vertically. Occasionally the growth of ice crystals at the expense of water droplets will reduce the entire cloud to diffuse trails of snow. Cumulus most often forms directly in clear air as a result of convection in air of sufficiently high moisture content for a condensation level to be reached. As a result, a distant diurnal cycle of cumulus frequency is observed. Over a landmass, the cumulus maximum occurs after midday (for a horizontal extent, early afternoon; for vertical extent, somewhat later). Over a water surface, the cycle is reversed and much less obvious, with the cumulus maximum generally recognized as occurring after midnight. The vertical growth of a cumulus cell is restricted and modified by the existence and character of layers of relative static stability above the cloud base. Cumulus may also evolve from the convective transformation of stratus or stratocumulus (Cu stratomutatus or Cu stratocumulomutatus). Cumulus may be generated by altocumulus and, again, stratocumulus (Cu altocumulogenitus and Cu stratocumulogenitus). Cumulonimbus is the ultimate manifestation of the growth of cumulus; therefore, at a certain point, it is difficult to differentiate between the two. If a cloud in doubt reveals no fibrous structure, it is still cumulus; if still in doubt, cumulonimbus further differs in that it is accompanied by lightning, thunder, and sometimes hail. The elements of altocumulus are smaller and, along with those of stratocumulus, tend to be more merged than the separated units of cumulus. Cumulus has the unique ability to penetrate other preexisting cloud layers, sometimes partially dissipating, at other times apparently fusing with, the impaled layers. The cumulus, in this instance, retains its identity as long as it remains primarily vertically developed, is physically (although perhaps not visibly) separate from the other cloud, and has a tower- or dome-shaped summit.

Cumulonimbus is the thunderstorm cloud; a mixed cloud of low, middle, and high altitude, with bases from 500 to 15,000 feet (152.4 to 4572 meters) and tops from 10,000 to 50,000 feet (3048 to 15,240 meters). It is exceptionally dense, tall, billowed, full of contrast from brilliant white to inky black. It occurs either as isolated clouds or as a line or wall of clouds with separated upper portions. It is vertically developed, and appears as mountains or huge towers, with at least a part of the upper portions being usually smooth, fibrous, or striated, and almost flattened. The upper portion often spreads out in the form of an anvil or a vast plume, and is known as incus, *anvil cloud*, or *thunderhead*. Cumulonimbus may be responsible for the formation of nearly all the other cloud genera.

These clouds appear as mountains or huge towers, at least a part of the upper portions of which is usually smooth, fibrous, or striated, and almost flattened as it approaches the tropopause. This part often spreads out in the form of an anvil (incus) or vast plume. Under the base of cumulonimbus, which is often very dark, there frequently exist virga, precipitation (praecipitatio), and low, ragged clouds (pannus), either merged with it or not. Its precipitation is often heavy and always of a showery nature. The usual occurrence of lightning and thunder within or from this cloud leads to its popular appellations: thundercloud, thunderhead (the latter usually refers only to the upper portion of the cloud), and thunderstorm. Cumulonimbus is composed of water droplets and ice crystals, the latter almost entirely in its upper portions. It also contains large water drops, snowflakes, snow pellets, and sometimes hail. The liquid water forms may be notably supercooled. Within a cold air mass in polar regions, the fibrous ice crystal structure may extend virtually throughout the cloud mass. Cumulonimbus always evolves from the further development of cumulus congestus, which, in turn, usually has resulted from the growth of cumulus (Cb cumulogenitus). This complete development may initiate also from stratocumulus castellanus (Cb stratocumulogenitus) or from altocumulus castellanus (Cb altocumulogenitus). In the latter case the cumulonimbus base is particularly high. It may also, but infrequently,

develop from a portion of altostratus or nimbostratus (Cb altostratogenitus or Cb nimbostratogenitus). The formative process of cumulonimbus starts as a result of convection from the earth's surface or instability in the upper air, or both simultaneously. It therefore has a predominant diurnal cycle similar to that of cumulus. Cumulonimbus is rare over the polar regions, and becomes increasingly frequent with decreasing latitude, and is, in fact, an almost regular climax of the diurnal cloud cycle in the humid areas of the tropical regions and in humid and unstable air masses penetrating the temperate latitudes. Because of its great vertical size and of the magnitude and variety of forces that act within and upon it, cumulonimbus is a vertical cloud factory. In addition to the complex of accessory features it may possess, which includes tornadoes (tuba), it may also be responsible for the formation of nearly all of the other cloud genera. Cumulus congestus always preexists, and therefore is often easily confused with, cumulonimbus. A cloud is called cumulus congestus until its upper portion begins to show the diffuseness or fibrous quality indicative of ice crystal predominance. Only cumulonimbus is accompanied by lightning, thunder, or hail; only cumulus congestus can rival the intensity of its shower-type precipitation.

Other Cloud Forms and Terms

Accessory Cloud. A cloud form that is dependent, for its formation and continuation, upon the existence of one of the major cloud genera. It is often an appendage of the parent cloud (as mamma, incus, tuba, arcus), but it also may be an immediately adjacent cloudy mass (as pannus, pileus, velum).

Amorphous Clouds. Clouds without any apparent structure at all, as may occur in a whiteout in a thick cloud or fog over a snow surface when one loses any sense of direction — up, down, or sideways.

Amorphous Sky. A state of the sky, characterized by an abundance of fractus clouds, usually accompanied by precipitation falling from a higher, overcast cloud layer. It is termed "amorphous" because the clouds lack any distinctive form (bands, undulations, clear-cut base, etc.).

Anvil Cloud. An anvil-shaped cloud that comprises the upper portion of mature cumulonimbus clouds; the popular name given to a cumulonimbus capillatus cloud, particularly if it embodies the supplementary feature incus (from the Latin for anvil).

Arcus. (Often called roll or shelf cloud.) A dense and horizontal roll cloud or wedge-shaped accessory cloud, sometimes appearing ragged and turbulent and other times smooth, occasionally with multiple layers. It is seen most often in association with cumulonimbus clouds on the leading edge of a gust front. When extensive and approaching, it gives the appearance of a menacing arch. It may also occur with fronts in the absence of a cumulonimbus or in the absence of any thermal boundary. See **Morning Glory**; and **Roll Cloud**.

Banner Cloud. Also called cloud banner, a cloud plume often observed to extend downwind from isolated, sharp, often pyramid-shaped mountain peaks, even on otherwise cloud-free days. The Matterhorn and Mount Everest are two notable peaks where banner clouds have been frequently observed. The physics of the formation of such clouds is not completely understood. The aerodynamics of the flow around the peak produces flow separation and dynamically induced pressure reductions to the lee of the mountain peaks. The magnitude of the leeside pressure deficits increases with height to a maximum near the top of the peak, producing an upslope pressure gradient and upslope flow along the lee slope of the mountain. When the air near the base of the mountain is sufficiently moist, it ascends in the upslope flow, condenses, and forms a triangular-shaped cloud, the banner cloud, to the lee of the peak. Because of its unusual shape and location, this cloud strongly resembles snow blowing off the peak (snow banner), and it is often difficult to tell the difference.

Billow Cirrus Clouds. Closely and regularly spaced wavelike cirrus on satellite imagery that form perpendicular to the jet stream axis. These clouds are a result of strong vertical wind shear.

Billow Cloud. Popular name for undulatus. Some forms are the result of shear instability (Kelvin–Helmholtz), and some result from gravity waves. Billow clouds are present when there is sufficient moisture present in the upward motion of the waves to make the wave structure visible by condensation of cloud droplets. Billows formed from gravity waves exhibit broad, nearly parallel, lines of cloud oriented normal to the wind direction, with cloud bases near an inversion surface. The distance between billows is on the order of 1,000–2,000 meters (3,281–6,562 feet).

Brown Cloud. Phenomenon particularly associated with smog episodes in cities such as Denver, Colorado. High concentrations of particulate matter suspended in the atmosphere lead to light scattering, resulting in a reduction in visibility and a reddish-brown sky coloration.

Cap Cloud. (Also called cloud cap). An approximately stationary cloud, or standing cloud, on or hovering above an isolated mountain peak. It is formed by the cooling and condensation of humid air forced up over the peak.

Castellanus. (Previously called castellatus.) A cloud species of which at least a fraction of its upper part presents some vertically developed cumuliform protuberances (some of which are taller than they are wide) that give the cloud a crenellated or turreted appearance. This castellanus character is especially evident when the cloud is seen from the side. The cumuliform cloud elements generally have a common base and usually seem to be arranged in lines. The species is found only in the genera cirrus, cirrocumulus, altocumulus, and stratocumulus. Cirrus castellanus differs from cirrocumulus castellanus in that its vertical protuberances subtend an angle of more than 1° when observed at an angle of more than 30° above the horizon. When altocumulus castellanus and stratocumulus castellanus attain a considerable vertical development, they become cumulus congestus and often develop into cumulonimbus. Stratocumulus castellanus should not be confused with stratocumulus pierced by cumulus.

Chimney Cloud. A cumulus cloud that has much greater vertical than horizontal extent. It frequently takes the form of a long "neck" protruding from the tops of a lower cloud mass where a locally strong convection current has penetrated the inversion. The shape results from the penetration into relatively moist air aloft which inhibits evaporation.

Chinook Arch. A mountain-wave cloud form that occurs along the east slopes of the Rocky Mountains, particularly in the Montana–Alberta area, where the range runs roughly north–south. The arch cloud has a sharp western (upwind) edge and a great cross-wind extent in the lee of and parallel to the Rockies. Arch clouds can stretch a few hundred km or more north–south as measured from the ground and from satellite. The arch refers to the shape of the western edge of the wave cloud as seen by an observer looking westward from the ground on the plains east (to the lee) of the mountains. The arch is especially noticeable when the blue sky to the west of it is completely clear of other cloud layers. Glider pilots sometimes refer to the clear area as the "window." The distinctive shape of the arch is due to the cloud height (usually middle or high cloud), its large cross-wind extent along the horizon, and the perspective of the observer, who sees the cloud and the mountain range converge with distance to the north and south. The arch cloud often presages a chinook. Because of the rapid temperature rises associated with a chinook, the arch has an important place in local weather lore as a predictor. See also **Chinook**.

Cirriform. Like cirrus; more generally, descriptive of clouds composed of small particles, mostly ice crystals, that are fairly widely dispersed, usually resulting in relative transparency and whiteness and often producing halo phenomena not observed with other cloud forms. Irisation may also be observed. Cirriform clouds are high clouds (*see* cloud classification) existing between −25° (−13 °F) and −85 °C (−121 °F). As a result, when near the horizon, their reflected light traverses a sufficient thickness of air to often cause them to take on a yellow or orange tint even during the midday period. On the other hand, cirriform clouds near the zenith always appear whiter than any other clouds in that part of the sky. With the sun on the horizon, this type of cloud is whitish, while other clouds may be tinted with yellow or orange; when the sun sinks a little below the horizon, cirriform clouds become yellow, then pink or red; and when the sun is well under the horizon, they are gray. All species and varieties of cirrus, cirrocumulus, and cirrostratus clouds are cirriform in nature.

Cirrus Spissatus. (Previously called cirrus densus, cirrus nothus; also called thunderstorm cirrus, false cirrus.) A cloud species unique to the genus cirrus, of such optical thickness as to appear grayish on the side away from the sun, and to veil the sun, conceal its outline, or even hide

it. These often originate from the upper part of a cumulonimbus, and are often so dense that they suggest clouds of the middle level.

Cirrus Uncinus. A species of cirrus without gray parts, the elements of which are often in the form of a comma, topped with either a hook or a tuft that is not rounded. The species uncinus is unique to the genus cirrus. The hook takes the shape of a reverse question mark under positive wind shear (wind increasing with height) conditions and the shape of a question mark under negative wind shear.

Cloud Absorption. The absorption of electromagnetic radiation within a cloud. With some exceptions, clouds typically absorb ≈10% of the (broadband) shortwave radiation and ≈95% of the longwave radiation incident on their boundaries. Thin clouds, notably thin cirrus, may absorb considerably less. The dominant absorber tends to be the water droplets or ice crystals making up the cloud, with water vapor playing a matching role only for shortwave absorption by upper tropospheric clouds.

Cloud Attenuation. Usually, the attenuation of microwave radiation by clouds. For the centimeter wavelength band, clouds produce Rayleigh scattering. The attenuation is due largely to scattering, rather than absorption, for both ice and water clouds. The cloud attenuation for one-way transmission is

$$\text{cloud attenuation}(\text{dBkm}^{-1}) = 0.454\frac{6\pi}{\lambda}\frac{\text{M}}{\rho}\text{IM}(-\kappa)$$

where M (g m^{-3}) is the liquid water content, ρ (g cm^{-3}) the density of water, λ the wavelength, and $\kappa = m^2 - 1(m^2 + 2)^{-1}$, where m^2 is the complex dielectric constant. The attenuation depends only on M, and in the range of wavelengths from 1 to 10 cm is approximately (1 to 100)$\times 10^{-2}M$ for water clouds, and (2 to 20)$\times 10^{-2}M$ for ice clouds.

Cloud Band. A nearly continuous cloud formation with a distinct long axis, a length-to-width ratio of at least four to one, and a width greater than one degree of latitude.

Cloud Bank. Generally, a fairly well-defined mass of cloud observed at a distance; a cloud bank covers an appreciable portion of the horizon sky, but does not extend overhead.

Cloud Bar. A heavy cloud bank that appears on the horizon with the approach of an intense tropical cyclone (hurricane or typhoon). It is the outer edge of the central dense overcast of the storm.

Cloud Base. For a given cloud or cloud layer, the lowest level in the atmosphere at which the air contains a perceptible quantity of cloud particles.

Cloud-drop Sampler. A general term for instruments that collect cloud droplets to determine their size or impurities; includes devices with direct-impaction surfaces that either capture or leave an impression of the impinging droplets, such as the cloud gun, as well as bulk samplers that capture and collect cloud droplets for chemical analysis, such as the rime rod.

Cloud Drop. A spherical particle of liquid water, from a few micrometers to a few tens of micrometers diameter, formed by condensation of water vapor on a hygroscopic aerosol particle (cloud condensation nucleus).

Such drops, apparently suspended in the air with other drops, form a visible cloud. Clouds may also contain interstitial haze particles, smaller than a few micrometers (μm) in diameter. Activation distinguishes a cloud from a haze, which contains only or mainly unactivated droplets. Cloud drops differ in size from drizzle drops and raindrops. A diameter of 0.2 mm has been suggested as an upper limit to the size of drops that shall be regarded as cloud drops; larger drops fall rapidly enough so that only very strong updrafts can sustain them. Any such division is somewhat arbitrary, and active cumulus clouds sometimes contain cloud drops much larger than this.

Cloud Echo. The radar signal returned from a cloud. A cloud echo is generally much weaker than that returned by precipitation and requires sensitive equipment or cloud-detection radar to be measurable.

Cloud Feedback. The change in the radiative effects of clouds in response to an external climate perturbation. The total cloud feedback is the combined result of changes in cloud cover, cloud height, and cloud reflectivity. The feedback is the net effect of these changes on the amount of sunlight absorbed by the earth and the amount of heat it radiates to space. Because many different properties of clouds contribute to cloud feedback, and because different types of clouds (e.g., cirrus vs stratus) have different effects on solar and terrestrial radiation, cloud feedback is difficult to specify with confidence. Current climate models disagree as to whether the overall cloud feedback is positive or negative. This disagreement is a major source of uncertainty in estimates of the overall sensitivity of the global climate to anthropogenic perturbations.

Cloud Flash. (Also called intracloud flash, cloud-to-cloud flash.) A lightning discharge occurring between a positively charged region and a negatively charged region, both of which may lie in the same cloud.

The most frequent type of cloud discharge is one between a main positively charged region and a main negatively charged region. Cloud flashes tend to outnumber cloud-to-ground flashes. In general, the channel of a cloud flash will be wholly surrounded by cloud. Hence, the channel's luminosity typically produces a diffuse glow when seen from outside the cloud and this widespread glow is called sheet lightning.

Cloud Microphysics. Cloud processes (growth, evaporation, etc.) taking place on the scale of the individual aerosol or precipitation particle as opposed to the scale of the visual cloud. See also **Cloud Physics**.

Cloud Microstructure. Structure of small-scale cloud features (cells, billows, wisps, etc.) resulting from the distribution of cloud particles on a scale larger than the particles themselves but smaller than the scale of the visual cloud. Such features may result from local motions, organized or turbulent, and be preferred sites for the development of cloud hydrometeors.

Cloud Model. A physical or numerical framework for the prediction of cloud behavior. A physical model might be the behavior of a lighter or denser fluid blob (thermal) when released into a large environment. A theoretical model begins with the equations of fluid flow and derives solutions in terms of the growth of particles in a prescribed mixing environment.

Cloud Shield. 1. In general, a broad cloud formation that is not more than four times as long as it is wide. 2. In synoptic meteorology, the principal cloud structure of a typical wave cyclone, that is, the cloud forms found on the cold-air side of the frontal system. The maximum areal coverage is usually found over the region in advance of the warm front, and the minimum behind the cold front. Within the area of the cloud shield, there is an idealized but smaller precipitation shield.

Cloud Streets. Linear cloud organization occurring atop the updraft branches of horizontal convective rolls when sufficient moisture is present.

Cloud streets are readily observed with satellite imagery and can extend for hundreds of kilometers, particularly where the underlying surface is uniform.

Cloud-to-ground Flash. A lightning flash occurring between a charge center in the cloud and the ground. On an annual basis, negative charge is lowered to the ground in about 95% of the flashes. The remaining flashes lower positive charge to the ground. This type of lightning flash, which can be contrasted with an intracloud flash or cloud flash, consists of one or more return strokes. The first stroke begins with a stepped leader followed by an intense return stroke that is the principal source of luminosity and charge transfer. Subsequent strokes begin with a dart leader followed by another return stroke. Most of the strokes use the same channel to ground. The time interval between strokes is typically 40 μs.

Cloudbow. (Also called fogbow, mistbow, white rainbow.) A large, faintly colored, circular arc formed by light (usually sunlight) falling on cloud or fog. The apparent center of the cloudbow is the antisolar point (the shadow of the observer's head or possibly the shadow of the plane in which the observer is flying). The term rainbow is a general term for this phenomenon, a cloudbow merely being a rainbow formed in the smaller cloud or fog droplets. The broad whitish appearance of the cloudbow and slightly smaller angular radius certainly demonstrate that an explanation that treats light as a series of rays does not work very well for small droplets.

Cloudburst. (Also called rain gush, rain gust.) In popular terminology, any sudden and heavy fall of rain, almost always of the shower type.

An unofficial criterion sometimes used specifies a rate of fall equal to or greater than 100 mm (3.94 inches) per hour.

Collar Cloud. A ring of cloud seen occasionally at the top of a wall cloud (usually in wall clouds that are rotating) where the wall cloud is attached to the updraft base above it.

Continental Cloud. A cloud forming in continental air, characterized by relatively high concentrations of cloud condensation nuclei and cloud droplets.

Convective Cloud. A cloud that owes its vertical development, and possibly its origin, to convection. See also **Convection**.

Crest Cloud. A stationary cloud that forms along a mountain ridge and remains in the same position relative to the ridge. These clouds develop in a current of air rising along the ridge or mountain when air reaches its condensation level along the slope.

Cumulonimbus Calvus. A species of cumulonimbus cloud evolving from cumulus congestus. The protuberances of its upper portion have begun to lose their cumuliform outline; they loom and usually flatten, then transform into a whitish mass with more or less diffuse outlines and vertical striations. Cirriform cloud is not present, but the transformation into ice crystals often proceeds with great rapidity. Most often, this cloud is accompanied by showers. By convention, the name cumulonimbus calvus is given to any highly developed cumuliform cloud that produces lightning, thunder, or hail, although the top shows no obvious trace of transformation into ice. The species calvus is unique to the genus cumulonimbus.

Cumulonimbus Capillatus. A species of cumulonimbus cloud characterized by the presence, mostly in its upper portion, of distinct cirriform parts, frequently in the form of an anvil (incus), a plume, or a vast and more or less disorderly mass of hair. This cloud is usually accompanied by a shower or thunderstorm, often by a squall, and sometimes by hail. It generally produces very apparent virga. The species capillatus is unique to the genus cumulonimbus.

Cumulus Congestus. A strongly sprouting cumulus species with generally sharp outlines and, sometimes, with a great vertical development; it is characterized by its cauliflower or tower aspect, of large size. Mainly in the Tropics, cumulus congestus may produce abundant precipitation. It may also occur in the form of very high towers, the tops of which are formed of kinds of cloudy puffs that, detaching themselves successively from the main portion of the cloud, are carried away by the wind, then disappear more or less rapidly, sometimes producing virga. Cumulus congestus is the result of the development of cumulus mediocris and, sometimes, of that of altocumulus castellanus or stratocumulus castellanus. Cumulus congestus often transforms into cumulonimbus; this transformation is revealed by the smooth, fibrous, or striated aspect assumed by its upper portion. The species congestus is unique to the genus cumulus.

Cumulus Humilis. (Also called fair-weather cumulus.) A species of cumulus characterized by small vertical development, uniform flat bases and a general similarity among clouds. Its vertical growth is usually restricted by the existence of a temperature inversion in the atmosphere; this in turn explains the unusually uniform height of the cloud tops of this cumulus species. A single cloud element that is able to penetrate the inversion may develop into cumulus congestus or even further to become cumulonimbus. As in all species of cumulus, wind shear with height may give rise to a hard appearance upshear, where cloud erosion in dry environment air is taking place, and a fuzzy appearance downshear. This species is unique to the genus cumulus.

Drop-Size Distribution. The frequency distribution of drop sizes (diameters, volumes) that is characteristic of a given cloud or of a given fall of rain.

Most natural clouds have unimodal (single maximum) distributions, but occasionally bimodal distributions are observed. In convective clouds, the drop-size distribution is found to change with time and to vary systematically with height, the modal size increasing and the number decreasing with height. For many purposes a useful single parameter representing a given distribution is the volume median diameter, that is, that diameter for which the total volume of all drops having greater diameters is just equal to the total volume of all drops having smaller diameters. The drop-size distribution is one of the primary factors involved in determining the radar reflectivity of any fall of precipitation, or of a cloud mass.

False Cirrus. A cloud species (*Cirrus Spissatus*) unique to the genus cirrus, of such optical thickness as to appear grayish on the side away from the sun, and to veil the sun, conceal its outline, or even hide it. These clouds often originate from the upper part of a cumulonimbus, and are often so dense that they suggest clouds of the middle level.

Floccus. A cloud species, found in the genera cirrus, cirrocumulus, altocumulus, and sometimes stratocumulus, in which each cloud element is a small tuft with a vertical development or rounded appearance, the lower part of which is more-or-less ragged and often accompanied by virga.

This species is found in the genera cirrus, cirrocumulus, altocumulus, and sometimes also in stratocumulus. Cirrocumulus floccus sometimes evolves as the result of the dissipation of the common base of cirrocumulus castellanus; in like manner, altocumulus floccus may evolve from altocumulus castellanus. Cirrus floccus differs from cirrocumulus floccus in that its elements subtend an angle of greater than 1° when observed at an angle of more than 30° above the horizon.

Foehn Cloud. Any cloudform associated with the foehn, usually referring to standing clouds of two types, orographic clouds and mountain wave clouds. Orographic clouds may include crest clouds and the foehn wall. Wave clouds may consist of lenticular (including altocumulus standing lenticular, or ACSL) clouds, lee-wave clouds and cloud bands, and rotors.

Foehn Wall. The leeward edge of the orographic stratiform cap cloud as seen from the lee side of a mountain barrier, preceding or during a foehn or chinook event. The edge is generally abrupt and resembles a wall of cloud ("foehnwand" in German). This cloud often signifies the occurrence of orographic precipitation, especially snowfall in the cold season, over the peaks. See **Foehn Cloud**.

Forced Cloud. Small cumulus clouds that are everywhere negatively buoyant compared to the surrounding environment, but that exist because the inertia of the rising thermals feeding them from underneath is sufficient to penetrate the lifting condensation level (LCL). Morphologically, these are often cumulus humilis clouds and are typically found at the top of the convective boundary layer during daytime over land, when a strong temperature inversion aloft prevents the clouds from growing deeper.

Fractus. Wind-torn clouds, sometimes referred to as *scud*; a cloud species, found in the genera cumulus and stratus, that presents a ragged, shredded appearance, as if torn. These clouds are irregular and generally small in size; and their characteristics change ceaselessly and often rapidly.

Funnel Cloud. A condensation cloud, typically funnel-shaped and extending outward from a cumuliform cloud, associated with a rotating column of air (a vortex) that may or may not be in contact with the ground. If the rotation is violent and in contact with the ground, the vortex is a tornado.

Funnel clouds can occur through a variety of processes in association with convection. For example, small funnel clouds are infrequently seen extending from small, dissipating cumulus clouds in environments with significant vertical wind shear in the cloud-bearing layer.

Ice-Crystal Cloud. A cloud consisting entirely of ice crystals (such as cirrus); to be distinguished in this sense from water clouds and mixed clouds. Ice-crystal clouds have a diffuse and fibrous appearance, quite different from that typical of water droplet clouds, resulting from growth in much weaker updrafts and different fall speeds of a wider size particle spectrum.

Incus. (Also called anvil, anvil cloud, thunderhead). A supplementary cloud feature peculiar to cumulonimbus capillatus; the spreading of the upper portion of cumulonimbus when this part takes the form of an anvil with a fibrous or smooth aspect.

IntortusA. cloud unique to the genus cirrus.

Intracloud Flash. A lightning discharge occurring between a positive charge center and a negative charge center, both of which lie in the same cloud; starts most frequently in the region of the strong electric field between the upper positive and lower negative space charge regions. In summer thunderstorms, intracloud flashes precede the occurrence of cloud-to-ground flashes; they also outnumber cloud-to-ground flashes. Intracloud lightning develops bidirectionally like a two-ended tree: one end of the tree is a branching negative leader, the other is a branching positive leader. Later in the flash, fast negative leaders similar to dart leaders (also called K changes) appear in the positive end region and propagate toward the flash origin. In weather observing, this type of discharge is

often mistaken for a cloud-to-cloud flash, but the latter term should be restricted to true intercloud discharges, which are far less common than intracloud discharges. Cloud discharges tend to outnumber cloud-to-ground discharges in semiarid regions where the bases of thunderclouds may be several kilometers above the earth's surface. In general, the channel of a cloud flash will be wholly surrounded by cloud. Hence the channel's luminosity typically produces a diffuse glow when seen from outside the cloud, and this widespread glow is called sheet lightning. See also **Lightning**.

Iridescent Clouds. Ice-crystal clouds that exhibit brilliant spots or borders of colors, usually red and green, observed up to about 30° from the sun. This irisation results from an optical diffraction phenomenon, usually of several orders. The cloud particles that occasion this phenomenon are very small (a few micrometers), and locally all are of nearly the same size; they result from local near adiabatic lifting and condensation in moist air often in a lenticular (wave) cloud, in pileus above a developing cumulus, or occasionally in irregular patches of uniform color in a region of shallow convection (in this case sometimes called mother-of-pearl cloud).

Lacunosus. (Formerly called lacunaris.) A cloud variety characterized more by the appearance of the spaces between the cloud elements than by the elements themselves. The gaps are generally rounded and often have fringed edges. The overall appearance is that of a honeycomb or net, the negative of that of clouds composed of separate rounded elements. This variety is a modification mainly of the genera cirrocumulus and altocumulus and may apply to the species stratiformis, castellanus, or floccus.

Lenticularis. Sometimes called lenticular cloud, a feather-shaped cloud species, found in the genera cirrocumulus, altocumulus, and rarely, stratocumulus, the elements of which have the form of more-or-less isolated, generally smooth lenses or almonds; the outlines are sharp and sometimes show irisation. These clouds usually form over mountain peaks or over terrain where the wind blows uphill; the air reaches the condensation level near the top of its flow. They also form in mid-air if there is considerable undulation in the horizontal winds and if the air rising on the crest of a wave reaches the condensation level. Clouds of this type do not travel with the wind, but remain practically stationary.

Mamma. Also called *Mammatus*, hanging protuberances, like pouches, on the undersurface of a cloud, sometimes associated with severe thunderstorms. They are indications of extreme turbulence, and occur mostly with cirrus, cirrocumulus, altocumulus, altostratus, stratocumulus, and cumulonimbus.

Maritime Cloud. A cloud forming in maritime air containing relatively low concentrations of cloud condensation nuclei. These clouds are characterized by a broader droplet size distribution and low droplet concentrations (some 100 cm^{-3}).

Mixed Cloud. A cloud containing both water drops (supercooled at temperatures below 0 °C (32 °F) and ice crystals, hence a cloud with a composition between that of a water cloud and that of an ice-crystal cloud. A mixed cloud is unstable in the sense that the equilibrium vapor pressure difference between water drops and ice crystals at subfreezing temperatures promotes growth of the ice crystals at the expense of the water drops, which is the basis for the Bergeron–Findeisen theory of precipitation. Most convective clouds extending into air colder than about −10 °C (14 °F) are mixed clouds, though the proportion of ice crystals to water drops may be small until the cloud builds to levels of still lower temperature. Some clouds (lenticularis, mountain wave clouds) form at temperatures near −35 °C (−31 °F) and contain only very small amounts of ice crystals.

Mixing Cloud. A cloud formed when two subsaturated volumes of moist air with different temperatures and vapor pressures mix isobarically and adiabatically to form a volume of moist air with an intermediate temperature and vapor pressure above the saturation value at that temperature. Popular but misleading terms for mixing clouds are steam, steam fog, and steam clouds. These terms obscure the essential mechanism by which mixing clouds are formed and confuse water vapor with liquid water. Mixing clouds are the consequence of neither cooling nor heating because both volumes enter into the mixture symmetrically. They are a consequence of the nonlinearity of the Clausius–Clapeyron equation together with the linearity of the first law of thermodynamics for moist air. An example of a mixing cloud is a condensation trail.

Moazagotl. A stationary bank of cirriform cloud marking the upper portion of the system of lenticular clouds formed in the lee wave produced by flow across the Sudeten Mountains in southeastern Germany; a type of foehn cloud. The Moazagotl reaches its maximum development in the colder months, but especially in the autumn. It usually occurs when the air is conditionally unstable and wind speeds exceed certain critical values.

Morning Glory. A wind squall or succession of wind squalls, frequently accompanied by a spectacular low roll cloud or a series of such clouds, that occurs early in the morning, mainly in the late dry season (September–October) at places around the southern coast of the Gulf of Carpentaria region of northern Australia. The cloud lines may be up to a few kilometers (mile) across in the direction of travel, usually from the east or northeast, and are of considerable lateral extent, often stretching from horizon to horizon with a remarkably uniform cross section.

Mutatus. A term used when the whole or a large part of a cloud undergoes a change from one genus to another. The new cloud is then given the name of the appropriate genus, followed by the name of the genus of the mother-cloud with the addition of the suffix "mutatus" (e.g., stratus stratocumulomutatus).

Noctilucent Clouds. Now rarely called luminous clouds, these are clouds of unknown composition, which occur at great heights (between 75 and 90 kilometers (47 and 56 miles). They resemble thin cirrus, but usually with a bluish or silverish color, although sometimes orange to red, standing out against a dark night sky. They become more and more brilliant as the night advances, and generally more frequent and brilliant before sunrise than after sunset. These clouds have been seen rarely, and only during summer months in both hemispheres. It is thought that they may be composed of very fine cosmic dust coming from space and accumulating near a discontinuity line located at a height of about 80 kilometers (50 miles).

Opacus. A variety of cloud (sheet, layer, or patch), the greater part of which is sufficiently dense to obscure the sun (betweeen 10 and 20 optical depths). This variety is found in the genera altocumulus, altostratus, stratocumulus, and stratus. (Note: cumulus and cumulonimbus clouds are inherently opaque.) In the case of altocumulus opacus or stratocumulus opacus the elements stand out in true relief at the cloud base, rather than as a consequence of varying degrees of opacity. Also, in these cases, this variety usually modifies the species stratiformis.

Open-Cell Cumulus. Cumulus clouds that align themselves in polygonal or elliptical shapes with clear center areas surrounded by clouds. Open-cell cumulus are found mainly over oceans in areas of strong cold-air advection.

Orographic Cloud. Mountain clouds produced by orographic lifting of moist air to saturation. Clouds formed by upslope winds are generally stratiform, those formed by mountain wave updrafts are often lenticularis-type or wave clouds, and those formed by heating, such as elevated heat source or leeside convergence effects, are generally cumuliform. Upslope and wave clouds are clouds with form and extent determined by the disturbing effects of orography upon the passing flow of air. Because these clouds are linked to the topography, they are generally standing clouds, even though the winds at the same level may be very strong. Orographic upslope clouds include stratiform cap or crest clouds and the foehn wall. Convective orographic clouds are also strongly tied to the topography. Banta[1990] finds that mountain flows, which are driven by the topography interacting with the large-scale winds and the diurnal heating cycle, "play a significant role in determining where convective cells will initiate, and often how precipitation from the showers will be distributed spatially ... they regulate not only the location of storm initiations, but also the timing."

Pannus. Numerous cloud shreds below the main cloud. These shreds may constitute a layer, which may be separated from the main part of the cloud, or attached to it. This accessory cloud occurs mostly with nimbostratus, cumulus, and cumulonimbus.

Passive Cloud. A cumulus cloud that is no longer dynamically connected with the atmospheric boundary layer via updrafts or downdrafts. These clouds decay and dissipate just above the boundary layer top and can leave behind a concentration of pollutants. The clouds are radiatively coupled with the boundary layer and shade the ground.

Perlucidus. Denotes distinct spaces in stratiformis, which permit the sun, moon, blue sky, or higher clouds to be seen.

Pileus. A small accessory cloud in the form of a cap, hood, or scarf above or attached to the top of a cumuliform cloud. Several pileus clouds fairly often are observed above each other. Pileus occurs principally with cumulus and cumulonimbus clouds.

Polar Stratospheric Clouds (PSC). Also called *nacreous clouds*, *mother-of-pearl clouds*; rarely, *luminous clouds*.) Clouds are cirrus or altocumulus lenticularis, and show very strong irisation similar to that of mother-of-pearl, especially when the sun is several degrees below the horizon.

They occur at heights about 20–30 kilometers (12–19 miles) above the earth. These clouds are rarely seen, and it would appear that they can be observed only in certain regions. They have been observed mainly over Antarctica due to the colder temperatures present there in the circumpolar vortex. They also form over Scotland and Scandinavia in winter during periods with an intense, broad, deep, and homogeneous westerly to northwesterly flow of air over northern Europe; they are also observed in Alaska. Less frequent sightings have been reported at lower latitudes. The simultaneous occurrence of various colors of the spectrum in more or less irregular patterns strongly suggests diffraction by spherical particles. The exact physical constitution of cloud particles has been determined by aircraft (e.g., the NASA ER2 aircraft) penetration showing the presence of nitric acid hydrates (in particular nitric acid tri-hydrate, type I) with the addition of water ice at temperatures a few degrees colder (type II). Nuclei for clouds are thought to be sulfuric acid aerosol, possibly of volcanic origin. The clouds form in regions where dynamic lifting or radiational cooling lowers the air to temperatures below saturation for these different constituents (about $-95\,^{\circ}\mathrm{C}$ ($-139\,^{\circ}\mathrm{F}$). PSC are thought to play a major role in the formation of the "ozone hole" because they absorb odd nitrogen from the atmosphere, which allows the catalytic destruction of ozone to occur. Nacreous clouds appear stationary and, by day, often resemble pale cirrus. At sunset, all the colors of the spectrum appear; as the sky darkens after sunset, they increase in brilliance. As the sun drops lower and lower below the horizon and the clouds are lighted by last rays, the various colors are replaced by a general coloration that is first orange and then becomes pink, contrasting vividly with the darkening sky. The clouds next become gray and the colors of the spectrum reappear but very weakly, then fade out rapidly. Later, up until about two hours after sunset, the nacreous clouds can still be distinguished standing out against the starry sky as tenuous and gray clouds. They can even be observed all night if there is moonlight. Before dawn, the same series of aspects.

Praecipitatio. Precipitation that reaches the earth's surface.

Prognostic Clouds. A set of prognostic equations containing parameterizations of various cloud microphysics processes, governing the evolution of cloud water. The term "prognostic clouds" is usually reserved for numerical models that predict weather and climate. Prognostic cloud schemes may differ as to the number of prognostic equations and parameterized microphysics processes (the sources and sinks of cloud water), and as to whether or not they advect cloud water. In current climate models, spectral size distributions of cloud water particles (and falling condensate) are almost always assumed, rather than predicted, and their (radiative) effective radii are specified. Most often, the cloud volume fraction is parameterized by diagnostic relationships, as in purely empirically based, diagnostic cloud parameterizations, but it can be prognostic. Key cloud radiative properties, such as cloud optical depth and emissivity, may be parameterized in terms of the prognostic cloud variables and the (radiative) effective radii of the cloud particles.

Radiatus. A cloud variety of the genera cirrus, altocumulus, altostratus, and stratocumulus, in the form of straight parallel bands, which seem to converge toward a point on the horizon or, when crossing the entire sky, toward two opposite points. A form of radiatus, popularly known as Abraham's tree, is an assembly of long feathers and plumes of cirrus, which seem to radiate from a single point on the horizon.

Roll Cloud. 1. The popular term for arcus. 2. A low-level, horizontal, tube-shaped arcus cloud associated with a gust front of a convective storm (or occasionally a cold front). Roll clouds are relatively rare; they are completely detached from the convective storm's cloud base, thus differentiating them from the more familiar shelf clouds. Roll clouds appear to be rolling about a horizontal axis because of the shearing effects and horizontal vorticity provided by the differing air masses.

Rotor Cloud. (Sometimes called roll cloud.) A turbulent, altocumulus-type cloud formation found in the lee of some large mountain barriers, particularly in the Sierra Nevada near Bishop, California. The air in the cloud rotates around an axis parallel to the range. The term was first applied to clouds of this type in Europe, especially in the Riesengebirge and on Crossfell. The rotation may extend to the ground, cause hazards to aircraft, and carry large amounts of dust aloft. Rotor clouds are often associated with lee wave (lenticular) clouds that may be present above.

Rope Cloud. A very narrow, long, sometimes meandering, cumulus cloud formation that is frequently visible in satellite imagery. It is generally associated with a cold front or a land–sea breeze front.

Scud. Ragged low clouds, usually stratus fractus or cumulus fractus, which occur below the main cloud base. They are often found in the vicinity of rainshafts. Several mechanisms may explain their occurrence. They may represent rising air that has greater-than-average humidity due to the evaporation of rain or water on the ground. They may evaporate before reaching the main cloud due to mixing with the intervening dry air. Scud may also be attributed to the breakup of raindrops. The breakup fragments that are able to accumulate in regions of high humidity in rainshafts may be the source of some scud. See **Pannus**.

Shelf Cloud. A low-level, horizontal, wedge-shaped arcus cloud associated with a convective storm's gust front (or occasionally a cold front). The shelf cloud is attached to the convective storm's cloud base. Rising motion can be seen in the leading (outer) part of the shelf cloud, while the underside appears turbulent and tattered.

Standing Cloud. Any stationary cloud maintaining its position with respect to a mountain peak or ridge, such as a banner cloud, cap cloud, crest cloud, or cloud of the species lenticularis.

Stratoformis. The most common form of the genera altocumulus and stratocumulus, consisting of a very extensive, not necessarily continuous, horizontal layer or layers.

Subfrontal Cloud. A cloud that forms in the cold air mass below the elevation of the frontal zone. Such clouds can be associated with either a warm front or a cold front.

Supercooled Cloud. A cloud composed of supercooled liquid water drops. The importance of such clouds lies in their unstable composition, since natural or artificial addition of ice crystals or other ice nuclei will initiate the rapid phase change to a mixed cloud or to an ice crystal cloud as described by the Bergeron–Findeisen theory. This type of cloud constitutes the principal source of aircraft icing.

Tail Cloud. Colloquial expression for a horizontal cloud band, often laminar and tube-shaped, but sometimes ragged and turbulent, that is attached to a wall cloud.

Thundercloud. A convenient and frequently used term for the cloud mass of a thunderstorm, that is, a cumulonimbus.

Thunderhead. A popular term for the incus ("anvil") of a cumulonimbus cloud; or, less appropriately, the upper portion of a swelling cumulus, or the entire cumulonimbus.

Trade-Wind Cumulus. (Or trade cumulus.) The characteristic cumulus cloud of the trade winds over the oceans in average, undisturbed weather conditions. These clouds are generally 5,000–7,000 feet thick (1,524–2,133 meters) at peak development and are based at about 2,000–2,500 feet (610–762 meters) altitude. The individual cloud usually exhibits a blocklike appearance since its vertical growth ends abruptly in the lower stratum of the trade-wind inversion. A group of fully grown clouds show considerable uniformity in size and shape.

Translucidus. A cloud variety occurring in a layer, patch, or extensive sheet, the greater part of which is sufficiently translucent to reveal the position of the sun, or through which higher clouds may be discerned.

This variety is found in the genera altocumulus, altostratus, stratocumulus, and stratus, and is usually a modification of the species stratiformis or lenticularis. (Note: With the exception of cirrus spissatus, all cirriform clouds are inherently translucent.)

Tuba. (Obsolete; commonly called *funnel cloud*; also called *pendant cloud*, *tornado cloud*.) In meteorology, a cloud column or inverted cloud

cone, pendant from a cloud base. This supplementary feature occurs mostly with cumulus and cumulonimbus; when it reaches the earth's surface it constitutes the cloudy manifestation of an intense vortex, namely, a tornado or waterspout. See also **Tornado** and **Waterspout**.

Upglide Cloud. Cloud formed by condensation within a mass of moist air that is subject to ascending motion above a frontal surface of discontinuity.

Velum. An accessory cloud veil of great horizontal extent draped over or penetrated by cumuliform clouds. Velum occurs with cumulus and cumulonimbus.

Wall Cloud. (Sometimes referred to as pedestal cloud.) A local, often abrupt lowering from a cumulonimbus cloud base into a low-hanging accessory cloud, normally a kilometer or more in diameter. A wall cloud marks the lower portion of a very strong updraft, usually associated with a supercell or severe multicell storm. It typically develops near the precipitation region of the cumulonimbus. Wall clouds that exhibit significant rotation and vertical motions often precede tornado formation by a few minutes to an hour.

Warm Cloud. Any cloud that is only in the liquid phase; levels are not present with temperature below 0 °C (32 °F); no ice is present. Any precipitation will originate from droplet coalescence. It is not to be confused with clouds extending to levels with temperature below 0 °C; here, precipitation may form from the ice phase but could form by the warm cloud coalescence process.

Water Cloud. Any cloud composed entirely of liquid water drops; to be distinguished from an ice-crystal cloud and from a mixed cloud. Above the 0 °C (32 °F) level some clouds may be entirely liquid within the limitations of measurement (1 crystal per 10 liters) even at low temperatures (−30 °C (−22 °F) as some lenticular clouds); on the other hand, some clouds not far below 0 °C may contain considerably higher ice concentrations.

Although these are Latin words, it is proper convention to use only the singular endings, e.g., more than one cirrus cloud is, collectively, cirrus, not cirri.

CLOUDSAT. Clouds exert an enormous influence on our weather and climate. They are the key element of Earth's hydrological cycle, bringing water from the air to the ground and from one region of the globe to another. Clouds also dominate the energy budget of Earth throughtheir influence on the exchange of solar and thermal energy within the atmosphere and between the atmosphere, hydrosphere, land surface, biosphere, and space.

Because clouds have such a large impact on Earth's radiation budget, even small changes in cloud abundance or distribution could alter the climate more than the anticipated changes in greenhouse gases, anthropogenic aerosols, or other factors associated with global change. Changes in climate that are caused by clouds may in turn give rise to changes in clouds due to climate: a cloud-climate feedback. These feedbacks may be positive (reinforcing the changes) or negative (tending to reduce the net change), depending on the processes involved. These considerations lead scientists to believe that the main uncertainties in climate model simulations are due to the difficulties in adequately representingclouds and their radiative properties.

CloudSat was selected as a NASA Earth System Science Pathfinder satellite mission in 1999 to provide observations necessary to advance our understanding of cloud abundance, distribution, structure, and radiative properties. CloudSat flies the first satellite-based millimeter-wavelength cloud radar — a radar that is more than 1000 times more sensitive than existing weather radars. Unlike ground-based weather radars that use centimeter wavelengths to detect raindrop-sized particles, the CloudSat radar will allow us to detect the much smaller particles of liquid water and ice that constitute the large cloud masses that make our weather. See also **Earth System Science Pathfinder (ESSP) Program**.

CloudSat was co-manifested with the CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations). Launch of the satellite took place April 28, 2006 at Vandenberg Air Force Bass in California aboard a Delta II rocket. See Fig. 1. CloudSat and CALIPSO joined three satellites already in orbit (Aqua, PARASOL, and Aura) to form a constellation of satellites known as the A-Train. See Fig. 2. The satellites will fly in a nearly circular orbit with an equatorial altitude of approximately 705 kilometers (438 miles). The orbit is sun-synchronous, maintaining a roughly fixed angle between the orbital plane and the mean solar meridian. CloudSat (Fig. 3) will maintain a close formation with Aqua and a particularly close formation with CALIPSO, providing near-simultaneous and collocated observations with the instruments on these two platforms. Combined data products are already planned using data streams from CloudSat + Aqua and CloudSat + CALIPSO.

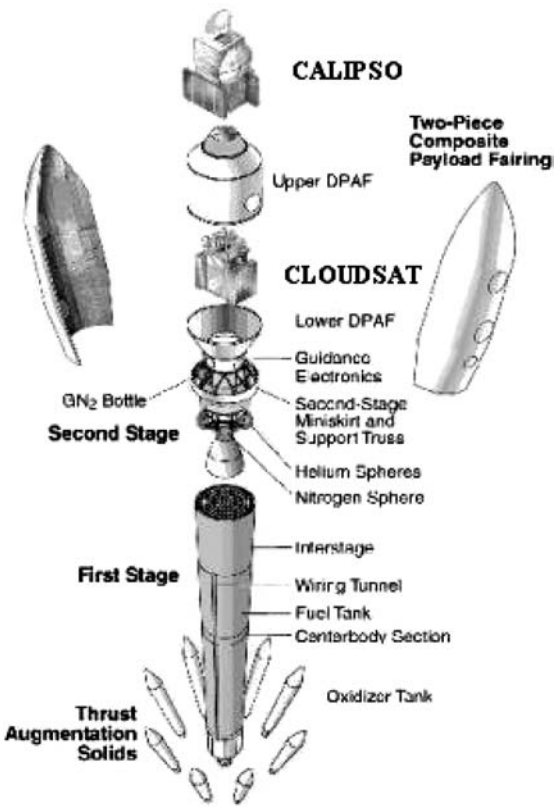

Fig. 1. Diagram of CloudSat and CALIPSO aboard a two-stage Delta 7420-10c launch vehicle.

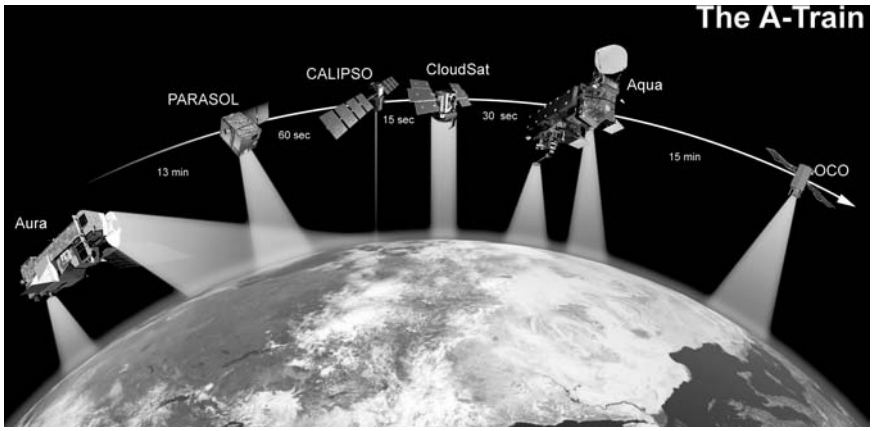

Fig. 2. The A-Train constellation of five (eventually six) Earth Observing satellites.

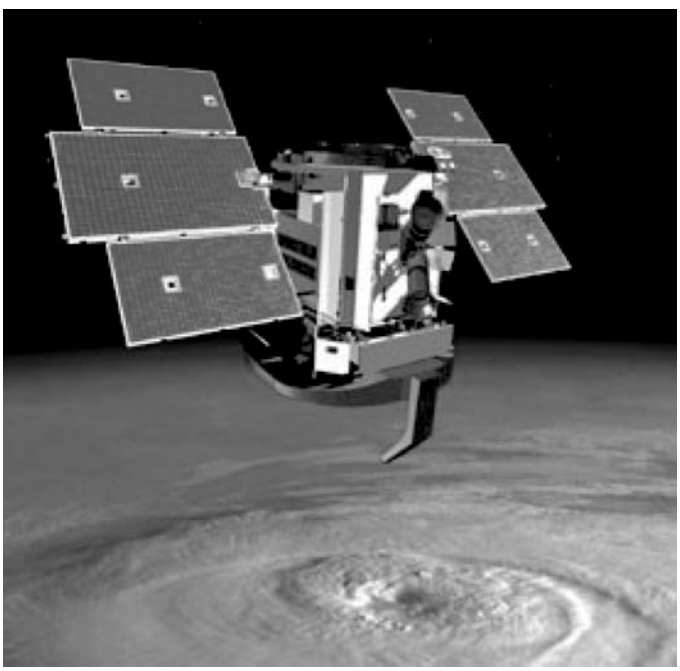

Fig. 3. CloudSat will provide, from space, the first global survey of cloud profiles and cloud physical properties, with seasonal and geographical variations, needed to evaluate the way clouds are parameterized in global models, thereby contributing to improved predictions of weather, climate and the cloud-climate feedback problem. **CloudSat** will measure the vertical structure of clouds and precipitation from space primarily through 94 GHz radar reflectivity measurements, but also by using a combination of observations from the A-Train.

Science leadership for CloudSat is provided by the Principal Investigator, Prof. Graeme Stephens of Colorado State University, in cooperation with the CloudSat Science Team. NASA's Jet Propulsion Laboratory provides overall project and mission management and development and implementation of CloudSat's instrument, the Cloud Profiling Radar.

Science Objectives

CloudSat has the following science objectives:

- Evaluate the representation of clouds in weather and climate prediction models.
- Evaluate the relationship between cloud liquid water and ice content and theradiative properties of clouds
- Evaluate cloud properties retrieved using existing satellite measurements and promote the development of new remote sensing methods for observing clouds.
- Contribute to an improved understanding of the indirect effect of aerosols on clouds by investigating the effect of aerosols on cloud formation.

Instrument Operation

The Cloud Profiling Radar (CPR) is a 94-GHz nadir-looking radar which measures the power backscattered by clouds as a function of distance from the radar. The CPR was developed jointly by NASA/JPL and the Canadian Space Agency (CSA). The overall design of the CPR is simple, well understood, and has strong heritage from many cloud radars already in operation in ground-based and airborne applications. Most of the design parameters and subsystem configurations are nearly identical to those for the Airborne Cloud Radar, which has been flying on the NASA DC-8 aircraft since 1998.

The design of the CPR is driven by the science objectives. The original requirements on CPR were: sensitivity defined by a minimum detectable reflectivity factor of -30 dBZ, along-track sampling of 2 km, a dynamic range of 70 dB, 500 m vertical resolution and calibration accuracy of 1.5 dB. The minimum detectable reflectivity factor requirement wasreduced to -26 dBz when the mission was changed to put CloudSat into a higher orbit for formation flying.

To achieve sufficient cloud detection sensitivity, a relatively low frequency (i.e.¡94 GHz) radar would require an enormous antenna and high peak power. At frequencies much greater than 100 GHz, a large antenna and high peak power are also needed due to rapid signal attenuation through cloud absorption. Furthermore, technologies at such high frequencies are less well developed. The 94-GHz frequency chosen by CPR offers the best compromise, meeting performance within the spacecraft resources. In fact, most existing airborne cloud radars operate at 94 GHz. These airborne radars provide extensive heritage for CPR on instrument design and technology, data processing, and retrieval algorithms. A primary frequency allocation of 94 GHz for spaceborne cloud radar sensing has been formally approved at the 1997 World Radio Conference.

The CPR capitalizes on existing radar expertise and experience at JPL. Other radarsalready flown successfully or being developed by JPL include the SEASAT SAR, SIR-A, SIR-B, SIR-C, SRTM, Cassini Radar, NSCAT, QuickScat, and SeaWinds.

Operations

The U. S. Air Force's Space Test Program will provide ground operations and manage communications for CloudSat. CloudSat mission data are transmitted via the spacecraft S-band downlink to the Air Force Satellite Control Network and then to the Research, Development, Test and Evaluation Support Complex at Kirtland Air Force Base in Albuquerque, New Mexico. It is expected that the data will be downlinked up to about 10 times per day, providing a data latency of about 2 to 4 hours. The data are then distributed to the Cooperative Institute for Research in the Atmosphere (CIRA) for science processing, with mission and state-of-health information being sent to Ball Aerospace & Technologies Corp. in Boulder, Colorado, and to NASA's Jet Propulsion Laboratory, Pasadena, California. CIRA will process the data into scientific data products, archive, and distribute the data to the international research community. Some portion of the data will be processed and distributed to operational centers for use in near-real-time assimilation and cloud forecast evaluations. NASA's Jet Propulsion Laboratory is responsible for mission management during mission operations.

During the operations phase of the mission, CloudSat data will be stored and distributed by the Cooperative Institute for Research in the Atmosphere (CIRA), which will provide an on-line data access system that will allow users to view browse images and order data by date/time interval and geographic location. Ordered data will be placed on an ftp server for retrieval by the requestor.

Several features of the data ordering system will allow users to request subsets of the larger CloudSat data product list-thus minimizing the volume of data that they will pull over to their local system. Users will be allowed to specify specific fields within a data product that they need for their research. They will also be able to create "custom products" that will combine fields from multiple standard data products into a singlefile. In addition, users will be able to set filters on the data to select, for example, orbits that contain a higher percentage of water (vs. land) points, or granules that contain less than 30 percent cloud cover, etc.

Data will be made available to the CloudSat science team followed by a release to the scientific community by CIRA within six weeks after the science team has assessed the data and its validation. Additional information on CloudSat data access can be found at the CloudSat Data Processing Center website: http://www.cloudsat.cira.colostate.edu.

Partners

In addition to the partners listed below, a host of U.S. and international universities and research centers provide support to the Science Team, including aircraft and ground-based observations for algorithm development and validation purposes.

Colorado State University, Fort Collins, Colorado. Scientific guidance for CloudSat is provided by the Principal Investigator (Prof. Graeme Stephens) and his team at Colorado State University. Educational Outreach for CloudSat is also managed at CSU. http://welcome.colostate.edu/

Jet Propulsion Laboratory, Pasadena, California. JPL provides mission management for CloudSat, including design, construction, and implementation of CloudSat's sole instrument, the Cloud Profiling Radar. http://www.jpl.nasa.gov/.

Ball Aerospace & Technologies Corporation, Boulder, Colorado. BATC, under contract with JPL, provides the spacecraft, I&T support, and support tomission operations. http://www.ballaerospace.com/.

Cooperative Institute for Research in the Atmosphere, Colorado State University, Fort Collins, Colorado. The Cooperative Institute for Research in the Atmosphere (CIRA) at CSU operates the CloudSat Data Processing Center, which processes and distributes CloudSat data. The PI and selected co-investigators provide data product software and quality control of the data processing activity at CIRA. http://www.cira.colostate.edu/.

USAF RDT&E Support Complex, Kirtland AFB, New Mexico. The U. S. Air Force Research, Development, Test and Evaluation Support Complex (RSC) at Kirtland Air Force Base conducts ground control of CloudSat satellite operations andreceives CloudSat data through its worldwide ground station network. http://www.smc.kirtland.af.mil/vo/vof.html.

NASA Langley Atmospheric Sciences Data Center, Hampton, Virginia. The Atmospheric Sciences Data Center at NASA Langley Research Center delivers subsetted data products from CALIPSO to the CloudSat Data Processing Center at CIRA. http://eosweb.larc.nasa.gov/.

Goddard Earth Sciences Data and information Services Center, Greenbelt, Maryland. The Goddard Earth Sciences Data and Information Services Center at the Goddard Space Flight Center delivers subsetted data products from MODIS to the CloudSat Data Processing Center at CIRA. http://daac.gsfc.nasa.gov/.

European Centre for Medium-Range Weather Forecasts, Reading, United Kingdom. The European Centre for Medium-Range Weather Forecasts provides meteorological forecast data fields to CIRA for use in processing CloudSat data products. http://www.ecmwf.int/.

Canadian Space Agency. The Canadian Space Agency provided the Extended Interaction Klystron (EIK) and the receiver for CloudSat's Cloud Profiling Radar. CSA is also supporting the Canadian CloudSat validation activities. http://www.space.gc.ca/asc/index.html.

Atmospheric Radiation Measurement Program, U.S. Department of Energy. The U. S. Department of Energy's Atmospheric Radiation Measurement (ARM) Program provides data validation and algorithm development support. http://www.arm.gov/.

The GLOBE Program, Boulder, Colorado. The international GLOBE Program is CloudSat's premier education partner with a subset of GLOBE schools (CloudSat Education Network) from around the world providing ground-based observations to mission scientists. http://www.globe.gov/.

CLOUD SEEDING. Cloud seeding is the deliberate treatment of certain clouds or cloud systems to affect the precipitation process within those clouds. The treating of clouds can alter weather conditions, thus cloud seeding is also called weather modification. The technology that led to cloud seeding has been developed only during the past 60 years. Yet as this technology becomes more efficient, increased worldwide application of cloud seeding for practical use is likely to continue into the future.

To understand how cloud seeding works, one must understand some facts about the weather. All air in the atmosphere contains moisture. Warm air rises from the earth's surface and begins to cool. As the air cools, the moisture condenses into tiny droplets that make up clouds. A cloud is almost 100% air. The tiny droplets composing clouds are not heavy enough to fall to the ground until they merge with millions of other droplets at temperatures below 32 °F and interact with dust, salt, or sand particles.

One type of cloud seeding, known as cold cloud seeding, introduces silver iodide and other agents to enhance ice crystallization in clouds colder than 32 °F. This is often called as the static seeding effect. Once the droplets within the clouds freeze, the resulting ice crystals grow at the expense of the water droplets surrounding them, a process called sublimation. Other crystals grow through contact with neighboring droplets; this is known as riming. Through these two processes, the tiny crystals form snowflakes. If these snowflakes are heavy enough, they fall from the clouds and, depending on the temperatures below, will come to the earth as snow, raindrops, or a mixture.

The other type of cloud seeding, warm cloud seeding, produces rainfall from clouds that are above 32 °F. This process involves introducing additional condensation nuclei (salt particles), which cause additional water droplets to condense within the clouds. If the collision of these particles makes the droplets heavy enough, precipitation can fall from the clouds. In each case, it will usually take the clouds 20 to 30 minutes to produce rain, making it crucial to monitor cloud movement.

Uses of Weather Modification

The primary goal of most weather modification projects is to increase levels of precipitation or to suppress fog or hail. Water agencies, local municipalities, farmers, ranchers, hydroelectric power facility operators, ski resort owners, and others sponsor cloud seeding activities. To date, cloud seeding has successfully stimulated precipitation in more than 50 countries. More than half of the United States now has some type of regulation concerning cloud seeding programs.

More recently, cloud seeding has been used to suppress certain damaging effects of weather. Airports have employed programs to disperse fog levels and increase flight visibility. And in areas damaged by hail, programs have been undertaken to decrease hailstorms.

As technology continues to enhance the weather modification process, it can be assumed that more entities will sponsor cloud seeding programs. Cloud seeding technology is highly portable and very flexible to changing weather conditions. For those who use it, cost/benefit ratios are typically very favorable.

Effectiveness

From the earliest experiment, which produced just a few droplets of rain, cloud seeding has progressed to make some significant and valuable impacts on weather. Various studies have documented the effects of different programs. For the most part, these programs are overwhelmingly successful. To augment precipitation, well-designed and well-conducted projects yield an average winter precipitation of 5 to 20% more in continental regions and 5 to 30% more in coastal areas; they have yielded as much as 100% more in warm weather. Increases depend on a variety of factors, including spatial coverage of suitable cloud systems and the frequency of different systems.

Environmental Health Concerns

To date, no significant environmental problems have been attributed to cloud seeding programs, though government agencies, private firms, and research institutions have conducted many studies. Researchers believe that any negative effects are minimal because relatively little seeding material is used compared to the large surface area that is targeted. For example, the most common seeding material, silver iodide, will yield a concentration of less than 0.1 microgram per liter in rainwater or snow. The U.S. Public Health Service states that the acceptable amount of silver iodide in water is 50 micrograms per liter.

One other common question about cloud seeding is whether the stimulation of rainfall in one area results in decreased rainfall in other areas. It does not. Clouds are inefficient in the way they gather and distribute moisture. They never gather or release all the moisture that is available; rather, clouds gather only about 1% of the moisture in the atmosphere. Even if a seeding program tripled the efficiency of cloud formation, the cloud would still contain only about 3% of the moisture, leaving 97% available. Furthermore, some analyses of precipitation data downwind from seeding projects have indicated small increases in precipitation. To date, no scientific studies have shown that some areas receive precipitation at the expense of their neighbors.

Future of Cloud Seeding

Despite all of the advances made during the past 60 years, weather modification continues to receive relatively little support. Many states and the federal government acknowledge and regulate cloud seeding, but few provide significant funding for weather modification studies or projects. Most scientists insist that more research must be done and more data must be gathered before weather-changing programs garner public trust on a larger scale. However, most researchers are optimistic that new studies and technological advances will continue to advance the science of weather modification.

CLOUD STREETS. See **Clouds and Cloud Formation**.

CLOVE TREE. Of the family *Myrtaceae* (myrtle family), the clove tree (*Eugenia aromatica*) is a small evergreen tree native to the Molucca Islands. The tree is universally known for its dried flower buds, the cloves of commerce. Cultivation of the tree was introduced many years ago to numerous other tropical locations, including Zanzibar, and Madagascar. The trees grow best when near the seacoast. Reaching a height of from 24 to 40 feet (7.2 to 12 meters), the clove tree has thick shining leaves, a smooth gray bark, and flower buds and flowers of deep red color. The fragrant oil is located mainly in the leaves and flower buds, and causes the air surrounding the tree to be richly scented. Flower buds are first formed when the tree is 4 to 5 years old. The tree bears fruit in about 7 to 8 years and may produce for nearly 100 years. In gathering, the branches are pulled down and the flower buds picked off by hand, or they may be pounded from the trees with bamboo sticks. After gathering, the pedicels, or short flower stems, are picked off, and the buds dried. These buds may then be used as a spice, either whole, or ground to a powder. A single tree may yield from 8 to 12 pounds (3.6 to 5.4 kilograms) of dried fruit per year. In addition to their use as spice, an oil is distilled. The oil is rich in eugenol and is used in making artificial vanilla.

CLUBFOOT. Talipes. A developmental deformity of the foot, usually characterized by marked flexion, inversion, adduction of the forefoot and internal rotation of the tibia. The condition may result from an intrauterine accident or maldevelopment, from pressure or constriction due to deficient amniotic fluid, or tumor in or around the uterus, interlocking of the feet, constriction of the umbilical cord, or pressure in the case of twins. Corrective treatment should commence shortly after birth and usually consists of progressively untwisting the foot by periodically changing plaster casts and directing the foot toward normal development. In some cases, tight tendons and stubborn contraction may require surgery. Generally, the results of treatment both cosmetically and functionally are very good. However, in older children the prognosis for a useful foot is not as promising. A similar, but less serious situation occurs much more frequently, a condition sometimes referred to as *pigeon-toes*. In this defect, the forefoot turns inward, but otherwise the foot is normal. The condition also is called *metatarsus adductus*. Treatment involves the use of plaster casts, followed by immobilization, as in a Dennis-Browne splint.

CLUSTER ANALYSIS. In statistics, the analysis of a set of multivariate observations to see whether they cluster into groups as distinct from being more or less uniformly scattered. Various methods have been advocated for the purpose and aggregates of any size require extensive computation. Cluster analysis, as generally understood, is a form of classification but is less general in that it does not, as a rule, take account of considerations such as biological lines of descent (as in Linnean classification) or varying criteria at different levels (as in libraries).

CNIDOBLAST. A stinging cell of the coelenterates, found in all forms, polyps, jellyfishes, and sea anemones. It produces nematocysts, which are discharged in defense and in securing food.

The *cnidocil* is a projection on the free surface of a cnidoblast that is sensitive to external stimuli.

COACERVATION. An important equilibrium state of colloidal or macromolecular systems. It may be defined as the partial miscibility of two or more optically isotropic liquids, at least one of which is in the colloidal state. For example, gum arabic shows the phenomenon of coacervation when mixed with gelatin. It also may be defined as the production, by coagulation of a hydrophilic sol, of a liquid phase, which often appears as viscous drops, instead of forming a continuous liquid phase. See also **Colloid System**.

COAGEL. A gel formed by precipitation or coagulation, as distinguished from gel formed by swelling of a solid colloid.

COAGULATION. 1. In its general scientific usage this term has two closely related meanings: (1) The process of complete or partial solidification of a colloidal solution to a gelatinous mass; or of the separation from a liquid system of a gelatinous mass. It involves the separation of the disperse from the continuous phase which fact distinguishes it from "gelation." (2) The result of an alteration of a disperse phase or of a dissolved solid which causes the separation of the system into a liquid phase and an insoluble mass, as the coagulation of egg albumin.

2. In cloud physics, coagulation is generally used synonymously with accretion. Less frequently, it refers to any process by which a cloud's numerous small cloud drops are converted into a smaller number of larger precipitation particles. When so used, the term is employed in analogy to the coagulation of any colloidal state. (See 1 above.)

3. In biological science, the term coagulation has two somewhat more specific meanings: (1) The clotting of blood or lymph. (2) The changes produced in tissue of the application of increased temperatures or by certain chemicals. See also **Anticoagulants**.

Coagulation value is the concentration of a coagulant that effects a given amount of coagulation of a colloidal, or other dispersed system.

COAGULATION (Hofmeister Series). A definite order of arrangement of anions and cations according to their powers of coagulation when their salts are added in quantity to lyophilic sols. Thus, the order of cations is $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+} > Li^{+} > Na^{+} > K^{+} > Rb^{+} > Cs^{+}$. The Hofmeister series is also called the *lyotropic series*, and the effect is called salting-out, a term applied strictly to the effect of electrolytes upon true solutions.

COAL. Containing more than 50% (weight) and 70% (volume) of carbonaceous material, including inherent moisture, coal is a readily combustible rock. Coal was formed from the compaction and induration of variously altered plant remains similar to those found in peat. Coal was formed during earlier geological periods, the process of formation acting slowly over extremely long periods of time. Coal is not a uniform substance, but reflects the conditions of its formation. These include:

1. *Differences in the kinds of plant materials* from which the coal was derived account for different types of coal.
2. *Differences in the degree of metamorphism occurring* during the formation of coal determine the different ranks of coal.
3. *Differences in the range of impurity* in coal account for the *different grades of coal*.

The fermentation of vegetable matter under conditions of no air and abundant moisture where volatiles are retained, resulting in the formation of bitumens, such as peat and coal, is known as *bituminous fermentation*. The metamorphic transformation of bituminous coal into anthracite is known as *anthracitization*. *Coalification* is the alteration or metamorphism of plant material into coal; the biochemical process of diagenesis and the geochemical process of metamorphism in the formation of coal. The peat-to-anthracite theory of coal formation is described as a process in which the progressive ranks of coal are indicative of the degree of coalification and, by inference, of the relative geologic age of the deposit. Peat, as the initial stage of coalification, is of recent geological age. Lignite, as an intermediate stage, is usually Tertiary or Mesozoic, and bituminous coal and anthracite, as the more advanced stages of coalification, are usually Carboniferous.

Status of Coal as a Major Energy Source

In 1991 coal furnished 55% of the total fuel required to generate electricity in the United States. One ton of coal consumed by a power plant generates approximately 2000 kilowatt hours of electricity. Then current consumption of 772 million tons/year for electricity generation was expected to rise to close to 1.3 billion tons by the year 2030. Clean coal technologies will be mandated. Even after installation of considerable environmental correction equipment, coal remains the least expensive of the fossil fuels by a wide margin. The cost to generate a million Btu of energy for petroleum is $2.63; for natural gas, $1.18; and for coal, $0.77. U.S. recoverable coal reserves are approximate at 268 billion tons and, at current rates, would not be exhausted until the year 2230. That provides technology scores of years to further develop and refine renewable energy sources. Refer to **Alphabetical Index** for other energy sources.

The other principal coal-using categories are coke plants, industrial chemical and transportation applications, and residential and commercial uses.

The capital costs of environmental controls for coal-burning electric utility plants rose from 5% of total plant costs in the early 1970s to well over 35% near 1990s. The operating costs of environmental controls have followed a similar pattern. New coal-consuming generating technologies, such as fluidized-bed combustion and gasification-combined cycle, integrate emission controls so that the plant has greater flexibility in meeting emissions standards with a wide variety of coal types and may reduce the total cost of using coal. Nevertheless, such advanced technologies consume large quantities of fuel and produce significant amounts of solid wastes. The pollution problems associated with coal combustion are covered in the article on **Pollution (Air)**; mine water pollution in the article on **Water Pollution**; the restoration of strip-mined land is covered in this article.

As reported by the World Energy Council, the United States has about 15% of the world's estimated recoverable coal, more than any other country except China. See Fig. 1. These statistics illustrate why the United States is a major exporter of coal.

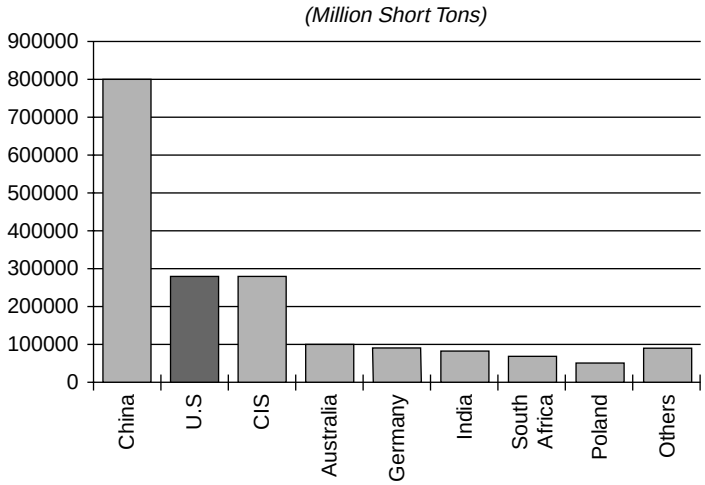

Fig. 1. World recoverable coal reserves (millions of short tons). (*World Energy Council*.)

Major Types of Coal

The major coals may be defined as follows:

Anthracite Coal. Coal of the highest metamorphic rank, in which the fixed carbon content is between 92 and 98%. It is hard, black, and has a semimetallic luster and semiconchoidal fracture. Anthracite ignites with difficulty and burns with a short, blue flame and without smoke. Anthracite coal is also known as hard coal, stone coal, kilkenny coal, and black coal.

Semianthracite Coal. Coal having a fixed-carbon content of between 86 and 92%. It is between bituminous coal and anthracite coal in metamorphic rank, although its physical properties more closely resemble those of anthracite.

Semibituminous Coal. Coal that ranks between bituminous coal and semianthracite. It is harder and more brittle than bituminous coal, has a high fuel ratio and burns without smoke. Semibituminous coal is also known as metabituminous coal which is defined as containing 89–91.2% carbon, analyzed on a dry, ash-free basis. The term smokeless coal also is used.

Bituminous Coal. Coal that ranks between sub-bituminous coal and semibituminous coal and that contains 15–20% volatile matter. It is dark brown-to-black in color and burns with a smoky flame. Bituminous coal is the most abundant rank of coal and is commonly Carboniferous in age. The most common synonym is soft coal.

Sub-bituminous Coal. A black coal intermediate in rank between lignite and bituminous coals, or in some classifications, the equivalent of black lignite. It is distinguished from lignite by higher carbon content and lower moisture content.

The sub-bituminous coals are further classified in terms of their calorific value:

Sub-bituminous A Coal — A type of sub-bituminous coal having 10,500 or more, but less than 13,000 Btu per pound (5838–7228 Calories/kg).

Sub-bituminous B Coal — A type of sub-bituminous coal having 9,500 or more, but less than 10,500 Btu per pound (5282–5838 Calories/kg).

Sub-bituminous C Coal — A type of sub-bituminous coal having 8,300 or more, but less than 9,500 Btu per pound (4615–5282 Calories/kg).

Lignite Coal. A brownish-black coal that is intermediate in coalification between peat and sub-bituminous coal; consolidated coal with a calorific value less than 8,300 Btu per pound (4615 Calories/kg), on a moist, mineral-matter-free basis. Synonyms include *brown lignite* and *brown coal*. Further classifications of lignite are made on the basis of calorific value:

Lignite A Coal — A lignite that contains 6,300 or more Btu per pound, but less than 8,300 Btu per pound (3503–4615 Calories/kg). Also known as *black lignite*.

Lignite B Coal — A lignite that contains less than 6,300 Btu per pound (3503 Calories/kg). Also known as brown lignite or brown coal.

Peat. This is an unconsolidated deposit of semicarbonized plant remains of a water-saturated environment, such as a bog or fen, and of persistently

high moisture content (minimum of 75%). It is considered an early stage or rank in the development of coal. The carbon content is about 60%; oxygen content is about 30%. Structures of the vegetal matter can be seen. When dried, peat burns freely.

Peat Coal. This refers to two materials: (a) a coal transitional between peat and brown coal or lignite; and (b) an artificially carbonized peat that is used as a fuel.

Cannel Coal. A compact, tough *sapropelic coal* that contains spores and that is characterized by a dull-to-waxy luster, conchoidal fracture, and massiveness. It is attrital and high in volatiles. By American standards, it must contain less than 5% anthraxylon. Synonyms include *candle coal, kennel coal, cannel, cannelite, parrot coal,* and *curley cannel.* A sapropelic coal is derived from organic residues (finely divided plant material, spores, algae, etc.) in stagnant or standing bodies of water. Putrefaction is under anaerobic conditions rather than by peatification.

Ranks of Coal

Coals are classified in order to identify end-use and also to provide data useful in specifying and selecting burning and handling equipment and in the design and arrangement of heat-transfer surfaces. One classification of coal is by rank, that is, according to the degree of metamorphism, or progressive alteration, in the natural series from lignite to anthracite. Volatile matter, fixed carbon, inherent or bed moisture (equilibrated moisture at 30 °C and 97% humidity), and oxygen are all indicative of rank, but no one item completely defines it. The classification of the American Society for Testing and Materials (ASTM) uses fixed carbon and calorific values, calculated on a mineral-matter-free basis, as the classifying criteria.

In establishing the rank of coals, it is necessary to use information showing an appreciable and systematic variation with age. For the older coals, a good criterion is the "dry, mineral-matter-free fixed carbon or volatile." However, this value is not suitable for designating the rank of the more recent, younger coals. A dependable means of classifying the latter is the "moist, mineral-matter-free Btu" which varies little for the older coals, but appreciably and systematically for younger coals.

Classification of major coals according to rank or age is given in Table 1. The criteria given in the prior paragraph are used in classifying the older and younger coals. Seventeen United States coals are arranged in order of the classification of Table 1 and presented in Table 2.

Classification of coals in Europe and other parts of the world differs somewhat from the American system. European classifications include: (1) the *International Classification of Hard Coals by Type*; and (2) the *International Classification of Brown Coals*. These systems were developed by a Classification Working Party established in 1949 by the Coal Committee of the Economic Commission for Europe. The term "hard coal" is defined as a coal with a clorific value of more than 10,260 Btu per pound (5705 Calories/kg) on the moist, ash-free basis. The term "brown coal" refers to a coal containing less than 10,260 Btu per pound (5705 Calories/kg). In European terminology, the term "type" is equivalent to rank in American coal classification terminology and the term "class" approximates the ASTM rank. Space does not permit a full comparison of the various systems. Reference to various ASTM publications is suggested.

Commercial Sizes of Coal

Anthracite Coal. Standard sizes for anthracite coal are indicated in Table 3. The broken, egg, stove, nut and pea sizes are largely used for hand-fired domestic units and gas producers. Buckwheat and rice are used in mechanical types of firing equipment.

Bituminous Coal. The sizes of bituminous coal are not well standardized, but the following sizings are commonly recognized:

TABLE 1. CLASSIFICATION OF COALS BY RANK (ASTM)

		Fixed Carbon Limits, % (Dry, Mineral-Matter-Free Basis)		Volatile Matter Limits, % (Dry, Mineral-Matter-Free Basis)		Calorific Value Limits, Btu/Pound (Moist*, Mineral-Matter-Free Basis)		
Class	Group	Equal or Greater Than	Less Than	Greater Than	Equal or Greater Than	Equal or Greater Than	Less Than	Agglomerating Character
I Anthracite	1. Meta-anthracite	98	—	—	2	—	—	Nonagglomerating
	2. Anthracite	92	98	2	8	—	—	Nonagglomerating
	3. Semianthracite[c]	86	92	8	14	—	—	Nonagglomerating
II Bituminous	1. Low volatile bituminous	78	86	14	22	—	—	
	2. Medium volatile bituminous	69	78	22	31	—	—	
	3. High volatile A bituminous	—	69	31	—	14,000[a]	—	Commonly Agglomerating[b]
	4. High volatile B bituminous	—	—	—	—	13,000[a]	14,000	
	5. High volatile C bituminous	—	—	—	—	11,500	13,000	
						10,500[b]	11,500	Agglomerating
III Subbituminous	1. Subbituminous A	—	—	—	—	10,500	11,500	
	2. Subbituminous B	—	—	—	—	9,500	10,500	Nonagglomerating
	3. Subbituminous C	—	—	—	—	8,300	9,500	
IV Lignitic	1. Lignite A	—	—	—	—	6,300	8,300	Nonagglomerating
	2. Lignite B	—	—	—	—	—	6,300	

*Moist refers to coal containing its natural inherent moisture, but not including visible water on the surface of the coal.

[a] Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis are classified according to fixed carbob, regardless of calorific value.

[b] It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in high-volatile c bituminous group.

[c] If agglomerating, the coal is classified in the low-volatile group of the bituminous class.

The terms, *mineral-matter-free fixed carbon*; and *mineral-matter-free Btu* are defined by the following formulas:

Parr formulas

$$\text{Dry, Mm - free FC} = \frac{\text{FC} - 0.15\text{S}}{100 - (\text{M} + 1.08\text{A} + 0.55\text{S})} \times 100, \%$$

$$\text{Dry, Mm - free VM} = 100 \times \text{Dry, Mm-free FC, \%}$$

$$\text{Moist, Mm - free Btu} = \frac{\text{Btu} - 50\text{S}}{100 - (1.08\text{A} + 0.55\text{S})} \times 100, \text{per pound}$$

Approximation formulas

$$\text{Dry, Mm -free FC} = \frac{\text{FC}}{100 - (\text{M} + 1.1\text{A} + 0.1\text{S})} \times 100, \%$$

$$\text{Dry, Mm-free VM} = 100 - \text{Dry, Mm-free FC, \%}$$

$$\text{Moist, Mm-free Btu} = \frac{\text{Btu}}{100 - (1.1\text{A} + 0.1\text{S})} \times 100, \text{per pound}$$

Symbols Used:Mm = mineral matter; Btu = heating value per pound; FC = fixed carbon,%; VM = volatile matter, %; M = bed moisture,%; A = ash, %; S = sulfur, %. all for coal on a moist basis.

Conversion Factor: 1 Btu/pound = 0.556 Calories/kg).

TABLE 2. REPRESENTATIVE UNITED STATES COALS ARRANGED IN ORDER OF ASTM CLASSIFICATION

Coal Rank				Coal Analysis, Bed Moisture Basis						Rank	Rank
Class	Group	State	County	M	VM	FC	A	S	Btu	FC	Btu
I	1	Pennsylvania	Schuylkill	4.5	1.7	84.1	9.7	0.77	12,745	99.2	14,280
I	2	Pennsylvania	Lackawanna	2.5	6.2	79.4	11.9	0.60	12,925	94.1	14,880
I	3	Virginia	Montgomery	2.0	10.6	67.2	20.2	0.62	11,925	88.7	15,340
II	1	West Virginia	McDowell	1.0	16.6	77.3	5.1	0.74	14,715	82.8	15,600
II	1	Pennsylvania	Cambria	1.3	17.5	70.9	10.3	1.68	13,800	81.3	15,595
II	2	Pennsylvania	Somerset	1.5	20.8	67.5	10.2	1.68	13,720	77.5	15,485
II	2	Pennsylvania	Indiana	1.5	23.4	64.9	10.2	2.20	13,800	74.5	15,580
II	3	Pennsylvania	Westmoreland	1.5	30.7	56.6	11.2	1.82	13,325	65.8	15,230
II	3	Kentucky	Pike	2.5	36.7	57.5	3.3	0.70	14,480	61.3	15,040
II	3	Ohio	Belmont	3.6	40.0	47.3	9.1	4.00	12,850	55.4	14,380
II	4	Illinois	Williamson	5.8	36.2	46.3	11.7	2.70	11,910	57.3	13,710
II	4	Utah	Emery	5.2	38.2	50.2	6.4	0.90	12,600	57.3	13,560
II	5	Illinois	Vermilion	12.2	38.8	40.0	9.0	3.20	11,340	51.8	12,630
III	1	Montana	Musselshell	14.1	32.2	46.7	7.0	0.43	11,140	59.0	12,075
III	2	Wyoming	Sheridan	25.0	30.5	40.8	3.7	0.30	9,345	57.5	9,745
III	3	Wyoming	Campell	31.0	31.4	32.8	4.8	0.55	8,320	51.5	8,790
IV	1	North Dakota	Mercer	37.0	26.6	32.2	4.2	0.40	7,255	55.2	7,610

Note: Definition of coal rank is given in Table 1.
M = equilibrium moisture, %; VM = volatile matter, %; FC = fixed carbon,%; A = ash, %; S = sulfur, %; Btu = high heating value, Btu per pound; Rank FC = dry, mineral-matter-free fixed carbon,%; Rank Btu = moist, mineral-matter-free Btu per pound.
All calculations are per the Parr formula defined in Table 1.
Conversion Factor: 1 Btu = 0.2520 Calorie.

TABLE 3. ANTHRACITE COAL SIZES

Name Used in the Trade	Diameter of Hole			
	Will Pass Through		Will Not Pass Through	
	Inches	~Centimeters	Inches	~Centimeters
Broken	$4\frac{3}{8}$	11.1	$3\frac{1}{4}$ to 3	8.3 to 7.6
Egg	$3\frac{1}{4}$ to 3	8.3 to 7.6	$2\frac{7}{16}$	6.2
Stove	$2\frac{7}{16}$	6.2	$1\frac{5}{8}$	4.1
Nut	$1\frac{5}{8}$	4.1	$\frac{13}{16}$	2.1
Pea	$\frac{13}{16}$	2.1	$\frac{9}{16}$	1.4
Buckwheat	$\frac{9}{16}$	1.4	$\frac{5}{16}$	0.8
Rice	$\frac{5}{16}$	0.8	$\frac{3}{16}$	0.5

(*Run of Mine*)—Coal that is shipped from the mine without screening. It is used for both domestic heating and commercial steam production.

(*Run of Mine*—8-*inch*)—This is run-of-mine coal with oversize lumps broken up, (8 inches = 20.3 centimeters.)

(*Lump*—5-*inch*)—This size will not go through a 5-inch round hole. It is used for hand-firing and domestic purposes. (5 inches = 12.7 centimeters.)

(*Egg*—5 *by* 2-*inch*)—This size goes through a 5-inch hole, but is retained on 2-inch round-hole screens. It is used for hand-firing, gas producers, and domestic firing. (5 × 2 inches = 12.7 × 5.1 centimeters.)

(*Nut*—2 *by* $1\frac{1}{4}$-*inch*)—This size is used for small industrial stokers, gas producers, and hand-firing. ($2 \times 1\frac{1}{4}$ inches = 5.1 × 3.2 centimeters.)

(*Stoker Coal*—$1\frac{1}{4}$ *by* $\frac{3}{4}$-*inch*)—This size is largely used for small industrial stokers and domestic firing. ($1\frac{1}{4} \times \frac{3}{4}$ inches = 3.2 × 1.9 centimeters.)

(*Slack*—$\frac{3}{4}$-*inch and under*)—This is used for pulverizers, cyclone furnaces, and industrial stokers. ($\frac{3}{4}$-inch = 1.9 centimeters.)

Geology of Coal

Coal is interspersed as individual beds within other types of sedimentary rock beds, including sandstones, limestones, clays, shales, and mixtures of these materials. The plant material that ultimately became coal deposits was accumulated in upland bogs, coastal or near-coastal swamps, or delta plains. It is envisioned that the conditions were somewhat similar to the conditions existing today in the Okefenokee Swamp in Georgia or the Everglades of Florida. These areas may have varied from a few acres to several hundreds of square miles (hectares/square kilometers). Hence, the variation in the occurrence of coal as we find it today.

For the geological processes (coalification) to convert such plant materials into coal, it was necessary that the original swamps be submerged—by way of rises in sea level or land subsidence. Probably many submersive actions occurred with intermittent deposition of calcareous materials deposited from water containing muds, sands, and slimes. As the result of a series of compactions, with varying depths of burial, heat, and pressure, and length of time, the progress of coalification also varied—from peat to lignite, to sub-bituminous coal, to bituminous coal, possibly to anthracite.

Major coalfields in the United States are shown in Fig. 2.

Coal Formation in the United States. It is postulated that coal formed in the U.S. during three major geological periods.

1. During the Pennsylvanian (Carboniferous) period which dates back approximately 300 million years. Deposits include the predominately bituminous coal beds in the Appalachian Province extending from Pennsylvania (including the anthracite beds in central Pennsylvania) into northeastern Alabama. Also the contiguous Eastern Interior Region of Illinois, southwestern Indiana, and western Kentucky; in the contiguous Western Interior Region of Iowa, Kansas, Missouri, northeastern Oklahoma and northwestern Arkansas; and in the separated central portion of Texas (excluding Texas lignite).

2. During the Cretaceous period which dates back approximately 100 million years. Deposits include the predominately bituminous and sub-bituminous coal beds in the Rocky Mountain Province, extending in large, separated regions from central Montana into northeastern Arizona and northwestern New Mexico.

3. During the Tertiary period which dates back approximately 65 million years. Deposits include the sub-bituminous coal and lignite beds in the Great Plains Province, which includes northeastern Wyoming, eastern Montana, western North Dakota, and northwestern North Dakota.

Coal beds form only a very small percentage of the total thicknesses of the overall sedimentary strata comprising the so-called "Coal Measures" in coal-bearing areas. The thicknesses of individual coal beds within the United States range from a few millimeters (horizon markers) to as much

Fig. 2. Main coalfields in the United States. In the United States coal is truly a national resource that is present in 38 states, stretching from the East to West coasts. About half of these coal deposits are located in the western United States, including Alaska; 28% of the deposits are in the interior of the country and 22% occur in Appalachia. The western United States includes a huge deposit called "Wyodak," which currently is the leading source of coal production. The Powder River Basin in Wyoming and southeastern Montana is part of this deposit. This western coal combines with significant low-sulfur reserves in the East to provide an important source of low-sulfur coal for electric power plants. Coal "seams" or deposits in this basin average 70 feet (21.3 meters) in thickness, although some exceed 100 feet (33.6 meters). In the East the most important deposits are in the Appalachian Basin, an area encompassing 72,990 square miles (189,044 square kilometers). The lighter shading shows a large lignite deposit. (*National Coal Association*.)

as 100 feet (30 meters) or more. The number of individual coal beds of commercial significance may range from less than 10 feet (3 meters) to over 100 feet (30 meters). The coal, however, is rarely found in full vertical sequence at any one particular spot, but usually is distributed unevenly in single beds or small groups of beds around the margin or within the interior of the generally basin-shaped areas of coal-bearing strata.

Depending on the desired or feasible rate of annual production, the amounts of coal reserves required to support a new mine designed for an economic life of 20 years or more may range from a comparatively few tons to 300 million tons or more. Such amounts are dependent upon the coal-bed thickness and the ease of mining and particularly whether surface or underground mining techniques will be required. Thus, a given mining area may range from as little as one thousand acres to as much as 50 square miles (130 square kilometers).

A variety of detrimental irregularities may accompany or interrupt an otherwise orderly accumulation of plant material either during swamp growth or shortly thereafter. While many coal beds or portions of beds are relatively low in ash content, other beds or portions of beds may contain depositional admixtures of particles of mud or silt which were washed or blown into the swamp during plant growth. Where relatively abundant, these particles serve to increase the ash content of the eventual coal bed and thus to decrease its quality correspondingly. During periods of prolonged swamp flooding, layers of mud or silt may have been deposited on the preexisting plant accumulations. Such deposition then may have been followed by additional plant accumulation. Such layers of impurities between underlying and overlying accumulations of plant materials, eventually hardening into shales or silty shales, are called *partings*. These may range from knife-edge thickness to thicknesses of up to a foot ($\frac{1}{3}$ meter) or more. Such partings within a single coal bed decrease the quality of the coal as mined and impair the mining procedures, particularly when such partings have become pyritized.

Such partings are not always evenly deposited over large portions or the entire extent of a coal-forming swamp, but may become progressively thicker toward the source of the deposited material. The partings may be wedge-shaped, with the overlying plant material occurring increasingly higher above the underlying plant material and sometimes becoming increasingly thinner to the point of disappearance. Deposition of impurities in this manner results in splitting the total thickness of the coal bed into two or more diverging *benches*. This causes mining difficulties and sometimes a bench may be so thin as not to be economically recoverable.

In some coal beds, relatively flat, lenticular masses ranging up to several feet in diameter, composed of pyrite, calcite or siderite, were formed during plant growth. Such materials (concretions) may represent the eventual immediate roof of the coal bed. These concretions impede mining operations and cause a hazard because of their tendency to drop out of the roof unexpectedly during operation of the mine.

From initial deposition and burial under overlying sedimentary materials through succeeding geological periods, coal beds are continually subject to the action of ground water. Thus, some coal beds have developed a system of essentially vertical fractures — thin cracks, often filled with coatings of pyrite, calcite, kaolinite and other minerals deposited from ground water. Impurities from these veins lower the quality of the coal.

During the long periods since formation, many coal beds have been subject to folding and sharp deformation, resulting in specific dislocations or faults. Such shifting may range from a foot or two (less than one meter) to several hundred feet (meters) and even up to thousands of feet (meters) in linear extent. The coal and lignite fields in the Great Plains Province are relatively undisturbed. The coal-bearing strata in the Appalachian Province are relatively flat along their northwestern margin, but increase in intensity of relatively mild but significant folding toward the southeast at right angles to the regional northeast-southwest trend of the component coal fields. The coal beds in the various basins comprising the Rocky Mountain Province range from comparatively gentle slopes of but a few degrees over areas of broad extent to areas of similar extent with prevailing dips of up to 20 or 30°, along with a few areas of limited extent where the coal beds are highly deformed.

Exploration Techniques. The diamond core drill historically has been the most extensively used tool in coal exploration. Cores of coal, properly recovered, enable accurate seam descriptions and measurements; also provide material for chemical analysis. Geologging or electric logging, used for several years in the oil and gas fields, is now gaining acceptance in coal-exploration technology. The system involves hoisting a sensor up the length of a drill hole while electric pulses are transmitted through the hoist cable to a console in a truck or on the surface. Here instruments record the variations in properties of the rock strata as a function of hole depth. The electric curves usually run in coal exploration are resistivity and spontaneous potential. Radiometric or nuclear curves include gamma ray, neutron, and the density or gamma-gamma log.

The impurities in coal beds, present either as distinct partings or disseminated throughout, are composed of clay materials that have a high density and a high natural radioactivity relative to coal. Consequently, the gamma ray and density curves, invaluable for bed correlation and thickness determination, also can be used as semiquantitative indices of coal quality.

Coal Production

It is authoritatively estimated that 56 billion tons of coal have been produced in the United States since the first mine opened more than 200 years ago. Statistics for the years 1980 through 1991 are shown in Table 4. The five leading coal producing states are Wyoming (194 million tons), West Virginia (166 million tons), Kentucky (157 million tons), Pennsylvania (66 million tons), and Illinois (59 million tons).

TABLE 4. U.S. COAL PRODUCTION (1980–1991) (millions of short tons)

Year	Total	East	West	Surface	Underground
1980	829.7	578.7	251.0	492.2	337.5
1981	823.8	553.9	269.9	507.3	316.5
1982	838.1	564.3	273.9	499.0	339.2

Coal Mining Technology

The manner in which coal is mined depends upon several factors, including depth of the coal bed from the surface and the geological character of the terrain. Generally, coal that is 200 feet (61 meters) or more from the surface is mined *underground*, using "deep mining" techniques. Shallow deposits are extracted by surface *mining* methods. Of the approximately 3500 operating mines in the United States, the number is virtually split between the two methods. The trend in total number of mines, since 1980, has trended downward, while the production per mine has increased to 500,000 tons of coal or more. This trend has resulted from greater mechanization, the use of large-capacity equipment, and access to large blocks of coal from which to form *mining units*, especially in the western states.

Surface Mining. This method of mining permits removal of as much as 90% of the total coal from a given deposit. Very large dragline excavators are used to remove the overburden (rock and soil covering the coal). Other equipment includes power shovels for loading operations, front-end loaders, trucks, and bucketwheel excavators. Land restoration has become an intimate part of the total surface mining operation. Reclamation is required by both federal and state laws.

Since passage of the federal Surface Mining Control and Reclamation Act (1977), the U.S. coal industry has reclaimed in excess of 2.5 million acres (1+ million hectares). This is an area larger than the state of Delaware. Also, more than 100,000 additional acres of abandoned mines, remnants of neglect from prior years, have been reclaimed through funds paid by coal producers into a national land trust. Responsible coal operators are guided by the principle that the right of coal extraction carries with it the responsibility of restoring the land. Reclaimed sites are returned to productive use, depending upon location, to farms, parks, and building sites. See also **Revegetation**, which appraises the biological and botanical problems and solutions in connection with strip mine reclamation. Surface mining equipment and methodologies are shown in Figures 3 through 9.

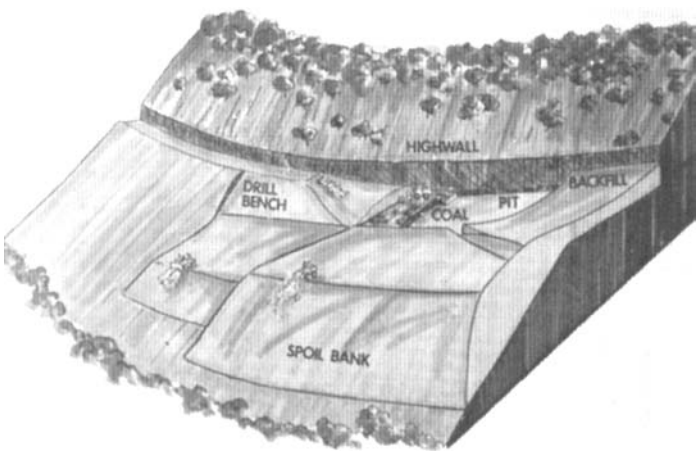

Fig. 3. Early method of contour surface mining. This was the predominant way of mining throughout Appalachia until passage of stringent legislation that ushered in a new integrated mining technique. (*Caterpillar Inc.*)

Underground Coal Mining. In general, most underground coal is mined by the room-and-pillar system, which involves excavating a series of "rooms" into the coalbed and leaving "pillars" or columns of coal to help support the mine roof. More than half of the coal taken from underground mines is produced by *continuous mining*, which uses a specialized cutting machine that mechanizes the entire extraction process. This "continuous miner" tears the coal from a seam and automatically removes it from the area by conveyor. See Figures 10 and 11.

Another form of underground mining is known as conventional mining. This process accounts for about 11% of deep-mined coal and consists of a series of operations that involve cutting the coalbed so that it breaks easily when blasted with explosives. The broken coal then is ready to be removed from the mine. Where the geology is favorable, this is the most practical and economical underground mining method.

Shortwall Mining. This method is used in relatively few underground mines. It involves the use of a continuous mining machine and movable

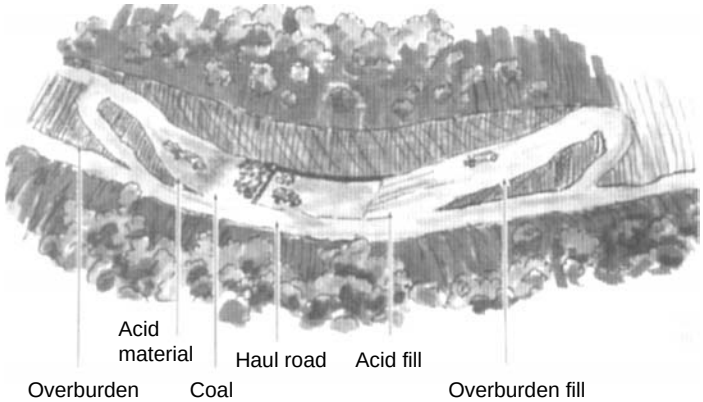

Fig. 4. Haulback method of surface mining. Using either scrapers or off-highway trucks, the major principle of this method is that all spoil except that from the initial cut is moved along the bench rather than being placed on the outslope. (*Caterpillar Inc*.)

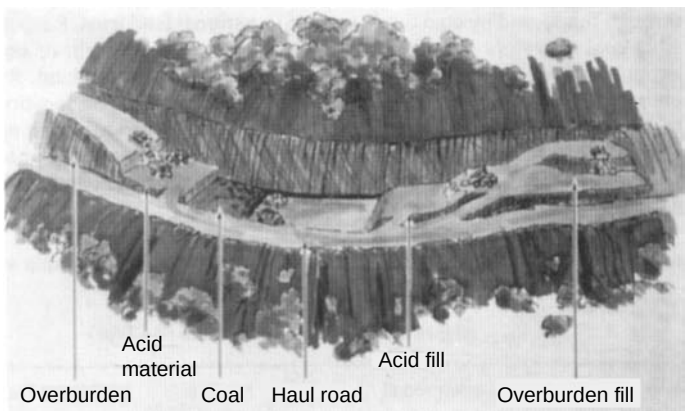

Fig. 5. Truck haulback method of surface mining is used mainly in rocky overburden, which is uneconomical for loading by scrapers. With either truck or scraper haulback operations, nonacid rock or clay overburden is placed over acidic material to facilitate revegetation. (*Caterpillar Inc.*)

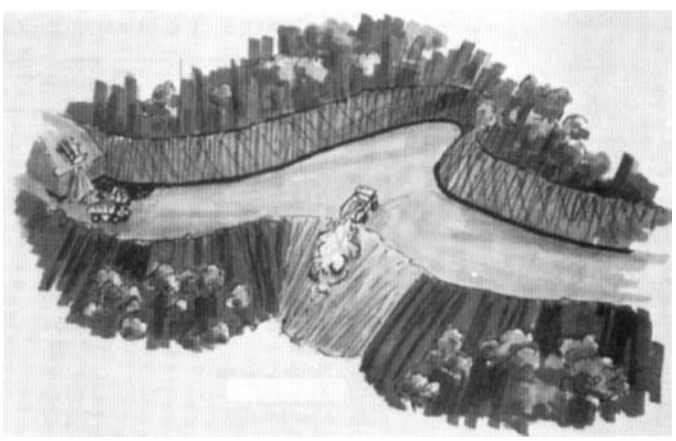

Fig. 6. Valley fill method of surface mining. In this method the miner generally hauls overburden in trucks and constructs fills over the side at bench height. When scrapers are used, the operator ejects overburden at bench height and tractors doze it over the edge. (*Caterpillar Inc.*)

roof supports to shear coal panels 150 to 200 feet (46–61 meters) wide and more than 0.5 mile (0.8 kilometer) long.

Longwall Mining. With favorable geology, an increasing amount of underground coal production is the result of *longwall mining*. This is one of the most important technological advances to impact the coal industry since the introduction of mechanized equipment a half-century ago. This methodology has made a significant contribution toward doubling underground mining productivity over recent decades. The production of

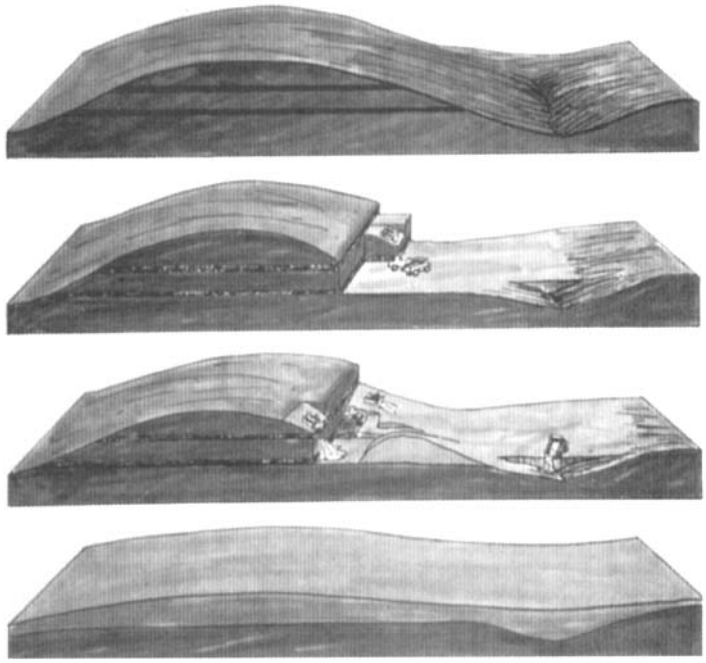

Fig. 7. In mountaintop leveling, a part of the mountain top is moved to fill an adjacent valley and build a near-level fill in the mined area. The reclaimed flat or gently rolling land that results from this type of operation can then be used for a variety of purposes which could increase the value of the land. (*Caterpillar, Inc*.)

Fig. 8. A 13.5 cubic yard (10.3 cubic meter) wheel loader working a load-and-carry operation in a surface mine. (*Caterpillar Inc*.)

coal per shift from longwall is, on average, more than double that of either conventional or continuous mining. Coal recovery rates of 80% are possible under favorable circumstances.

In the longwall system, which originated in Europe, two parallel entries are excavated from the main mine entry directly into the coal seam. The parallel entries, which may be as much as 750 feet (365 meters) apart or more, are then joined together at their far end by a crosscut. The coal face that is formed at the crosscut is called the "longwall."

In a longwall operation, a rotating shear or plow on a mining machine moves back and forth across this long seam, cutting and transporting the coal from the face by a conveyor system that is part of the mining machine. The machine has its own movable electrohydraulic roof supports, or "walking props," that are advanced as the seam is removed. The mined-out areas behind the roof support are allowed to cave. In addition to

Fig. 9. An 85-ton capacity off-highway truck for use in hauling overburden in a surface mine. (*Caterpillar, Inc.*)

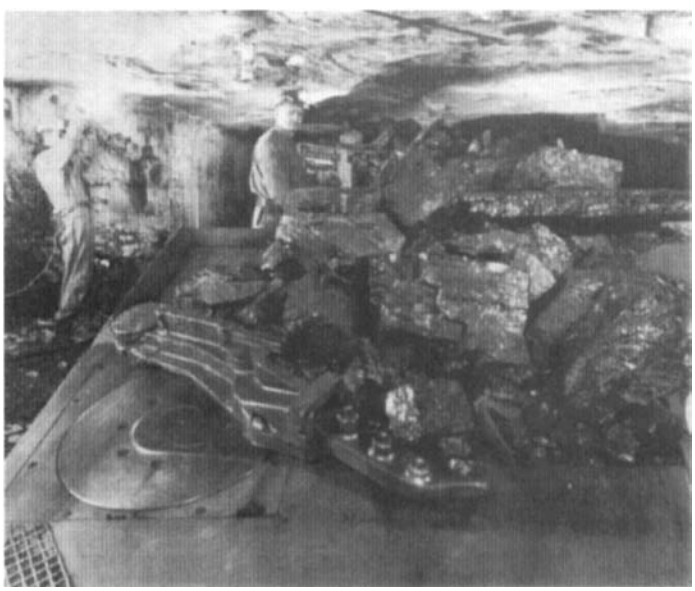

Fig. 10. Continuous mining machine used in underground mine. As coal accumulates on the mine floor, the helical screw effect of the cutting head constantly moves the pile toward the center of the head, contributing to fast loading and improved productivity and cleanup. Two powerful motors handle all motions of the machine. Safety provisions are incorporated in the design. (*National Coal Association.*)

supporting the roof, these props also help protect the work area, increasing safety. Longwall mining units and the mining cycle are remotely controlled, usually by a miner stationed in one of the entries.

There are about 100 longwall mining installations in U.S. underground mines, most of which are located in Appalachia and the Midwest. The applicability of the methodology to a specific coalbed depends upon several factors, including the thickness and suitability of the seam and the strength of the surrounding strata. See Fig. 12.

High-Pressure Mining Techniques. In the early 1990s a joint effort was undertaken by the University of Missouri and the National Aeronautics and Space Administration's Jet Propulsion Laboratory, to develop a prototype of a machine known as RAPIERS (Room and Pillar In-Seam Excavator/Roof Supporter). This machine employed a pair of jet-lances to carve a horizontal slot in the center of the face of the seam. Hydraulic jets then progressively cut vertical slots, using wedge-shaped cutters to move

Fig. 11. Closeup of cutting edge and helical screw, which cuts and removes coal from the mine seam. (*National Coal Association.*)

the coal toward the center slot. Mechanical arms transferred the cut pieces of coal onto a conveyor belt. With the use of water, coal dust was kept to a minimum. The machine also could support the tunnel ceiling prior to the installation of support bolting.

Coal Preparation Plants

Raw coal from the mine must be treated (washed, sized, sorted, etc.) prior to shipment to the end user. The amount of refuse discarded may be up to 20% of the raw coal. Power plants and other coal consumers use transport systems, furnaces, heaters, reactors, and the like that demand *uniform* feedstocks. Coal preparation plants are not highly standardized because of differences in the physical and chemical properties of the raw coal from one mine location to the next. See Fig. 13.

Since most coal impurities have specific gravities greater than coal, the density of a coal particle is a direct measure of its purity. The differences in this physical parameter is the basis for mechanical separation of coal from refuse. Both gravity and centrifugal force devices are used and these may employ air or liquids as washing media. There are relatively few instances where air washing will work because of the moisture required to be on the coal to meet mining regulations. The few cases where the raw coal is dry enough for air washing require a complete dust collection system to meet air pollution standards. Thus, few plants utilize air washing. There may be a trend to air washing in the western coal fields because of the scarcity of water.

Washing processes fall into three classes: (1) hydraulic separation; (2) dense medium separation; and (3) centrifugal (cyclone) separation.

Hydraulic separation depends on a process called jigging, which creates a particle stratification from an alternate expansion and compaction of a bed of particles by a pulsating fluid flow. As originally developed, a basket filled with material was moved up and down in a tank filled with water. The more modern Baum jig process utilizes an air impulse concept in which the water is moved by air pressure from an adjacent sealed chamber. There are several refinements of the process, including the McNally Norton standard washer.

More accurate separations are made in dense medium vessels. Coal is slurried in a medium with a specific gravity close to that at which the separation is to be made. The lighter coal tends to float and the refuse to sink. The two fractions then can be mechanically separated. Theoretically, any size particle can be treated by the dense medium process. Practically, the sizes range from about 0.5 millimeter to about 6 inches (15 centimeters). Organic liquids, salt solutions, aerated solids and water suspensions have found use as commercial media. Water suspensions meet most practical requirements and are the least costly. The bulk of coal mechanically cleaned by the dense medium process is separated in suspensions of magnetite in water.

Fig. 12. Example of longwall mining. (*National Coal Association*.)

The use of centrifugal force as an aid in coal-refuse separation is a relatively recent addition to the coal-cleaning process. As originally developed, the device employed a dense working medium. The latest units do not employ an artificial gravity suspension and are known as hydrocyclones. Design of the unit allows the formation of a hindered settling bed as the dense particles move down the side wall under the force of gravity. Less dense particles are unable to penetrate this heavy bed and move back into the main hydraulic current and are discharged out the top of the unit.

Tables are also used to wash coal. The reciprocating action of a table stratifies the high-gravity coal particles on the bottom and the low-gravity particles rise to the upper level of the bed. As the low-gravity particles rise, they are moved across riffles that separate the high- and low-gravity material by the water flowing to the low side of the table deck. The refuse is trapped in the riffle troughs and the motion of the deck moves the refuse to discharge off the end.

For separating fine coal particles from refuse particles, flotation is often used. Finely disseminated air bubbles are passed through a coal slurry. The fine coal particles adhere to the air bubbles and rise to the top where they are removed as a concentrate while the heavy refuse particles sink and are removed by the flow of water through the flotation cell. A frothing reagent, such as methylisobutylcarbinol, is added to the feed. See also **Classifying (Process)**.

Water remaining on marketable coal is a contaminant as serious as the undesirable ash. It may cause problems in handling and shipping, increase freight cost, and reduce heating value per unit weight. The difficulty of dewatering increases with increases in the surface area of the material. Several processes are used, depending upon the particle size of the coal. Vibrating-screen type centrifuges may be used. For the removal of very fine material (28-mesh and smaller), a filter process may be required. Both disk-type and drum-type filters are used. Where filters are required, filtration is usually preceded by sedimentation. Chemical flocculants sometimes are used to assist the settling process. A final reduction of moisture content frequently is accomplished by thermal drying. The use of fluidized bed coal dryers is increasing.

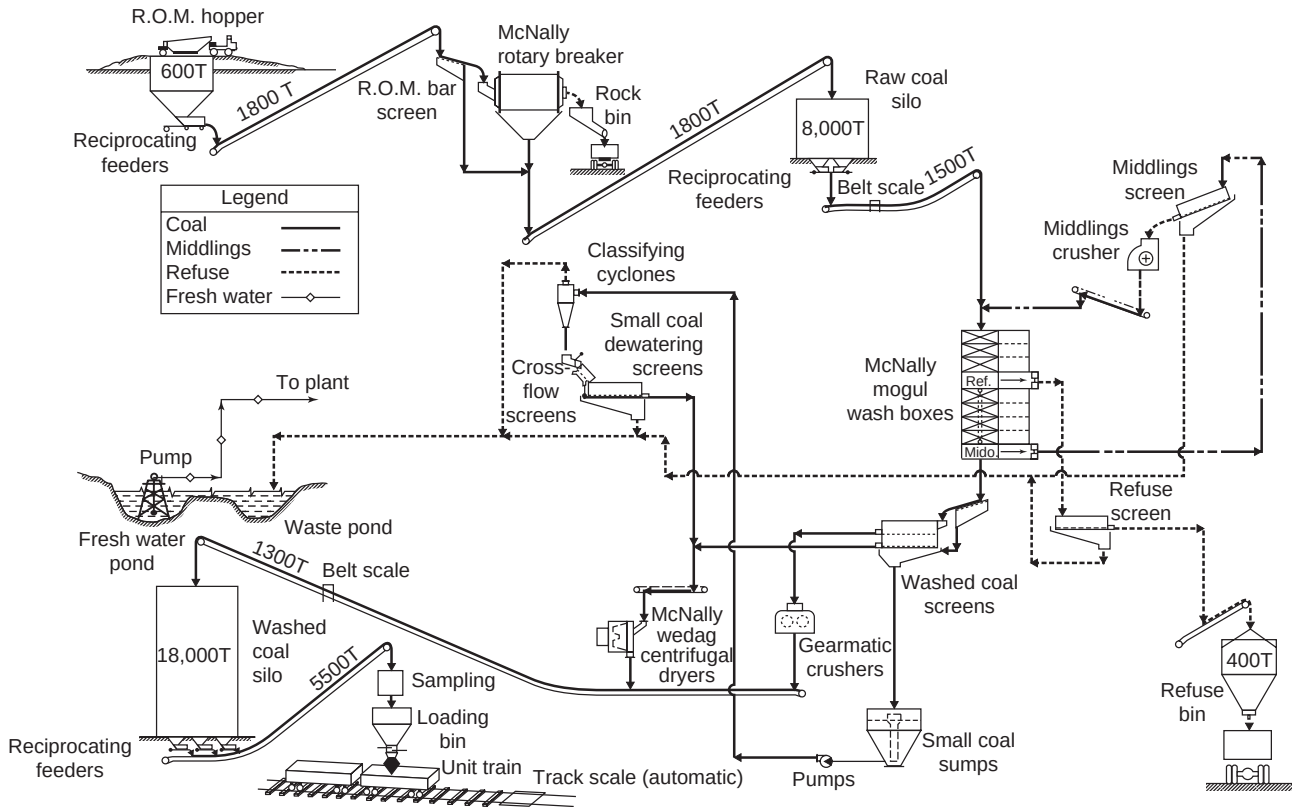

Fig. 13. Coal preparation plant. (*McNally Pittsburgh Mfg. Corp.*)

Transportation of Coal

Railroads handle approximately 60% of the coal mined in the United States during some part of its journey from mine to point of consumption or shipment overseas. Most American railroads offer four distinct types of service for the transportation of coal: (1) single carload; (2) multiple carload; (3) trainload volume; and (4) unit train. Each type of freight service has its own operating characteristics, which result in a distinct level of operating cost and freight rates. The first two methods are self-evident. Trainload volume is the tendering of a sufficient number of carloads of freight on one day from one origin to one destination to permit the carrier to handle the movement in a special train. The number of carloads required to form a trainload will vary from one railroad to the next. Trainload volume movements are an irregular movement on an irregular schedule. The basic operation requires simplified switching and terminal operations, resulting in economies in rail operation. Trainload volume trains use rail cars assigned to a car pool. The trains are governed by tariff provisions requiring a limited control over the loading and unloading of the railroad equipment and occasionally requiring a minimum annual volume.

A unit train movement is an integral movement of coal moving from a single origin to a single destination on a regularly scheduled train, avoiding all terminals and switching operations. Unit trains utilize specialized loading and unloading facilities and specialized railroad equipment assigned to dedicated service. The unit train movement is governed by tariff provisions requiring both controlled loading and unloading of the railroad equipment and a minimum annual tonnage. The loading of a unit train at the York Canyon Mine (New Mexico) is shown in Fig. 14. When large volumes of coal are to be loaded within a short time, some form of flood-loading is required, permitting the coal to free fall into the cars. The four basic types of flood-loading are: (1) Ground storage with loading tunnel; (2) ground storage with loading bin; (3) silo storage; and (4) silo storage with loading bin. The first type is used in the system shown in Fig. 14. A unit train being loaded from a storage silo is shown in Fig. 15.

The unloading of coal cars can be accomplished by several methods. A unit train with conventional hopper cars would be unloaded with the cars being spotted over the storage area. The gates on the cars would be opened by laborers stationed alongside the rail cars. After the first cars over the unloading area were discharged, the train would move forward until the next loaded car is moved into place. This spotting, unloading, and spotting sequence must be repeated perhaps a hundred times until the entire train is unloaded.

A unit train with quick-opening bottom-drop cars would be unloaded by having the gates on the rail cars opened by either a mechanical tripping mechanism or by an electrical device as the cars roll over the pit or trestle. After the cars are unloaded, the gates on the cars would be closed by a similar mechanical or electrical mechanism. Motion unloading systems, although costly, represent many advantages. Proceeding across the pit area at 4 to 5 miles (6.4 to 8 kilometers) per hour, a 100-car, 10,000-ton (9000-metric ton) unit train can be unloaded in 15 minutes. Considering startup time, the total unloading time may approximate one hour. The same 100-car unit train, in an efficient two-car rotary dump facility, will require from 4 to 5 hours to unload the train. If a single-car rotary dump facility were used, the unloading time will range from 8 to 12 hours. A motion unloading facility is illustrated in Fig. 16.

After coal arrives at its destination for consumption — say an electric power generating plant — considerable handling remains prior to the coal-fired boilers. See Figs. 17 and 18.

Barge and Truck Transport of Coal. Approximately 28% of U.S. coal is transported by barges over inland waterways. Trucks account for approximately 13% and used mainly for deliveries of 100 miles (161 kilometers) or less. Because of weight limitations, trucks are not used for long hauls.

Coal Slurry Pipelines. The first patent covering the pumping of coal and water dates back to 1891. In 1914, the first commercial transport of coal in water was carried out in England, when a short 8-inch (20-centimeter) pipeline was used to carry coal from river barges to a power plant. Thereafter, several proposals were submitted for the long distance transport of coal from mine to market in the eastern United States, but failed to materialize for several reasons, not the least of which were technical problems. Intensive research into slurry transport was continued and, by 1957, technology and engineering had advanced to the point where the first long distance transportation of coal in water was feasible. The result was construction and operation of the Consolidation Coal Pipeline, 10 inches (~25 centimeters) in diameter and 108 miles (174 kilometers) in length, transporting 1.25 million tons (~1.1 million metric tons) of coal per year from Cadiz, Ohio, to an electrical generating

Fig. 14. Unit train being loaded at a New Mexico mine. (*McNally Pittsburgh Mfg. Corp.*)

station 20 miles (32 kilometers) east of Cleveland on the shores of Lake Erie. The pipeline was powered by three pump stations, spaced about 35 miles (56 kilometers) apart, where discharge pressures reached 1,000 psi (6.9 mPa). Coal with a graded size consist, 8 mesh by 0, and a concentration of 50% solids was transported. Consist means the size makeup of the solid phase of the coal slurry. The term 8 mesh by 0 indicates coal with a graded size makeup in the range of 8 mesh and zero (dust).

Although the Ohio line operated successfully, transporting 7 million tons (6.3 million metric tons) of coal, some unexpected operating problems had to be resolved. Much investigation was conducted with variables, such as size consist and slurry concentration and the resultant effect on slurry stability. After 7 years of operation, the line was shut down in 1963, when the unit train concept resulted in much lower freight rates on significantly higher amount of coal movement.

Economics vary in different locations, however, and slurry pipelines can be particularly, attractive where no railroad facilities exist. Thus, throughout the world today there are about ten operating coal slurry pipelines. The only one (1991) in the United States is the Black Mesa Pipeline, 273 miles (440 kilometers) long, mostly 18-inch (~46 centimeters) diameter, but with some 12-inch (7.6-centimeters) diameter sections.

Coal slurry pipelines have been constructed in several countries, including a 38-mile (61-kilometer) 12-inch (30.4-centimeter) diameter pipeline in Russia, a 51-mile (82-kilometer) pipeline in Poland, as well as others in France and other locations in Europe. The feasibility of slurry transportation depends upon the resolution of a number of variables, the most important of which from a hydraulic standpoint are: (1) Size consist; (2) velocity; and (3) concentration. The selection of a proper size consist (gradation) is important in order that homogeneous flow can be achieved at prudent operating velocities. For coal slurry, such a consist is on the order of 8 mesh by 0 (approximately 0.1-inch (2.5-millimeter) particle size to dust). Homogeneous flow (solids evenly distributed across the pipe diameter) is important if excessive wear in the bottom of the pipe is to be avoided and stable operation achieved.

Of equal importance and directly related to size consist is the proper selection of velocities for transport. The velocity cannot be excessive so as to cause abrasion of pipe wall and inordinately high pressure drops. Conversely, the velocity should not be so low as to cause heterogeneous flow, with resultant excessive wear in the pipe bottom or bed formation which will cause unstable operation.

Fig. 15. Unit train is loaded with coal as it passes through base of storage silo.

The two prime disadvantages facing coal slurry pipelines are: (1) An adequate and assured water supply is required. In water-short areas of the

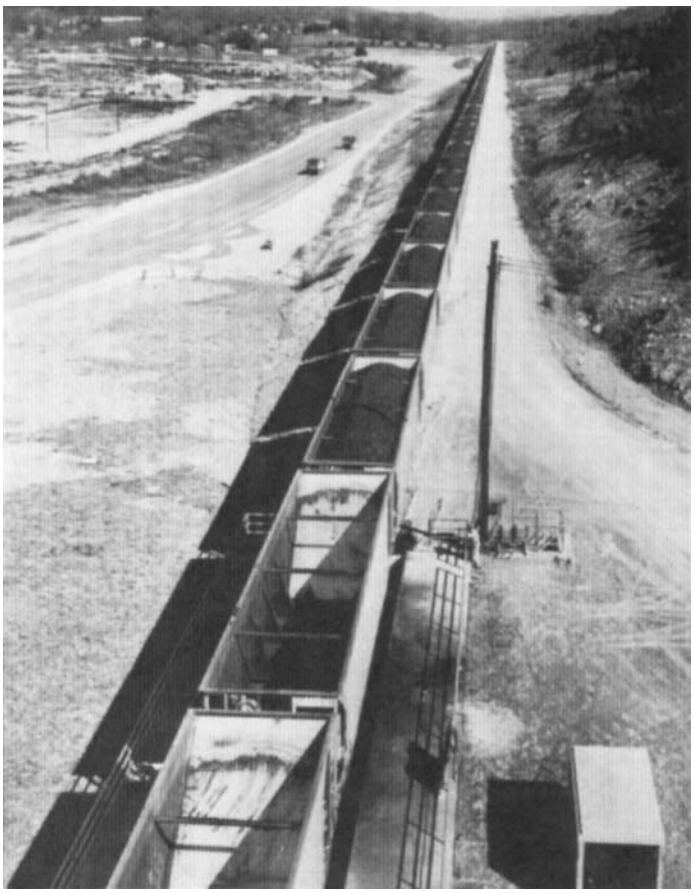

Fig. 16. A unit train with motion unloading of hopper cars being unloaded at large power plant in Tennessee. (*TVA.*)

western United States, this is a major consideration; (2) dewatering slurry for consumption at a power plant, or for transshipment by barge is required. Centrifuging is the primary method used to date. While reduction of coal particles to the very small size needed for movement by pipeline serves the requirements of a generating station for a finely-ground coal, the fine size makes dewatering difficult.

Testing of Coal

Proximate Analysis. This includes the determination of total moisture, volatile matter, and ash; and the calculation of fixed carbon for coals and cokes. The term "Proximate" should not be confused with the word "approximate," since all Proximate Analysis tests are performed according to rigid specifications and tolerances. Proximate Analysis results may be used to establish the rank of coals; to show the ratio of combustible to incombustible constituents, to provide the basis for buying and selling coal, and to evaluate for beneficiation, or other purposes.

Moisture in coal takes three forms: (1) free or adherent moisture, essentially surface water; (2) physically bound or inherent moisture (that moisture held by vapor pressure and other physical processes); and (3) chemically bound water (water of hydration or "combined" water). The ASTM defines *total moisture* as a loss in weight in an air atmosphere under rigidly controlled conditions of temperature, time, and air flow. Total moisture represents a measurement of all water not chemically combined. Total moisture is determined by a two-step procedure, involving air-drying for removal of surface moisture from the gross sample, division and reduction of the gross sample, and determination of residual moisture in the prepared sample. An algebraic calculation is used to obtain the total moisture value.

Ash is the noncombustible mineral matter left behind when coal is burned under rigidly controlled conditions of temperature, time, and atmosphere.

Total nitrogen is determined by chemical digestion (Kjeldahl-Gunning) methods.

Oxygen content is determined by calculations, subtracting total carbon, hydrogen, sulfur, nitrogen, and ash from 100%.

Chlorine is commonly included as part of the ultimate analysis.

Other important chemical and physical tests performed to characterize coal include: (1) Heating value (Btu content); (2) sulfur forms; (3) ash fusibility temperatures; (4) ash analysis; (5) trace elements; (6) free swelling index; and (7) hardgrove grindability.

Heating value is determined by burning a coal sample in an oxygen bomb and measuring the temperature rise. See also **Calorimetry**.

Three *sulfur forms* recognized by ASTM are: (1) sulfate sulfur, which may be in the form of calcium or iron sulfate; (2) pyritic sulfur, which is sulfur combined with iron in the form of minerals pyrite and/or marcasite; and (3) organic sulfur, which is bonded to the carbon structure.

Ash fusibility can be defined broadly as the melting temperature of the ash.

Ash analysis is the term used to designate analysis of the major elements commonly found in coal and coke ash. The elements, expressed as oxides, are SiO_2, Al_2O_3 ,Fe_2O_3, TiO_2, CaO, MgO, Na_2O, K_2O, P_2O_5, and SO_3.

Interest in *trace element analysis* has increased by environmental concerns.

Volatile matter is defined as the gaseous products, exclusive of moisture vapor, driven off during standardized test conditions. The combustible gases are carbon monoxide, hydrogen, methane, and other organic hydrocarbons. Those generally classified as noncombustible are carbon dioxide, ammonia, hydrogen sulfide, and some chlorides. Volatile matter tests are used to establish the rank of coals, to indicate coke yield upon carbonization, and to establish burning characteristics.

Fixed carbon is the solid residue, other than ash, resulting from the volatile matter test. The value is calculated by subtracting moisture, volatile matter, and ash from 100%.

Total carbon is determined by catalytic burning of the sample in oxygen to form carbon dioxide, which can be readily measured.

Total hydrogen also is determined by catalytic burning of a sample in oxygen to form water. The water is absorbed in a desiccant and weighed directly. Hydrogen results as determined include the hydrogen present in both the sample moisture and water of hydration.

Mining Safety and Health. Although steady technological progress has taken place over a number of years concerning the health and safety of coal mining personnel, a strong impetus toward further improvements has come from legislation at the state and national level over the past score of years. Studies and improvement programs continue to be well funded. Efforts have fallen into the following major categories.

Ground Control — with the objective of developing technology to prevent accidental falls of roof, rib and face, and coal bumps. Study areas include: (a) artificial support, (b) hazard detection, and (c) design of mine openings. Horizontal roof strain indicators for detection of unstable roof conditions have been tested. Other research programs have included a microseismic fracture warning system, polymeric roof bolts, and chemical impregnation techniques.

In late 1991 Australian government researchers announced the development of a remote-controlled vehicle that can scout ahead of a rescue crew to locate missing and injured miners. Three stereo-video cameras permit the vehicle to operate in murky areas of a mine. The vehicle also includes gas analysis instrumentation. A fiber-optic cable, wound on a large drum, permits surface operators to convey instructions to the vehicle and to receive the results of gas analysis data and images of what the vehicle "sees." The vehicle is named after a burrowing marsupial, *Numbat.*

Fire and Explosion Prevention — study areas have included: (a) ignition, (b) flame propagation, (c) fire detection and alarm, (d) suppression and extinguishing, and (e) methanometry. Devices and techniques tested have included explosion-proof bulkheads, coal dust and rock dust analyzers, ignition suppression devices for face equipment, and remote sealing techniques.

Industrial-type Hazards — with the objective of identifying hazard sources in electrical, mechanical, illumination, and non-emergency communication fields. Developments have included (a) advanced remote surveillance and communication systems, (b) portable-area illumination systems, (c) trolley-phone wireless systems, and (d) protective canopies for use on underground low-coal machines.

Methane Control — with the objective of developing safe methods for mining methane-laden coalbeds. Study areas have included: (a) predictions of concentrations and flow; (b) control in advance of mining; and

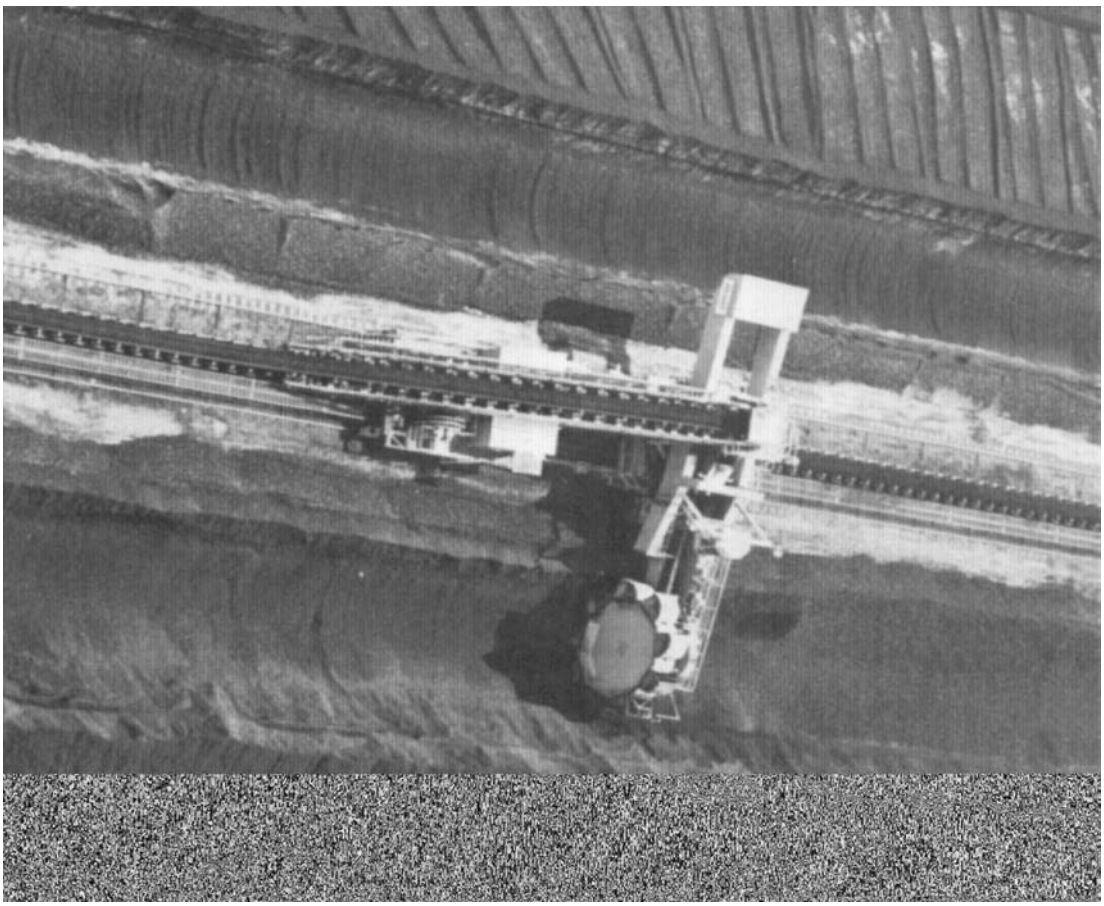

Fig. 17. Looking down on a bucket-wheel stacker-reclaimer for handling coal. The machine is moving along a 1200-foot (366-meter) stockpile near Uniontown, Kentucky. Incoming coal from the conveyor moves to the top of the machine and is dumped into 30-foot (9-meter) trenches beside the tracks which support the machine. Later, the bucket wheel will recover coal from the trench. Excess coal is pushed back and forth from the trench by bulldozer as required (*Dravo Corporation*.)

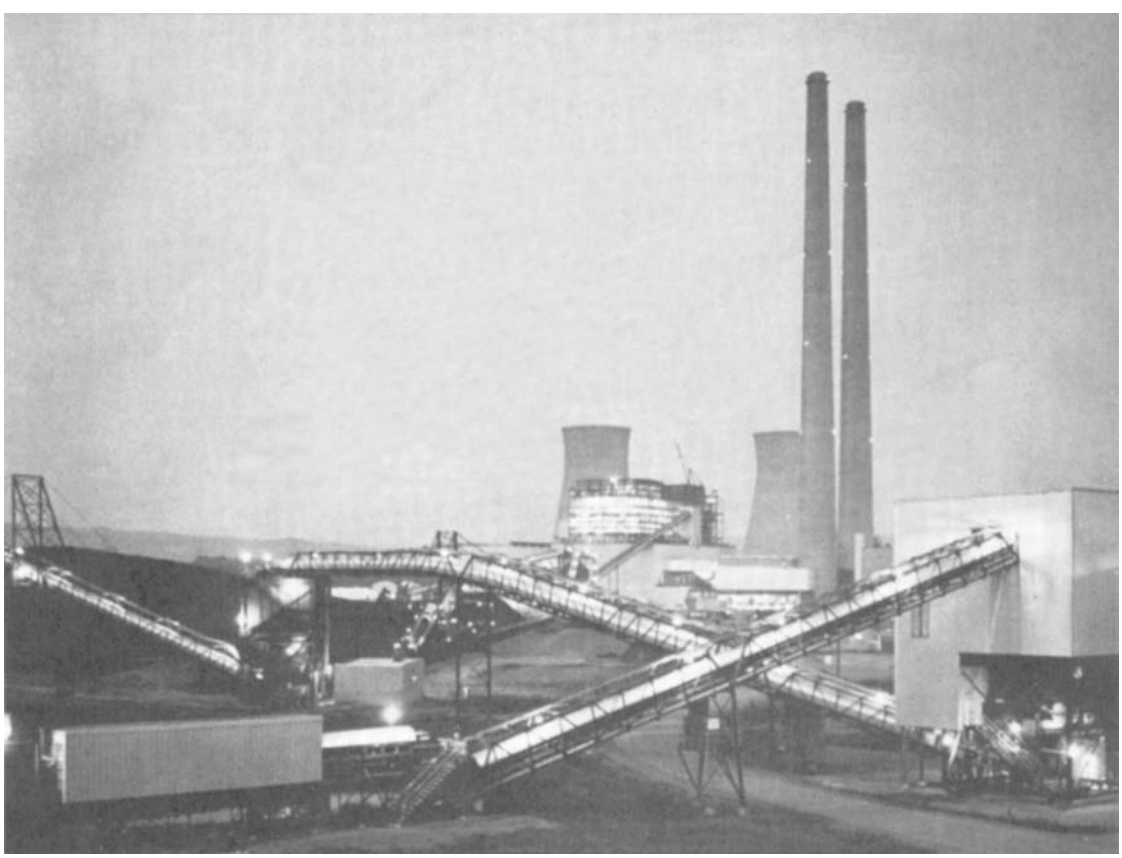

Fig. 18. Electric generating station in central Pennsylvania is one of several large mine-mouth electric power generating plants in the area which consume coal from nearby mines. Clearly visible are the long conveyor lines required to move the coal once it is received at the plant. (*New York State Electric and Gas Corporation*.)

(c) control during mining. Techniques tested have included water infusion to reduce methane in the face area, degasification through vertical boreholes, the plugging of oil and gas wells that penetrate coal beds, and the complete degasification of operational mines.

Respirable Dust — with the objective of providing improvements for protecting miners from exposure to respirable coal mine dust. Study areas have included: (a) dust formation; (b) dust control, and (c) dust measurement. Tests have included: the infusion of water into coal beds for control of respirable dust; the use of water-based, high-expansion foaming systems in conjunction with continuous mining machines, to reduce dust at the face; the use of foam systems for dust suppression on conveyors and transfer points; and the use of prototype dust meters. See also **Pneumokonioses**.

Noise — with the assessment of permissible noise levels for communication and warning signals and the development of technology for noise abatement and control. Developments have included an audio dosimeter to replace conventional sound-level meters, discriminating earmuffs, and a noise control muffler system to reduce pneumatic drill noise.

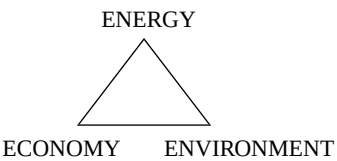
COAL BALLS. Concretions composed of mineralized plant fragments preserved as petrifactions. Because the original structure of the plants has been so well preserved, the coal-ball flora has been of aid to paleobotanists in determining the character of the carboniferous flora.

COAL CONVERSION (CLEAN COAL) PROCESSES. Coal, representing a major reserve of energy in the United States and a few other countries (see also **Coal**), currently accounts for well over half of the electricity produced in the United States. Thus, although coal poses environmental threats and problems, until other essentially renewable energy sources can be developed technologically, coal obviously will be a major energy source for well into the 21st century. The problem, then, is to determine how coal can be treated or converted and how coal combustion processes can be altered so that their impact on the environment can be minimized and, of course, fall within the practical economic limitations realistically imposed on the *value of energy*. Among energy alternatives, coal probably is at the apex of the triangle made up of three interacting forces: the energy supply, the environment, and the national economy.



Coal conversion and utilization technology, although less spectacular, rivals the space program's engineering in terms of the numbers and difficulties of problems requiring solution. This is attested to by the scores of approaches suggested, studied, and applied in test situations. Coal has proved to be a very stubborn, scientifically unpliable substance to manipulate. Coal conversion or combustion processes are not amenable to much laboratory benchwork, but usually require fairly large and expensive pilot plants for process testing. Scale-up problems are equally difficult. For example, those coal conversion processes that have reached the large-scale testing phase pose severe materials problems and operate under high temperatures, high pressures, and with severely corrosive and abrasive materials at various stages in the process. Thus, advances in materials engineering (need for new alloys, ceramics, etc.) parallel the other processing problems of coal conversion. (These are reminiscent of materials problems encountered in the space program — for example, solving the reentry heating problems in the early days of the space shuttle.)

Assuming that coal will be required for several future decades as a major source of energy, what options are open for the near, intermediate, and far term? There is a considerable consensus that converting raw coal into essentially a new form of fuel, as through gasification, liquefaction, or treated solid forms, will provide minimum ultimate impact on the environment. However, without some breakthrough, unknown as of 1992, an idealized concept will require much more time and funding.

Discounting the obvious conservation of energy (easy to preach; difficult to practice), there are two main avenues of approach for the immediate and short term:

1. Improving coal combustion processes to maximize electric generation efficiency, partially with the obvious target of using less coal/kilowatt and thus directly helping the environment; and
2. Designing processes that either:
   a. Create reduced air pollution; or
   b. Treat pollutants prior to their emission into the air.

Considerable progress along these lines has been made as a result of the Clean Air Act and other forces that are demanding environmental protection. Recent revisions of the Clean Air Act have placed high responsibilities on the operators of electric utilities. Emissions reduction in the absence of an entirely new coal fuel technology is extremely costly. Although the more recent amendments award and penalize operators for emissions reduction performance, the political aspects of which are not described here, the bottom line is higher electricity costs for the consumer, reemphasizing the strong inverse relationship between energy and the environment. Location of electric generating plants that fall within "allowances" program are shown in Fig. 1. This program obviously is tied in with international concerns over SO_2 emissions. See also **Acid Rain**; and **Electric Power Production and Distribution**.

For those readers who are not familiar with past achievements in coal conversion, the following several paragraphs and examples are included. The use of coal is tersely reviewed prior to major environmental concerns, which belatedly did not become part of the public psyche until the mid-twentieth century.

Early Chronology of Coal and Steam

As pointed out in the entry on **Coal**, the principal ingredient of coal is carbon and, as described in the entry on **Combustion**, it is the combination of carbon with atmospheric oxygen to produce carbon dioxide (CO_2), an exothermic reaction that releases 14,100 Btu/pound (7840 Calories/kilogram) of carbon, that provides the heat energy derived from burning coal. Depending upon the composition of the coal, other heats of reaction will occur from the combustion of hydrogen and sulfur in the coal with air, but these are secondary factors. The fixed carbon content of coal ranges from about 98% for a Class 1 anthracite or hard coal, as may be mined in Pennsylvania, to as low as about 32% for a Class 17 brown coal or lignite, as may be mined in North Dakota.

Direct use of coal, as in pulverized form for the firing of boilers in the electric utility industry, poses a number of environmental problems that can be solved only through the use of costly and elaborate antipollution measures and equipment. But, also in considering the expanded use of solid coal as a major source of energy, there are several other limitations over and beyond the environmental.

Aside from coal-powered steam locomotives and seagoing ships, which essentially were retired from most regions of the world over the past several decades, solid coal is quite unsuited for transportation energy. The energy density of raw coal means that a significant portion of the energy obtained from combusting it is required to move it (as part of a transportation vehicle). This is further amplified by the equipment required to burn coal — massive, heavy furnaces and boilers — which also have to be moved with the vehicle.

Transportation power needs dictate high energy density with fuels that are easy and convenient to handle and that can be converted to power by

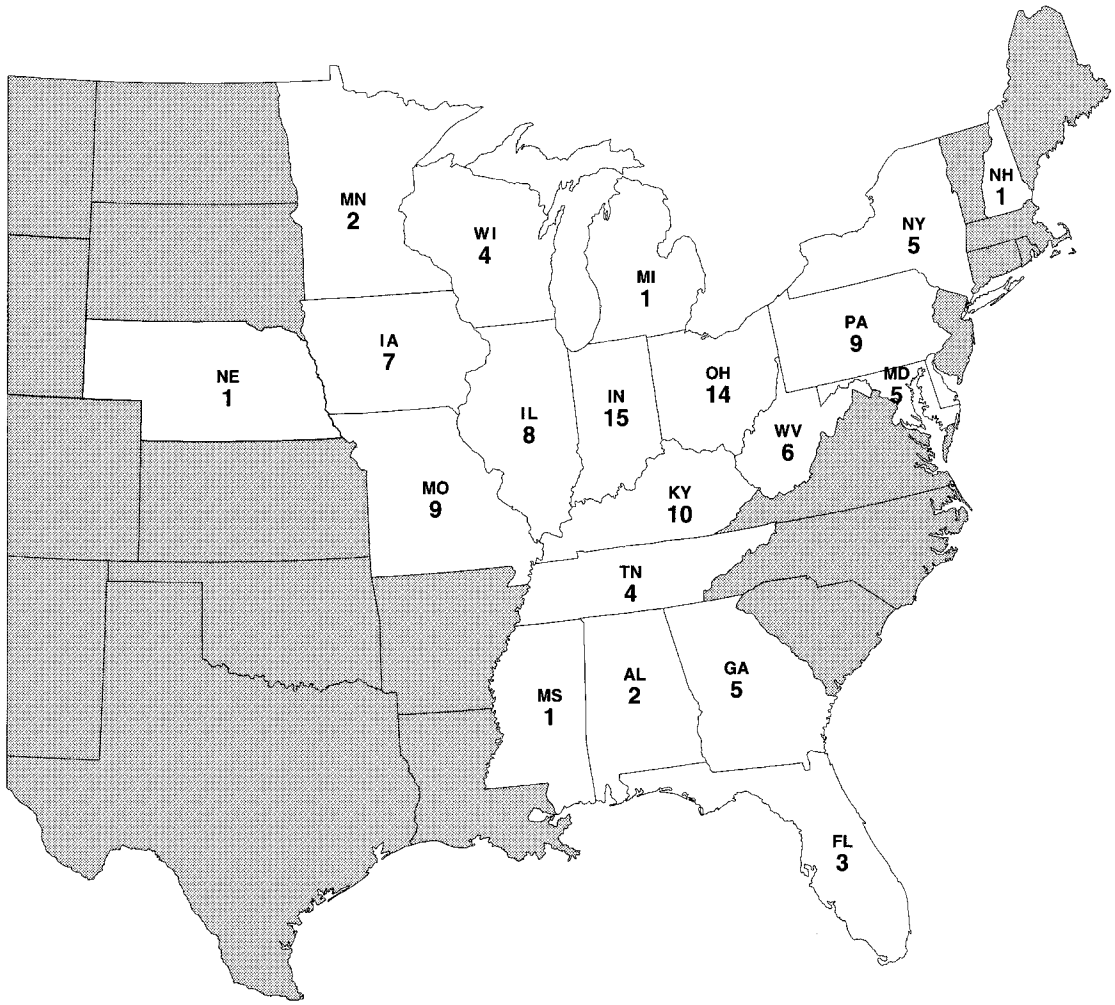


Fig. 1. States with coal-burning electric power plants that are targeted by Clean Air Act revisions, requiring that by 1995 such plants must reduce their emissions of sulfur dioxide (SO_2). Complicated politically, the program is measured in terms of allowances, one allowance equaling 1 ton of SO_2. Depending upon the size of the power plant, allowances range from 1000 to 255,000 units of SO_2. Because of plant size variations, current state of cleanup equipment, and the fact that several plants are under the same management, the program allows for certain trade-offs. In other words, reduction at some plants may be applied to plants not performing as well environmentally. Allowances also may be purchased from other plants. In essence, this will allow some older plants to continue operating for the next few years, while others are modernizing or while new plants are being constructed. Thus, the regulatory targets are for the total 111 plants to accomplish a large regional reduction by 1995.

much smaller, lighter-weight engines. It follows, then, that for coal to be a useful energy source for transportation, it must be preconverted in some way to overcome the aforementioned objections.

Even for stationary use, particularly where energy needs are much less concentrated than in the case of a central electric power plant, such as for commercial and residential heating and large numbers of industrial plants, the conversion of coal into liquid or gaseous forms is required to provide the needed convenience, improved cleanliness, and use efficiency. Probably of equal importance is the cost of transporting large amounts of coal from sources to many tens or hundreds of thousands of locations where it can be used. With liquid or gaseous fuels, pipeline transportation, for example, becomes attractive. It is true (see entry on **Coal**) that there has been considerable attention given to coal slurry pipelines, but these are practical only for certain combinations of situations — because of the slurry preparation and handling equipment, costly and elaborate, required at both ends of the pipeline.

Since the time of Watt, the energy of coal has been converted to a gas — in the form of steam. Steam or hot water can be effectively distributed within relatively small areas, as throughout a given manufacturing plant or complex, or even a commercial and residential neighborhood. This type of district heating has been used for domestic and commercial heating in some parts of the world for many years and, in fact, is undergoing a revival in some areas. District heating (although from geothermal energy rather than from coal) has been common in parts of Iceland for many decades. But thermal losses from transporting steam or hot water limit this approach to relatively small distances.

For many years coal has also been converted into possibly the most ideal form of energy of all — electricity. Electricity has been used extensively for powering machines, lighting, communications, etc. The use of electricity for direct heating, particularly in commercial and domestic installations in many regions, has proved quite costly in recent years. In some regions, a heat pump may be attractive economically. See **Heat Pump**.

"Artificial" or "City" Gas in Perspective

The concept of synthetic fuels is far from new. In fact, in the mid-to-late 1800s and carrying into the first third of the 20th century, what are now called synfuels were used on a daily basis in many parts of the world. Thus, one might say that synthetic fuels and the role of coal in bringing them about is a situation of revival in technology rather than anything of an entirely new or pioneering nature. Petroleum fuels essentially represent a phenomenon of the automotive age (the spectacular salt dome at Spindletop, Texas was put into crude oil production in 1902). Natural gas as a major and widely distributed fuel really did not get underway on a large scale until the 1930s. Thus, for the greater part of the 20th century, with natural crude and natural gas, both excellent, convenient, generally clean and inexpensive fuels, the question could have been posed, "Who needs synthetic fuels?"

Artificial gas for use as a heating fuel and derived from coal or coke was widely used during the latter part of the nineteenth century and during the first few decades of the twentieth century. Although natural gas had been discovered and used by the Chinese some 2,000 years ago (piped from shallow wells through bamboo poles for burning under large pans

for evaporation of sea water to obtain salt), the first hard evidence of commercial use of natural gas dates back to 1802, when it was used for lighting the streets of Genoa, Italy. The first natural gas utility company was formed in 1858 (The Fredonia (N.Y.) Gas Light Company). The numerous advantages of a gaseous fuel that could be piped to industrial, commercial, and residential users for heating purposes were recognized long before natural gas was found on a large scale and made available to communities hundreds and more miles from the originating wells. Thus, for many decades, artificial gas was used. The local gas utility was characterized by having one or more so-called "gas works" in which a rather poor grade of gas (on present standards) was produced essentially from coal or coke and steam. In the manufacture of producer gas, a deep hot bed of coal or coke was blasted continuously with a mixture of air and steam. The products of the process were carbon monoxide, nitrogen (from the use of air), small amounts of hydrogen, and some carbon dioxide. Because of the large percentage of nitrogen in the gas, the heating value was low [125 to 150 Btu per cubic foot (1113 to 1335 Calories per cubic meter) as compared with natural gas having a value of from 900 to 1.200 Btu per cubic foot (8,010 to 10,680 Calories per cubic meter)]. Blue water gas, carbureted water gas, and coal gas were also produced from coal or coke and, in some instances, enriched with oil and later natural gas. Because of the great availability and, at one time, apparent inexhaustible supply of natural gas in the United States (and a few other areas of the world), manufactured gases were phased out rapidly. The use of natural gas increased 730% between 1940 and 1970 in the United States, during which period the gas industry produced 313 trillion cubic feet (8.9 trillion cubic meters) of natural gas. In other areas of the world, however, where natural gas was not available locally, manufactured gas, sometimes referred to as town gas, city gas, etc., persisted. Thus, it is not surprising that the current new coal gasification technology essentially stems from Europe and the United Kingdom, where an interest in improving artificial gas manufacture continued long after such interests mainly disappeared in the United States. During the 1930s and 1940s, only a few projects for converting coal into gas were conducted in the United States — for example, the U.S. Bureau of Mines project at Louisiana, Missouri.

Pre-Energy Crisis Coal Fuel Developments

Prior to the "Energy Crisis" of the 1970s, efforts were made in parts of the world that had no or few petroleum reserves (unlike the United States, for example) to research the conversion of coal into superior fuels. The efforts of the Republic of South Africa were outstanding for that period and, with further improvements, continue successfully today. Germany also retained an interest in coal conversion as an extension of its primary major experiences in designing processes for converting coal into "artificial gas," previously mentioned. Much of the South African program relied upon German technology. South Africa had the motivation because there are no signs of important petroleum deposits in the country.[1] As early as 1927, a White Paper already had been published discussing the processes then available for production of oil from coal. Developments in Germany were closely followed and especially the Fischer-Tropsch process, as its operating conditions did not appear to be very extreme and the process had already been demonstrated in a number of plants. A South African mining corporation, the Anglo Transvaal Consolidated Investment Company, better known as Anglo Vaal, acquired in 1935 the South African rights to the German Fischer-Tropsch process.

During the next few years, Anglo Vaal devoted much attention to the development of a scheme for the production of oil from coal. Tenders were asked for, but because of the complications of World War II, no orders for equipment were placed. However, during the war and in the postwar years, Anglo Vaal remained in close contact with developments. In 1943, negotiations held in America led to the procurement of the rights to the American variation of the Fischer-Tropsch process. In 1946, a new study was undertaken, and an application was made to the government to create a suitable framework within which a long-term industry could be established. During 1947, the Liquid Fuel and Oil Act was passed and, in 1950, an agreement was reached between the South African government and Anglo Vaal in which the Anglo Vaal rights were taken over by the government. The South African Coal, Oil and Gas Corporation Ltd. was formed and incorporated under the Companies' Act as an ordinary public company. The government appoints the majority of directors, including the chairman, and the remaining directors are appointed by the Industrial Development Corporation, which is a government-owned organization with the objective, as the name implies, of stimulating industrial development in the country. Sasol operates like a normal business concern, with an autonomous board of directors, and is subject to South African company law and taxation like any other company.

A site for the plant was selected close to the banks of the Vaal River, which is South Africa's major source of water, 50 miles (80 kilometers) south of Johannesburg and on top of a vast coal field. Sasol acquired approximately 8000 acres (3200 hectares) for the plant and its township which was to have the name of Sasolburg. The site was in the middle of an area where cattle grazing and corn (maize) production were the only activities and Sasol had to create its own infrastructure from scratch.

Although it was clear that the plant would be based on the synthesis of hydrocarbons from hydrogen and carbon monoxide as invented and developed by Fischer and Tropsch, it still had to be decided which processes to choose for the individual steps in this integrated complex. For gasification, the Lurgi pressure gasification process with steam and oxygen was selected because this process had already been demonstrated in gasifiers of a smaller size. It had the advantage of being able to work on the rather low-grade, high-ash coal available to Sasol. The fact that it operated at a pressure of approximately 350 psi (2.4 mPa), which is also the desired operating pressure for the Fischer-Tropsch plant, was an additional advantage. This avoided cumbersome compression of large volumes of gas arising from low-pressure gasification. A small part of the Sasol I facility is shown in Fig. 2. Generalized flowsheet for the Sasol II facility is given in Fig. 3.

The production of synthetic motor fuels, pipeline gas, ammonia, and chemicals, where coal gasification is the key to successful production, was first commenced in 1955. Extensive experience was gained from 20 years of operation and a large expansion (Sasol II) was commenced in 1975 and completed in the spring of 1980. The newer facility processes 40,000 metric tons of coal per day and produces the equivalent of 60,000 barrels per day of petroleumlike fuels. New mines were developed nearby to feed coal over a conveyor system into a feed preparation facility. Two huge coal piles have been built up to provide continuous operation in event of a temporary shutdown of the mines. The coal is charged to a gasification section where synthesis gas is prepared in the presence of steam and oxygen. Ash content of South African coal is relatively high (about 25%) and thus some 10,000 metric tons/day of ash are produced in the gasifiers. The gasification section contains 36 Lurgi gasifiers which produce the raw synthesis gas. These are improved versions of the gasifiers used at the original Sasol I plant. The original plant also produced town gas as well as liquids. In the new facilities, no gas will be sold. The oxygen requirements of the new facility are quite high, and six air separation plants, each with a capacity of 2500 metric tons/day, represent one of the largest oxygen facilities in the world. Liquors from the gasification section are charged to a Lurgi Phenosolvan unit where ammonia and phenols are recovered and wastewater effluents are cleaned. The raw gas has to be further treated and this is accomplished in a Lurgi Rectisol unit, where carbon dioxide, hydrogen sulfide, and other impurities are removed. The heart of the plant is the liquefaction section. This is where the synthesis gas is liquefied in the presence of an iron-based catalyst. This Fischer-Tropsch reactor technology is proprietary to Sasol but is licensed.

Methane reforming units receive methane-rich gas from a cryogenic product recovery facility and subject the gas to partial oxidation. Some of the carbon dioxide content is removed and the gas recycled to the reactors. Once liquids are recovered, the stream goes to essentially conventional refining units. The plant's production is primarily transport fuels. Most of the gasoline production is currently sold to other refineries for blending with their stocks, but a portion of the product is marketed directly to consumers.

Other early coal conversion processes are shown in Figures 4, 5, 6.

Synfuels Program

The Arab Oil Embargo (1973) jolted many world governments into developing programs that would make their economies immune to future energy crises. In the United States a *Synfuels Program* was legislated. The primary thrust then was to develop fuels that would substitute for

[1] As partially related by Jan C. Hoogendoorn, Manager, Research and Development, South African Coal, Oil and Gas Corporation Ltd., Sasolburg, Republic of South Africa.

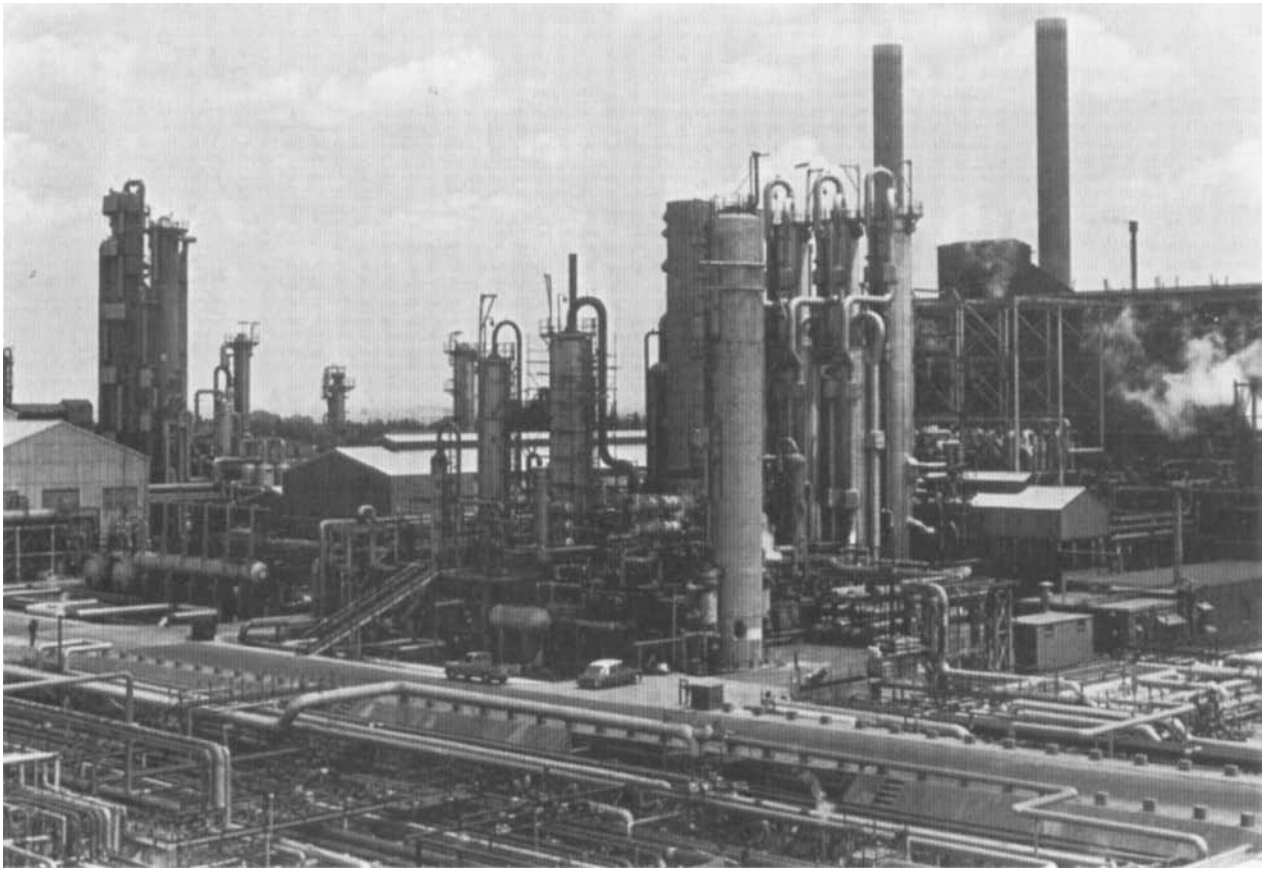

Fig. 2. Gas purification portion of coal gasification complex of Sasol 1 facility at Sasolburg. (*South Africa Coal, Oil and Gas Corporation Limited.*)

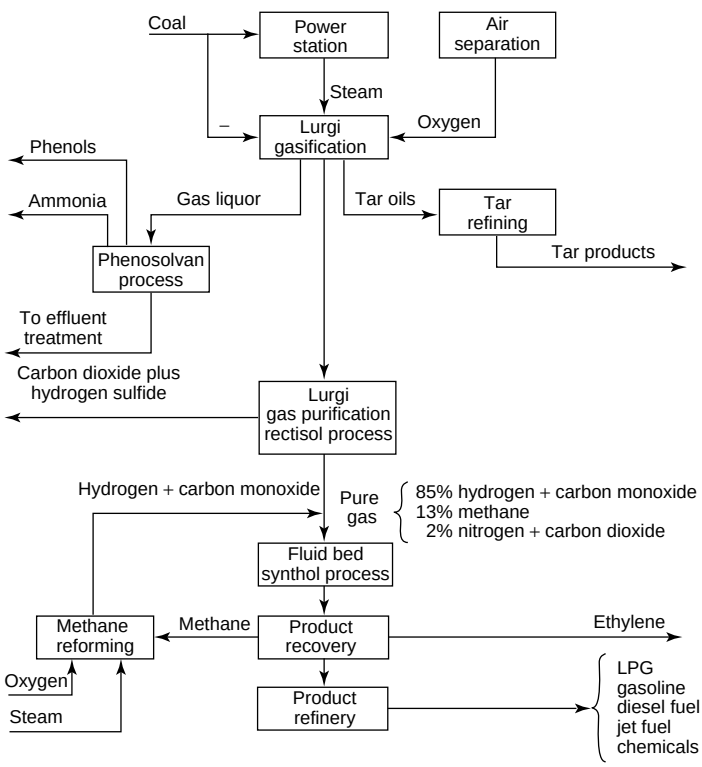

Fig. 3. Generalized flowsheet of Sasol II project. (*South Africa Coal, Oil and Gas Corporation Limited.*)

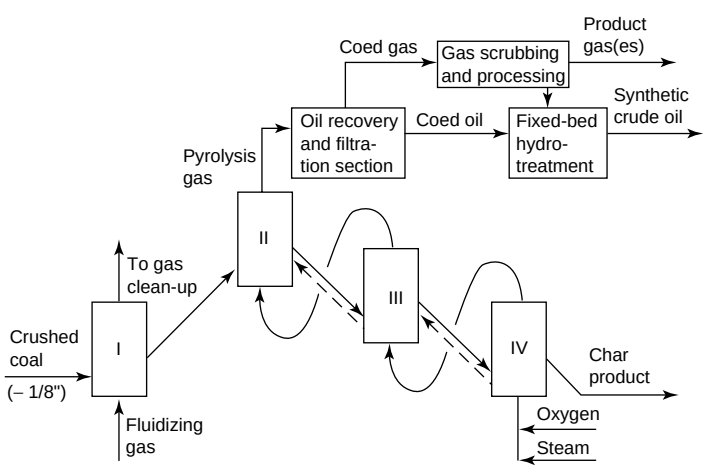

Fig. 4. Early (1970s) process for coal pyrolysis.

crude petroleum as a starting point. The attention given to coal conversion was mainly to derive petroleum-like fuels from coal rather than simply to process control for the well-established coal burning plants of that day. However, the technology of the Synfuels Program later became the basis for converting coal adaptable to traditional coal combustion power plants — not so much in the interest of meeting an energy crisis, but rather to avoid a future environmental crisis. Thus, current programs directed toward environmental protection had somewhat of a running start because much of the technology previously described, such as the Lurgi processes, was a starting foundation. As international relations improved and oil supplies were again reassured, considerable and progressive complacency on the part of government and the public set in — with the exception of so-called "dirty coal" power plants. Thus, as of the mid-1980s, interest in coal technology had reawakened.

Clean Coal Programs of the 1990s

Traditional coal handling practices that resulted in excessive quantities of pollutants in the air with associated ill effects on the environment, including

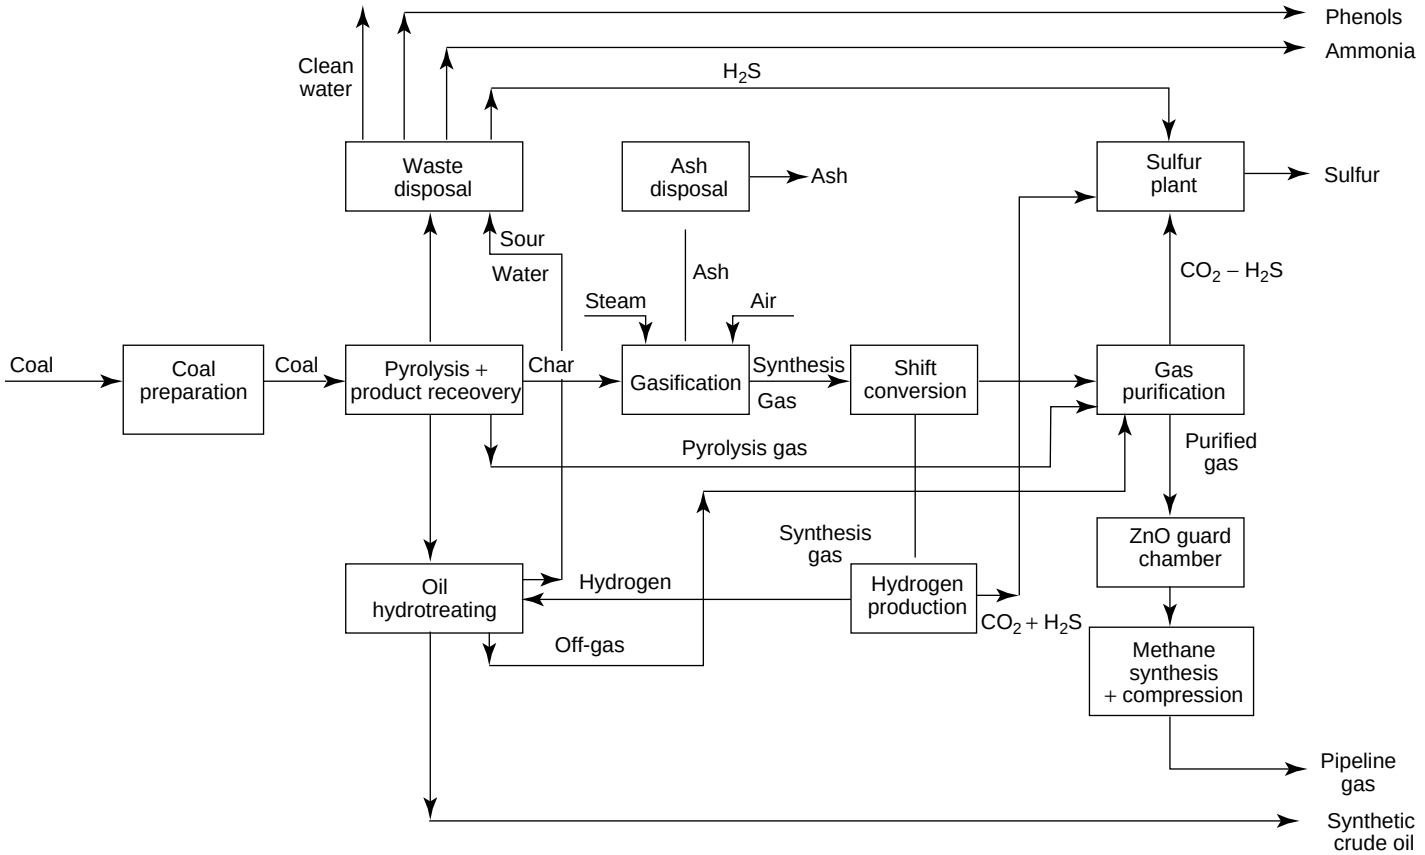

Fig. 5. Early (1970s) process for making pipeline gas from coal.

acid rain in the northeastern United States and parts of Canada are being tackled through the joint cooperation of government and private electric power interests. One of the first major goals to be achieved was set for 1995. Further background is given in Fig. 1 at the start of this article. See also Fig. 7.

Many Options to Consider. In evaluating the use of coal for electric power generation, there are many options that must be considered. Recalling the ENERGY-ENVIRONMENT-ECONOMY interdependent triangle mentioned at the beginning of this article, option preference varies — power consumers (both industrial and public), the coal mine workers, and the environment regulators, among others. This article concentrates on the environment.

Coal Preparation and Pretreatment Technology

The principal measure of the previously mentioned "allowances" program (see Fig. 1) is expressed in terms of tons of sulfur dioxide (SO_2) emitted. However, close behind the environmental effects of SO_2 are emissions of nitric oxides (NO_x). Unfortunately, the chemistry of SO_2 removal differs from that of NO_x removal.

Targeting SO_2 Emissions. As described in the article on Coal, various types of coal contain different amounts of sulfur. Thus, using low-sulfur coals provides the utility operator with a major headstart. But low-sulfur coals are not as abundant as, for example, subbituminous coal, which costs more. The relative location of a utility and the mine also is a factor because of high transportation costs. Also, when combusted, low-sulfur coals create more ash and yields fewer Btus (thermal energy). Several processes have been or are being developed to lower sulfur content by pretreatment.

Sulfur in Coal. Sulfur occurs in coal in two forms: (1) *organic* sulfur, which is chemically bonded to the coal, and (2) *pyritic* sulfur, which occurs in tiny, iron-associated and separate particles in the coal. This is a physical rather than a chemical impurity.

Pyritic sulfur can be removed by froth flotation, which takes advantage of the differences of specific gravity of the two types of sulfur. To be effective, the coal must be pulverized into particles in the micron region. The process can be enhanced by adding limestone, catalyst, and soda ash to the coal dust. After treatment, the coal is formed into briquettes for ease of handling by conventional conveyors.

By way of genetic engineering, microorganisms with metabolic capacities, unknown of as recently as 15 years ago, have been produced. Coal bioprocessing developments are directed to three objectives:

1. Reduce the sulfur content;
2. Solubilize coal and convert the soluble product to liquid or gaseous fuels; and
3. Convert coal-derived synthesis gas to liquid or gaseous fuels.

In addition to direct operations to remove or reduce sulfur content, coal liquefaction or gasification can accomplish similar results indirectly.

Coal Gasification Processes

U.S. federal and private funding have intensified competition among design engineering firms as well as some universities and government-owned laboratories. This has resulted in a proliferation of proposals and projects. Inasmuch as the objective of reducing air pollution is also strong outside the United States and probably regarded as even more urgent in such countries as Germany, the Netherlands, and Japan. There is a dueling among design firms for what can become a major market for equipment over the foreseeable future. Several of these processes are described in the following paragraphs. As of 1993 most of these projects are in the pilot or demonstration plant phase.

Most of these processes are designed for combined-cycle power plants, which are defined in the accompanying footnote[2].

[2] Steam turbine systems cannot take full advantage of the high temperatures available from the combustion of fossil fuels because of material limitations, nor of the heat available at the low temperature end of the steam cycle because of economic considerations. The combination of two or more heat engine cycles that cover different parts of the temperature range is referred to as a combined-cycle plant. The combination of two different cycles represents a *binary cycle*. The addition of a second cycle at the high temperature end of the steam cycle is referred to as a *topping cycle*; if added at the low temperature end, it is a *tailing* or *bottoming* cycle. The most common binary cycle power plants are comprised of

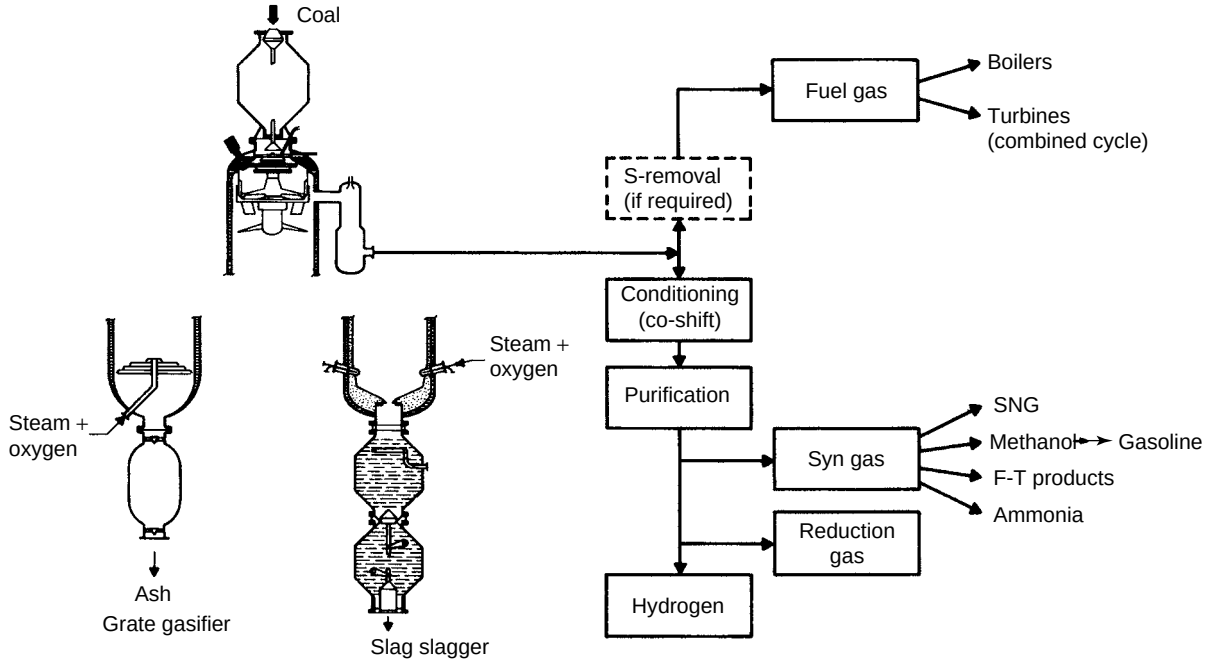

Fig. 6. Basic schemes for Lurgi gas production, the fundamental technology of which dates back to the era of "artificial" gas. The process shown here (circa early 1970s) permitted selection of various gasifiers and/or changing operating pressures to influence the final crude gas composition, as dictated by the end use and economics. (*Lurgi Kohle und Mineralotechnik GmbH, Frankfurt, Germany*.)

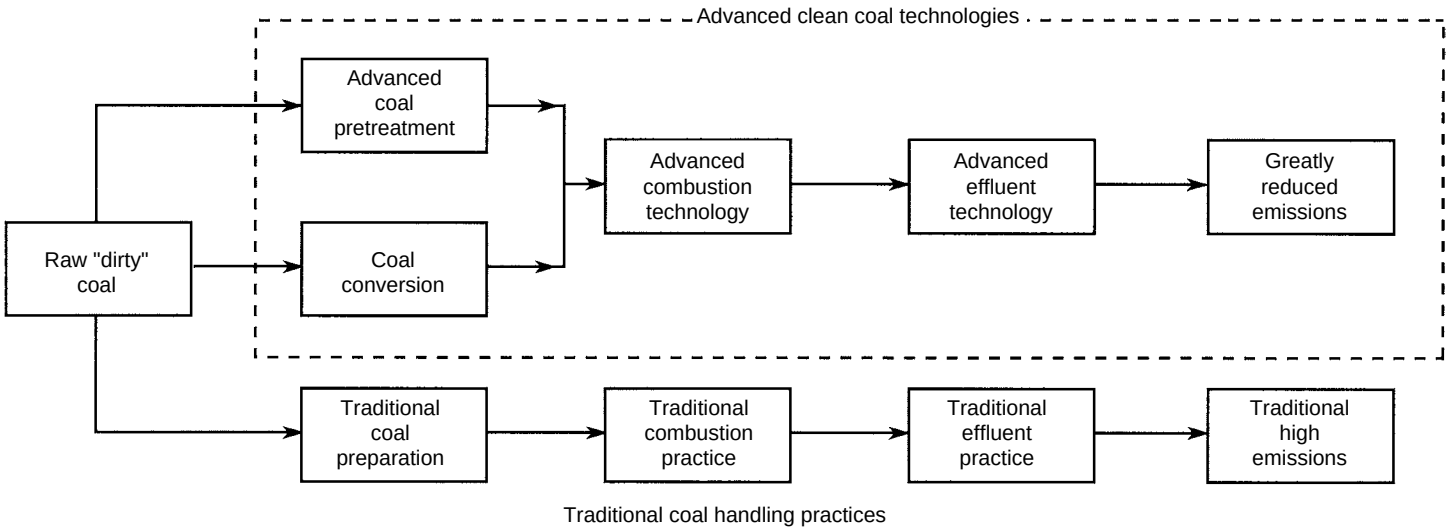

Fig. 7. Overview of coal preparation, conversion, combustion, and effluent treatment technologies that are designed to markedly reduce deleterious emissions and thus protect the environment. The line at the bottom, indicating traditional practices, now *fully* applies only to the very oldest coal-energized electric power plants. The Clean Air Act (U.S.) and the "Clean Coal" program call for progressive upgrading or modernization for achieving major goals by 1995, as described in the text. It should be mentioned that traditional practices have been improved over the years, but these have not been sufficient to meet environmental goals. Better results can be achieved only by way of marked advances in technology.

Texaco Coal Gasification Process. This process uses an oxygen-blown, pressurized, entrained slagging gasifier and a coal/water slurry as the fuel. The process was developed originally to partially oxidize heavy oil. The process was modified to gasify coal. Research to develop practical radiant and convective syngas coolers to recover the high sensible heat in the raw syngas was carried out in Germany by Ruhrkohle Oelund Gas and Ruhrchemie A.G. The first commercial-scale coal-gasification combined-cycle (IGCC) plant was built in Oberhausen, Germany. It is a 165-tons/day demonstration plant.

Shell Coal Gasification Process. This process uses an oxygen-blown, pressurized, entrained slagging gasifier and dry pulverized coal as the fuel.

a steam turbine cycle topped with a gas turbine cycle. In this combined cycle, the hot exhaust gases from the gas turbine are used to generate steam for the steam for the steam turbine generators. Cycle efficiency near 45% can be achieved.

Syngas coolers are used to recover the sensible heat of the raw syngas, and both saturated and superheated steam are produced. Syngas recirculation is used to reduce the temperature of the gas entering the syngas coolers. As of mid-1992 the pilot plant had been in operation 4 years, in which a broad range of coals was tested. The results of the EPRI (Electric Power Research Institute) have shown very favorable results of this oxygen-blown, dry-feed, entrained-flow process. The process offers high cold gas efficiency (a measure of the amount of chemical energy in the clean cold syngas and is expressed as the ratio of the chemical energy of the syngas to that of the feed coal). The process also offers efficient utilization of the sensible heat of the syngas, high carbon conversion, and good selectivity toward the fuel components of the syngas. Carbon monoxide, hydrogen, and methane together make up over 90% (vol) of the dry syngas.

Dow Coal Gasification Process. This design uses an oxygen-blown, pressurized, two-stage entrained slagging gasifier and a coal/water slurry as the fuel. Syngas coolers are used to recover the sensible heat of the

raw syngas, and both saturated and superheated steam is produced. The process was tested (36 tons/day) in a pilot plant in 1979 and later in a 1600-tons/day demonstration plant in the early 1980s.

British Gas-Lurgi Process. This is a slagging, moving-bed process that is based on the earlier Lurgi oxygen-blown, pressurized, moving-bed dry-ash gasifier. The Lurgi gasifier was modified by increasing the temperature above the melting point of the coal slag and decreasing steam consumption, thus markedly increasing efficiency. A syngas cooler is not needed because hot gases from the slagging bottom preheat the coal bed above. Tars and other organics produced contribute to difficulties in water treatment.

Kellogg/Rust and Westinghouse Process. An oxygen-blown or air-blown pressurized, agglomerating fluidized-bed gasifier is used. A 35-tons/day pilot plant has been tested. Present research is targeted to modifying the process in an effort to allow high-temperature desulfurization by injecting limestone into the fluidized bed.

Kilngas Process. This design uses an air-blown agglomerating bed gasifier. The main feature is a rotary kiln, in which the coal is gasified by adding air and steam at moderate pressures (400 to 700 kPa; 60 to 100 psi). A 600-tons/day demonstration plant is being tested by the designer, Allis-Chalmers, in East Alton, Illinois.

High-Temperature Winkler Process. The process employs an oxygen-blown, pressurized, fluidized-bed dry ash gasifier designed for lignite. The process was developed by Rheinische Braunkohle Werke AG, with an 800-tons/day demonstration plant in Germany.

Molten-Iron Pure Gas (MIP) and Klockner Molten Iron Processes. This concept is being developed in a joint effort by Sumitomo Metal (Japan) and Klockner (Germany). Coal is gasified with oxygen in a top- or bottom-blown liquid iron bath. The process accomplishes desulfurization and particulate removal in one step.

Extensive testing in a 40-tons/day pilot plant led to the construction of two 800-tons/day demonstration plants in Germany and Sweden.

VEW Coal Conversion Process. This design uses an air-blown, pressurized, entrained slagging gasifier/combined-cycle unit, in which the coal is only partially gasified. Hot exhaust gases and char from the gasifier are fed into a conventional pulverized coal boiler. After syngas is cleaned, it is combusted in a gas turbine. A 240-tons/day pilot plant is located in Germany.

It will be noted that there are a number of similarities in the various designs. Although several designs may be required to satisfy varying compositions of coal feed, it would appear that ultimately coal gasification processes will be fewer in number in the future, once the demonstration plants complete their tests.

Combustion System Modifications

The foregoing processes incorporate the combustion phase as part of their overall design. The combustion operation also has been studied in a piecemeal manner, the results of which include fluidized-bed technology, bulk mixing of coal and limestone (can reduce SO_2 emissions up to 90%), injection of dry sorbents into boiler (or stack), and the injection of natural gas, among other approaches.

Final Emissions Clean-Up. In addition to engineering processes that create smaller amounts of objectionable pollutants, much research continues to neutralize emissions prior to their introduction into the atmosphere. Improvements are being made almost continuously to precipitation and scrubbing systems. As an example, in a process developed in Japan, flue gases are bubbled through a vessel containing an alkaline slurry. Upon absorption of SO_2, the slurry is centrifugally dried to form solid gypsum ($CaSO_4$).

Coal Liquefaction

In addition to cleaning up coal for use in electric-generating plants, research continues for converting coal into useful liquid fuels that can substitute for petroleum-based products, demanded largely for transportation and for use as raw materials by the chemical industry. Present impetus in this area, however, is much less because reasonable costs of petroleum detract from business incentive.

The basic chemistry of coal in terms of creating liquid fuels is the hydrogen-to-carbon ratio. In raw coal this ratio is less than unity, whereas a ratio of 1.5 to 2 or more is needed to produce desirable liquid fuels. In hydroliquefaction processes, the first step is pyrolysis, followed by the addition of hydrogen from another source.

Underground Coal Gasification. In situ gasification of coal was suggested by Siemens in 1868, and the first patent for a process was granted to Betts in 1909. The first experiment was conducted in England prior to World War I and in Russia as early as 1933. Much interest was shown for this concept during the energy crisis of the 1970s, and considerable research was undertaken, for example, at the Lawrence Livermore National Laboratory. In the long term, incentives for the concept include the use of coal seams that are unsuitable for mining and less disturbance of land by

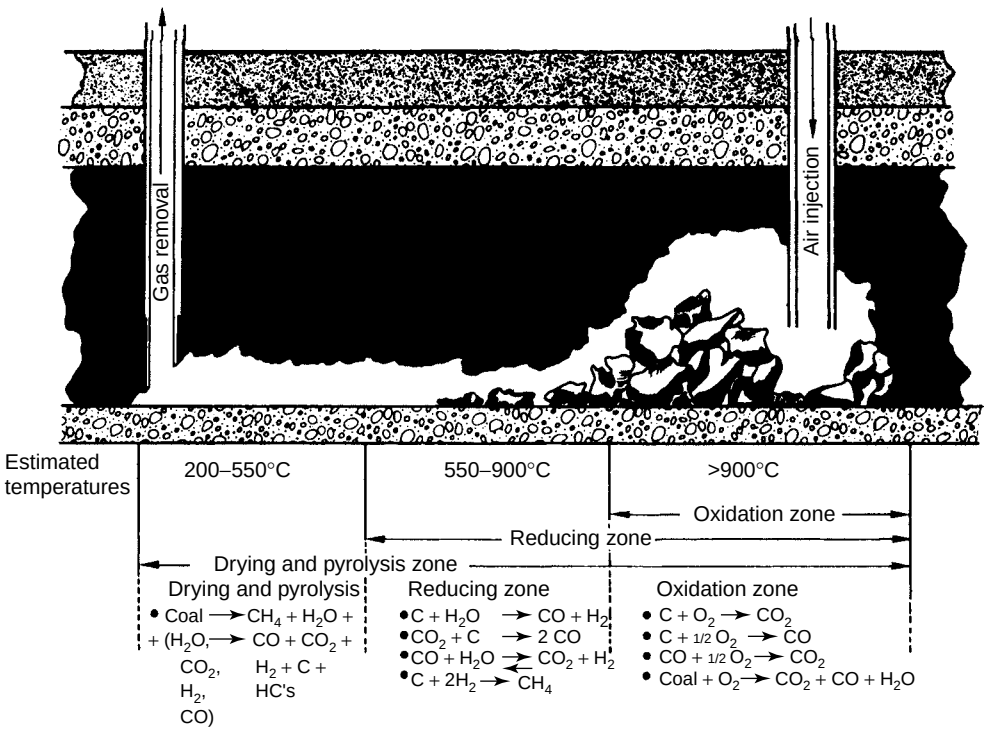

Fig. 8. Conceptual view of channel during underground coal gasification. (*U.S. Department of Energy*.)

comparison with present surface-mining techniques. A proposed system is shown in Fig. 8.

COALESCENCE. In cloud physics, the merging of two water drops into a single larger drop after collision. Coalescence between colliding drops is affected by the impact energy, which tends to increase with the higher fall velocities of larger drops. Colliding drops having negligible impact energy compared to their surface energy behave as water spheres that collide with a collision efficiency (the fraction of small drops that collide with a large drop within the geometric collision cross section) predicted by the theory for falling spheres. The result of increasing impact energy is to flatten the colliding drops at the point of impact, impeding the drainage of the air and delaying contact between them. As the distortion relaxes, the drops rebound, reducing the coalescence efficiency for cloud drops and drizzle drops colliding with smaller drops. At larger impact energy, separation will occur if the rotational energy (fixed by conservation of angular momentum) is higher than the surface energy of the coalescing drops. This phenomenon, termed temporary coalescence, can result in satellite droplets considerably smaller than either of the parent drops. This phenomenon is also called partial coalescence because the large drop may gain mass as a result of the higher internal pressure in the small drop. At still larger impact energy, drop breakup occurs for the smaller drop. About 20% of the high-energy collisions between large raindrops ($d > 3$ mm) and drizzle drops ($d > 0.2$ mm) result in the disintegration of both drops. Other factors that affect coalescence are electric charge and electric field, both of which promote coalescence, leading to earlier onset of coalescence during an interaction so that coalescence efficiencies are increased by suppression of rebound and temporary coalescence. All of these processes are important in formation of precipitation in all liquid clouds both above and below 0°C (32°F).

COAL TAR AND DERIVATIVES. Coal tar constitutes the major part of the liquid condensate obtained from the "dry" distillation or carbonization of coal (mostly bituminous) to coke. The three major products of this distillation are (1) metallurgical coke, (2) gas which is suitable as a fuel after appropriate chemical treatment, and (3) condensable liquids which leave the coke oven along with the gas and which are constituted principally of ammonia liquor and coal tar. The condensable materials and gas impurities are separated from gas in the condensation and purification train of the coke oven plant. The purified coke oven gas is used as fuel to heat the coke ovens and steel producing furnaces. Prior to the widespread use of natural gas as a domestic fuel, coke oven gas was widely used for this purpose after additional purification as residential fuel.

Since metallurgical coke for use in blast furnaces is the prime product of coal carbonization, coal tar production is tied closely to the demand for metallurgical coke. Although steel production has increased progressively over many years, the demand for metallurgical coke has remained reasonably steady, for several reasons. Large improvements in blast-furnace efficiency have occurred. The amount of coke required to produce one ton of pig iron has dropped from 1760 pounds coke/ton of pig iron (878 kilograms coke/metric ton of pig iron) to 1250 pounds coke/ton of pig iron (624 kilograms coke/metric ton of pig iron) and in some modern blast furnaces, the rate is below 1000 pounds coke/ton of pig iron (500 kilograms/metric ton of pig iron). Further, coke has been partially replaced by lower-cost carbonaceous materials, such as natural gas, petroleum oils, powder coal, and tar. Fundamental changes in the production of steel are expected to further reduce the need for coke.

A number of years ago, coal tar was the primary, if not the sole, source for hundreds of important organic chemicals and derivatives, notably the phenols, cresols, naphthalene, and anthracene, as well as other important coal tar end-products, such as solvent naphtha and pitch. In recent years, synthetic processes for the production of phenol, the cresols and later the xylenols, have been developed and thus, to a large extent, have pushed coal tar into the background as a source of feedstocks for the chemical industry.

Carbonization Process

Present coking processes generally are of two types: (1) *high-temperature* ($900-1200^\circ$C) carbonization for producing metallurgical coke and (2) low-temperature ($500-750^\circ$C) carbonization, still practiced in some countries where there is a market for "semi-coke" as a smokeless home fuel and tars as feedstock for synthetic liquid fuels.

Currently, in the United States, slot ovens with byproduct recovery systems are used almost exclusively. These ovens are built in the shape of narrow chambers placed side by side with interspersed flues for heating. Usually, up to 90 chambers are placed together to form a battery. The chambers are charged individually with coal from the top. After carbonization is complete (14–20 hours), the chambers are discharged on one side by pushing with a ram from the opposite side. Each chamber is connected at the top to one or two collecting ducts, or mains, which carry the gas evolved and the distillate (tar) to suitable coolers and receivers. By high-temperature carbonization, one obtains generally from one ton (metric) of coal: 748 kilograms coke, 343 cubic meters of coke oven gas, and 37.9 liters of tar.

Processing of Crude Tar

With reference to Fig. 1, the crude tar, after being separated from ammonia and other gases, is subjected to an initial distillation (called *topping*) which separates the desired chemical constituents from the higher-boiling, more viscous tar constituents. In a typical case, the distillate from this operation (sometimes referred to as *chemical oil*) has an upper boiling point of about 250°C and contains (1) phenols (*tar acids*), (2) napthalene, which is the most prevalent single constituent of coal tar (6–10%), (3) pyridine-type bases (*tar bases*), and (4) neutral oils. The tar acids constitute about 1.5–3% of the coal tar.

Tar Acids

These materials are recovered by extraction of the chemical oil with aqueous alkali, usually caustic solution. The aqueous layer is separated from the dephenolized (*acid-free*) oil. The phenols then are recovered in crude form by acidification (*springing*) of the aqueous solution, usually by injecting carbon dioxide, followed by gravity settling. The crude phenols then are fractionated to obtain phenol, cresols, and the higher-boiling phenols (mostly xylenols). See also **Phenol**.

Tar Bases

These materials are extracted from the dephenolized oil with aqueous solutions of mineral acids. This operation may be carried out on the entire neutral oil, or it may be done on the solvent naphtha fraction. In the latter case, only the lowest-boiling bases (picolines and lutidines) are recovered, and the higher-boiling bases (mostly quinoline and isoquinoline) can be recovered from postnapthalene fractions or left in the residue for disposal. In European practice, the topping is carried out so that several

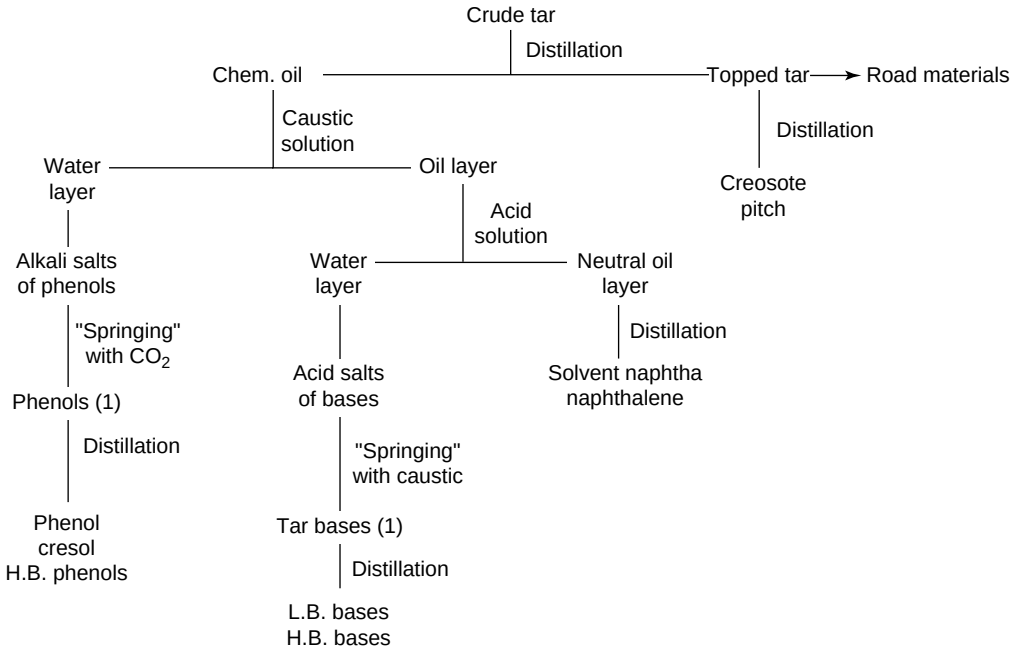

Fig. 1. Bulk fractions from crude coal tar.

fractions are obtained: *carbolic oil,* which yields the phenols and lower-boiling bases; and *naphthalene oil,* from which naphthalene is recovered by crystallization.

The tar bases form water-soluble salts with mineral acids which are separated from the oil. They are recovered from their salts by contacting with aqueous alkali (*springing*) and separating the crude bases from the salt solution. The lutidines constitute the major part of the lower-boiling bases. **See** also **Pyridine and Derivatives**.

Solvent Naphtha

The lower-boiling fraction of the neutral oil is a very powerful solvent, particularly for coatings containing coal tar and pitch. The material also is a source of unsaturated compounds, such as indene and, in a lesser amount, coumarone and homologues of these compounds. Resins are formed in situ from these compounds when solvent naphtha is treated with Friedel-Crafts type catalysts. See also **Friedel-Crafts Reaction**. These resins are useful in the manufacture of inexpensive floor tiles and coatings. The remaining solvent is recovered by distillation and used as a solvent.

Naphthalene

This compound finds a ready market principally for the production of phthalic anhydride. There is a great variety of processes to isolate napthalene from the acid-free or neutral oils. Frequently, the naphthalene is first concentrated by distillation, and the enriched oil then is worked up by crystallization. This process is prevalent in Europe. It is also possible to isolate the naphthalene by careful fractionation. Depending on the purity desired, additional chemical treatments may be required. Naphthalene usually is traded with freezing point as a measure of purity (80.3 °C) for pure naphthalene. A good quality commonly used is "78 °C" naphthalene, which is about 96% pure. See also **Naphthalene**.

Topped Tar

With reference Fig. 1, it will be noted that topped tar is the residue remaining from the topping operation where the chemicals are separated as the distillate. The principal use of topped tar is in road materials. A number of standard grades (RT-1 to RT-12) are available, the grade depending on the "consistency" or viscosity of the tar. Road tar has excellent weather and skid resistance, but its use is limited by availability and price as compared with asphalt. This is borne out by the respective amounts used for road building (United States) with about 90% using asphalt.

Creosote

Chemically, creosote is a mixture of a great number of compounds, almost exclusively of cyclic structure. Individual compounds present in creosote in concentrations of 2–4% are acenaphthene, fluorene, diphenylene oxide, anthracene, and carbazole. Only one compound, phenanthrene, is present in a larger concentration (12–14%). For many years, chemists in many countries have tried to isolate individual compounds and to find profitable uses for them. Most of these attempts have failed with exception of those involving anthracene. See also **Anthracene**. The principal use of creosote is for preservation of wood. Railroad ties, poles, fence posts, marine pilings, and lumber for outdoor use are impregnated with creosote in large cylindrical vessels. If properly treated, the life of the wood is greatly extended. Materials that are competitive with creosote for wood-preservation purposes include various petroleum oils, and pentachlorophenol. Pentachlorophenol is used in solutions of creosote or of petroleum oils. Blends of creosote with petroleum oils also are used for economic reasons.

Pitch

This is the residue from the processing of coal tar. Since pitch constitutes over 50% of the crude tar, its utilization has a major effect on the economics of tar processing. Coal tar contains an estimated 5,000–10,000 compounds; it is reasonable to assume that about half of this number is contained in the pitch. Of the roughly 300 compounds identified in coal tar, about one-half must be in the pitch on the basis of their boiling points. It is probable that none of these compounds is present in pitch in concentrations of more than a fraction of 1%. Coal tar pitch is a black, shiny material that is solid and brittle at low temperatures and liquid at high temperatures. Since it is composed of a great number of different compounds, many of which interact to form eutectic mixtures, it does not show a distinct melting or crystallizing point. Pitch usually is characterized by the *softening point,* which can be measured in several ways.

Because of the importance of pitch in various industries, many studies have been made to elucidate its composition. Solvent fractionation has been used to subdivide pitch into fractions by molecular weight, the higher-molecular-weight fractions requiring more powerful solvents. However, even the highest-molecular-weight compounds are only of moderate molecular weights, ranging up to 6 or 7 condensed rings with molecular weights in the range of 350–400. Constituents isolated from pitch have been identified and appear to be crystalline, well-defined substances. It is generally believed that the glasslike state of pitch is caused by association forces and by the mutual melting-point depression exerted by a large number of multiring compounds that tend to form eutectics. The uses of pitch fall in two general classes: (1) applications based upon the binder properties of carbonized pitch (*pitch coke* or *binder coke*); and (2) uses based upon the other physical qualities of pitch.

Carbon pitch is used for carbon electrodes in electrolytic reduction processes, such as aluminum reduction or the production of electro-steels in arc furnaces. Refractory pitch is used in the manufacture of refractory brick, usually burned magnesite or dolomite, the pores of which are filled with pitch by hot impregnation. Upon firing, the pitch in the brick is converted to carbon by carbonization. The remaining pitch coke within the refractory product retards penetration of molten metals and slags, thus prolonging the life of the brick furnace lining. Coke pitch is used in the production of foundry cores.

Roofing Pitch

A substantial amount of pitch is used as covering membrane on flat roofs on industrial plants, large office and apartment buildings, parking garages, and similar structures. Pitches of 50–60 °C softening point generally are used.

GEORGE R. ROMOVACEK, Koppers Company, Inc., Monroeville, PA, and G. G. LAUER, Pittsburgh, PA

COASTAL FRONT. A shallow (typically <1 kilometer (0.6 mile) deep) mesoscale frontal zone marked by a distinct cyclonic windshift in a region of enhanced thermal contrast (≈5°–10°C/10 kilometers) (≈41–50°F/6 miles).

These fronts typically develop in coastal waters or within 100–200 kilometers (62–124 miles) of the coast during the cooler half of the year when the land is cold relative to the ocean. In the United States coastal fronts are most frequent in New England, the Middle Atlantic states, the Carolinas, and Texas. The typical coastal front is oriented quasi-parallel to the coast and may extend for several hundred kilometers. During the winter, the coastal front may mark the boundary between frozen and nonfrozen precipitation. Given that coastal front development usually precedes synoptic-scale cyclogenesis and marks an axis of enhanced thermal contrast and a maximum in cyclonic vorticity and convergence, the coastal front often serves as a boundary along which intensifying synoptic-scale cyclones move poleward. Surface coastal front development typically occurs beneath the forward side of advancing troughs following the passage of the ridge axis aloft. Coastal fronts most frequently form equatorward of cold anticyclones where a warmer onshore flow encounters a colder continental air stream. Damming of cold air on coastal orographic barriers such as the Appalachians often appears to play an important role in coastal front development. Coastal thermal contrasts are augmented by differential diabatic heating where the onshore flow has passed over oceanic thermal boundaries such as the Gulf Stream and the adjacent continental airstream has passed over snow-covered land. Coastal fronts may form independently of cold anticyclones and associated cold air damming. In situ coastal front developments can occur near mountain barriers where upslope flow results in differential airmass cooling and stabilization and where offshore troughs form due to differential heating across oceanic thermal boundaries. Coastal front dissipation typically occurs with the cessation of onshore flow following cyclone passage. See also **Ocean**.

COASTAL UPWELLING. The rising of water from between 200 and 400 meters (656 and 1,312 feet) to the surface along coastlines where an alongshore blowing wind has the coast on its left in the Northern Hemisphere or on its right in the Southern Hemisphere. Because the surface currents of the Ekman spiral are deflected offshore in these situations, the surface water is drawn away from the coast, causing the colder water from deeper layers to upwell. The associated lowering of the sea surface temperature results in atmospheric heat loss and modifies the local climate. The upwelled water is also rich in nutrients, and coastal upwelling regions are among the most important fishing regions of the World Ocean. The most important coastal upwelling regions are found in the eastern boundary currents of the subtropical gyres, that is, in the Peru/Chile, California, Benguela, and Canary Currents. The Somali, East Arabian, and South Java Currents develop upwelling on a seasonal basis. See also **Ocean**; and **Ocean Currents**.

COASTAL WATERS. Coastal waters are usually defined as those waters in a zone whose landward boundary is the limit of tidal influence and whose seaward boundary is the edge of the continental shelf (or a depth of 200 m if there is no continental shelf). Salinity, temperature, turbidity, and other characteristics of coastal waters vary considerably in this transitional and very dynamic zone.

The effects of waves, wind, and other processes create two distinct layers in coastal waters: an upper surface layer known as the "mixed layer," which varies in thickness from tens to hundreds of meters thick, and a lower "deep layer." The mixed layer is warmer and less saline than the deep layer. The deep layer generally contains more nutrients due to the decomposition of organic matter that has fallen to the ocean bottom. The transition between the two layers, called the pycnocline, is usually very abrupt, occurring over a space of a meter or less.

The majority of coastal waters occur in three types of environments: the relatively low energy environments of estuaries and bays, the high-energy environments of waters along rocky shores and beaches, and the deeper waters of the continental shelf. All coastal waters are subject to the effects of tides, waves, and currents, to varying degrees. Coastal waters are also often affected by activities in coastal terrestrial areas, especially in parts of the world where urban and suburban development in coastal areas is intense.

Physical Processes in Costal Waters

Waves. Waves in coastal waters are produced by the wind and modified by their interaction with the coastline itself. There are two general types of waves: chop, which are the short steep waves seen on windy days; and swell, which are the long gentle waves that are present even on calm days. Chop is produced by local wind conditions, whereas swell is produced by storms very distant from the coastline. Waves are often described by their period (the time between two successive crests passing the same point), length (the distance from one crest to another), height (the distance from the trough to the crest of the wave), and their speed, which is determined using the equation

$$C(\text{speed}) = \Lambda(\text{length})/T(\text{period})$$

As waves move from the deep ocean to shallow coastal waters their speed is affected by the depth of the water as defined by the equation $c = \sqrt{gH}$, where g is the acceleration due to gravity and H is the water depth. As waves approach the shore, the speed of the wave crests becomes greater than the speed of the wave troughs, creating the characteristic "breakers" that crash onto the shore.

If waves approach a shoreline at an angle they will be refracted: that is, they will bend so that they become more parallel to the shore. Wave refraction affects where wave energy is concentrated; for example, a protrusion of the shoreline will cause waves to bend toward it, concentrating wave energy in that area. Areas of wave convergence are usually subject to intense erosion, whereas areas of wave divergence tend to be depositional; thus the overall effect of waves is to straighten the coastline. See also **Wave and Wave Mechanics**.

Tides. Tides are created by complex interactions between astronomical forces and the earth's geomorphology. One can begin to understand tides by imagining that the earth is covered with a layer of water with uniform depth. Gravitational and centrifugal forces associated with the moon and, to a lesser extent, the sun produce a bulge in the water at points both closest to the moon and on the opposite side of the earth. As the earth completes one rotation, a hypothetical point on the earth's surface will pass through a bulge twice, generating two high tides (and two low tides), which is known as a semidiurnal tide. Because the moon is rotating around the earth, each high tide theoretically occurs a bit later (approximately 30 min) than 12 h after the previous one. The sun's effect on tides produces the difference in tidal range seen during the lunar cycle. When the earth, moon, and sun are aligned, the tidal bulge is largest and the coast sees the highest high tides and the lowest low tides (both are known as "spring" tides). When the sun and moon are aligned at right angles with respect to each other and the earth, the tidal bulge is decreased, resulting in reduced tides (know as "neap" tides).

The actual dynamics of tides is much more complex than this simple theory alone can explain. Tides are affected not only by astronomical factors but also by the sizes, shapes, and depths of water bodies, by winds, by the earth's rotation, and by changes in barometric pressure. A wide range of tidal cycles and tidal ranges occurs around the world. Although most parts of the world have semidiurnal tides, some have only one high tide and one low tide per day (diurnal tides), and some experience a phenomenon known as "double low water," where two extreme low tides occur between high tides occurring 24 h apart. Tidal ranges vary not only with the lunar cycle but geographically, from a few centimeters in the

Gulf of Mexico to the famous 12-m tides in the Bay of Fundy. However, at any given location along the coast, the tidal cycle is fairly constant, allowing prediction of tidal periodicity and height based on data from past years. As physical oceanographers become more adept at modeling tidal dynamics, predictions also can be made for areas without such records. See also **Tides** .

Currents. Both waves and tides, as well as the wind, generate currents in the ocean that circulate water between numerous and sometimes disparate oceanic and coastal environments. Where these currents are close to shore, they strongly influence not only the coastal waters but the shape of the coastline itself. Of most importance, however, is the way currents transport nutrients, sediments, and marine life along the coasts. Currents generally fall into three categories: tidal currents, drift currents, and a phenomenon known as upwelling.

Tidal Currents. Among the strongest forces affecting coastal waters are tides. Tidal currents are strongest where a constriction (such as a narrow tidal inlet) or other topographic feature (a valley in the continental shelf) concentrates the tidal flow. Tidal current velocities range between zero at slack tide (exact high or low tide) to midtide maximums that are generally in the range of 1–5 km/h (0.6–3 mi/h). Under the Golden Gate Bridge in San Francisco, tidal currents sometimes reach 9 km/h (5.6 mi/h), and at Seymour Narrows, British Columbia, they can reach 24 km/h (15 mi/h). Tidal currents have long been considered a source of renewable energy and are being used to generate power in Canada, Russia, and France. These projects involve damming a portion of an estuary and using the force of the tide leaving the estuary to turn turbines. More recently, proposals have been made to place undersea "windmills" in areas of strong tidal currents to generate power without incurring the environmental cost of damming an estuary. See also **Tidal Energy**.

Drift Currents. Drift currents are caused by winds moving the surface layer of water. The strength of a drift current depends on wind speed, duration (how long the wind has been blowing), and fetch (how wide the body of water is). The velocity of drift currents rarely exceeds 1–2% of wind speed. Drift currents tend to move in the direction the wind is blowing but are also affected by the rotation of the earth, which creates a phenomenon known as the Coriolis effect. The Coriolis effect is best known for describing the direction in which a whirlpool or hurricane will rotate (clockwise in the northern hemisphere, counterclockwise in the southern hemisphere), but it also affects currents the same way. Thus, drift currents in the northern hemisphere will tend to curve to the right (and in the southern hemisphere to the left), giving rise to what is known as "Ekman drift." Finally, when a drift current encounters a coastline, it will tend to parallel the coastline in what is known as "littoral drift."

Upwelling. Upwelling refers to the vertical movement of water that occurs when the surface layer is pushed offshore by wind and Ekman drift, causing deeper waters to rise up and take its place (Fig. 1). While upwelling can be localized and transitory, prevailing winds create major upwelling areas along the coasts of Oregon in the United States, Peru in South America, northwest Africa, southwest Africa, and the western Indian Ocean. Where winds are steady, the upwelling is likewise fairly constant, for example, the Peruvian upwelling system; but where winds fluctuate (northwest Africa) or are only seasonal (the monsoon winds of the eastern Indian Ocean), upwelling is also periodic or seasonal. Upwelling introduces deep waters rich in nutrients into the coastal ecosystems, creating areas of high productivity and high concentration of marine life.

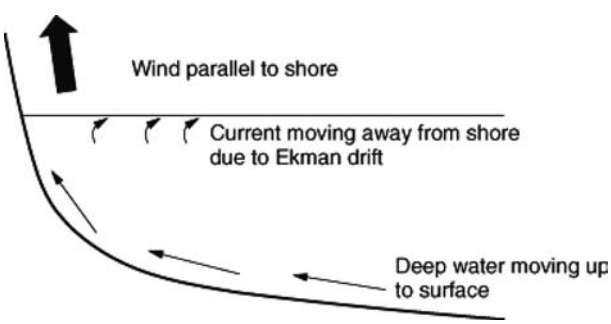

Fig. 1. Upwelling along a coast.

Chemical Characteristics

Although fresh water is an important component of estuaries, ocean water is the primary component of most coastal waters. The primary dissolved constituents of ocean water (in greatest to lowest concentration) are calcium, magnesium, sodium, potassium, bicarbonate, sulfide, chloride, and bromide. These molecules combine in various ways to create salts, of which sodium chloride (table salt) is the most common. Salt content, or salinity, is measured in parts per thousand (ppt). The average salinity of ocean water is 35 ppt, but in coastal waters salinity can be reduced by the addition of fresh water from rivers, overland runoff, and/or groundwater discharge.

Ocean water also contains nutrients in the form of nitrogen and phosphate salts. The concentration of these nutrients is very low in the surface layer of the open ocean, only 0.001–0.08 mg/L N and 0.002–0.003 mg/L P, but can be 10–100 times higher in the deep layer. Oxygen, a very important constituent for biological activity, is dissolved in ocean water at concentrations from about 8 cm^3/L(for cold waters near the poles) to 4.5 cm^3/L (for warm waters at the equator). Other dissolved gases in ocean water include nitrogen, carbon dioxide, and hydrogen sulfide. The pH of ocean water varies between 7.9 and 8.3. See also **Ocean Water**.

With 44% of the world's population living within 150 km (93 miles) of the coast, human activities have a significant influence on the chemistry of coastal waters. Garbage, sewage, effluent from manufacturing plants, runoff from industrial and agricultural areas, as well as many other sources contribute nutrients, sediment, metals, pesticides, hydrocarbons, and other pollutants to coastal waters. Clumps of floating garbage, dead fish, and oiled beaches are some of the most visible effects of humans on coastal waters, but more recent concern has centered on "dead zones," areas where excess nutrients have led to overproduction of plant material, which in turn leads to oxygen depletion in a process known as "eutrophication". Nutrient enrichment of coastal waters is a global problem that continues to grow as more countries increase their use of fossil fuels and inorganic fertilizers, the two principal sources of anthropogenic phosphorus and nitrogen.

Types of Costal Waters

Esturaries and Bays. An estuary is "a semi-enclosed coastal body of water which has a free connection with the open sea and within which sea water is measurably diluted with fresh water derived from land drainage". Although the "land drainage" is not specified in Pritchard's classic definition, it is generally assumed that the freshwater source is a river, as is mentioned in many other definitions of an estuary. The tidal portion of streams that drain into estuaries is also considered to be part of the estuary. Bays are also semienclosed bodies of water, normally open to the ocean, but they differ from estuaries in not being associated with a river. Estuaries are much more common along the world's coasts than bays, although the term "bay" is often used in the name of an estuary, for example, Chesapeake Bay. Both estuaries and bays provide protected aquatic environments for marine life, but estuaries are more diverse and often more productive due to the range of habitats created by the salinity gradient and input of nutrients from streams. Dyer described four physiographic types of estuaries: coastal plain estuaries (such as the drowned river valleys along the southeast coast of the United States), fjords (such as the submerged glacial valleys of Canada and New Zealand), lagoons (estuaries created by spits or bars), and tectonic estuaries (such as San Francisco Bay).

Rivers bring fresh water into an estuary, and tides bring saline water into the estuary. Where mixing is minimal, a layered water body is created with the less dense fresh water on top and the more dense saline water on the bottom (Fig. 2).

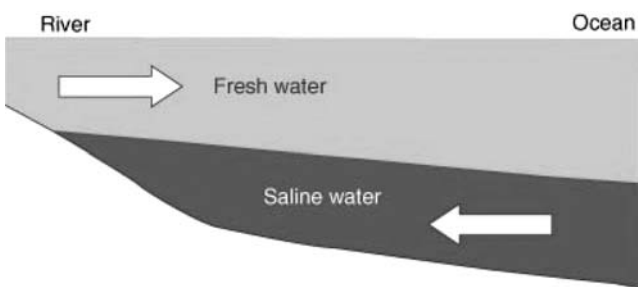

Fig. 2. Layers of fresh water and saline water in a stratified estuary.

Turbulence in the water causes mixing of the two layers, which increases the thickness of the fresher upper layer as it moves from the landward part of the estuary toward the ocean. The degree of mixing between the layers depends on the amount of freshwater input, the strength of tidal flow, and the effects of wind. Estuaries are often described as being one of three types: salt-wedge, partially mixed, or vertically homogeneous. When an estuary has a large freshwater input relative to tidal flow, the saline water tends to remain at the bottom with minimal mixing and the tip of this "salt wedge" changes location with the seasonal variation of freshwater flow. In partially mixed estuaries, the effects of tides and/or wind create a transition zone between the saline and fresh water layers. The mixing of the layers results in resuspension of sediments and nutrients brought into the estuary by the river and tide. In a vertically homogeneous estuary, there are no longer two water layers, but rather a single mixed body of water with a salinity gradient from low at the river mouth to high at the estuary's outlet to the ocean. In fjords, a sill at the mouth of the estuary traps saline water behind it, and mixing of fresh and saline water only occurs at the surface in water lying above the sill. The deeper waters behind the sill are replaced only when storm events disrupt this balance.

River discharge and tidal exchange both bring sediment and nutrients into an estuary. Estuaries tend to act as sediment traps due to two changes that occur when river discharge meets seawater. First, when clay particles in fresh water encounter saline water, the particles tend to flocculate (creating what is called a "turbidity maximum") and ultimately sink to the bottom of the estuary. Second, as rivers discharge fresh water at the surface of the estuary and tides bring saline water into the bottom of the estuary, current velocities decrease, causing sand particles to settle out. Complex hydrodynamics determine how much sediment stays in the estuary and how much is transported through the estuary to the ocean. Ultimately, sediments in estuaries undergo many cycles of transport by tides, currents, and waves before they find a permanent resting place.

Nutrients can be brought into estuaries in particular form, as dissolved constituents, or even via the atmosphere. Phosphorus, one important nutrient, has natural sources in soils and rocks. Weathering creates small particles with phosphorus bound to them that are carried into estuaries. Nitrogen, another important nutrient, is also found naturally in soils, but it is much more soluble than phosphorus and so tends to enter an estuary predominantly in dissolved form. Natural sources of nitrogen and phosphorus are generally small when compared to human-related sources such as agriculture (inorganic fertilizers), wastewater, and fossil fuel. Atmospheric deposition of nitrogen derived from fossil fuel combustion or animal waste is thought to be an important source of excess nutrients to estuaries in the United States. See also **Estuary**.

Rocky Shores and Beaches. Rocky shores and beaches are high energy environments. Waves and currents keep the water almost constantly in motion and well aerated. The shoreface is a transition zone where waves become influenced by the bottom and change shape, increase in height, and realign to become more parallel to the shoreline. In the surf zone, currents are driven by the interaction of waves with the shoreface and with other waves. In some places the water draining off the shoreface creates very strong seaward-moving currents known as "rip currents." Offshore from the surf zone, currents are dominated by wind and tide energy but still tend to parallel the coastline.

Plants and animals must have special adaptations to thrive in these environments. Kelp and seaweed have strong attachment systems to keep them in place, and the dominant invertebrates have protective shells. Furthermore, the vigorous movement of water along rocky shores and beaches is essential to the survival of these organisms because they feed by filtering the water or snatching debris as it floats by. Sandy areas are the most dynamic because not only is the water constantly moving, but the substrate itself tends to move as well. Although many beaches seem devoid of plant or animal life, that appearance occurs only because most beach inhabitants are buried in the sand.

Shelf Waters. Seaward of estuaries and the coastline are the waters overlying the continental shelf. Tides continue to influence these waters, creating turbulence that results in a mixed water layer that can extend for tens of kilometers outward from the coast. Beyond this mixed layer, coastal waters become stratified into the surface and deep layers described earlier. Areas of high productivity tend to occur at the transition between mixed and stratified waters.

Coastal shelf waters are an important component of ocean circulation. Prevailing winds and the earth's rotation create a system of major currents that circle the ocean basins and in some cases move water from one basin to another. The strongest currents occur on the western sides of ocean basins, where they carry water toward the poles, and weaker currents occur on the eastern sides of ocean basins, where they carry water toward the equator. These major currents, which transport volumes ranging from 10 to 100 m^3/s, serve many important biological functions related to migration, dispersal of juvenile organisms, and transportation of nutrients. One of the best-known oceanic currents is the Gulf Stream, which occurs off the east coast of North America. Coastal waters also contain coastal boundary currents that trend parallel to the coastline, their overall direction determined by the shape of the coastline and the way winds tend to reorient perpendicular to the coast as they approach the coastline. For example, landward of the Gulf Stream in the western north Atlantic Ocean, a coastal boundary current flows south — opposite to the direction of Gulf Stream flow. Coastal boundary currents transport lesser volumes of water than oceanic currents — about 10 m^3/s on the average.

COASTAL WETLANDS. Coastal wetlands include a variety of wetland types such as salt marshes, bottomland hardwood swamps, fresh marshes, seagrass beds, and mangrove swamps. Although many people think of tidal salt marshes when they hear "coastal wetlands," there are many wetlands in coastal areas that are neither tidal nor salty. Coastal wetlands can be defined as all wetlands in coastal watersheds, that is, watersheds that drain to the ocean or to an estuary and extend landward to the limit of tidal influence (Fig. 1). Great Lakes wetlands are often considered coastal wetlands as well, but the remainder of this discussion focuses on coastal wetlands associated with the Atlantic and Pacific Oceans and the Gulf of Mexico. Coastal wetlands can be next to streams, behind barrier beaches, on deltas, in isolated depressions, or in numerous other places in coastal landscapes. Coastal wetlands such as seagrass beds also occur in bays, estuaries, or other shallow coastal waters. Whether a coastal wetland is tidal or nontidal, fresh or saline, it influences and is influenced by the entire coastal watershed.

Like all wetlands, coastal wetlands are sometimes easy to recognize, but they also can be very difficult to distinguish from uplands when obvious signs of water are absent. Coastal wetlands can occur in areas with

Fig. 1. Coastal watersheds based on U.S. Geological Survey hydrologic units.

standing water, tidal flooding, or only periodic or seasonal flooding. Coastal wetlands, like other coastal environments, are very dynamic, responding to the effects of waves, winds, currents, sea level changes, subsidence, and human alterations of the landscape and hydrology. For example, barrier beaches along the Atlantic coast of the United States tend to "roll" toward the land in response to relative sea level rise, causing the salt marshes directly behind these beaches to be buried by the beach as new areas of salt marsh become established behind the beach on areas where wind or water carries sand. Coastal marshes around brackish ponds can change from salt marshes to fresh marshes if the pond's connection to salt water is blocked by drifting sand or a road. Coastal fresh marshes along streams may expand or shrink depending on the changing location of the river channel.

Coastal wetlands make up about 30% of the wetlands in the continental United States, or approximately 27 million acres. The Gulf of Mexico region includes 51% of the coastal wetlands in the lower 48 states. The south Atlantic region contains another 30%, which means that approximately 81% of coastal wetlands in the continental United States are in the southeast. The entire Pacific coast (excluding Alaska and Hawaii) contains less than 2%. Most coastal wetlands (77%) occur in or adjacent to estuaries. The Ten Thousand Islands estuary in southern Florida, known for its mangroves and extensive areas of forested, shrub, and fresh marsh in the Everglades, contains the largest acreage of coastal wetlands in the United States, followed by the Mississippi Delta estuary, and the Albemarle/Pamlico Sound estuary.

Only approximately 18% of coastal wetlands are truly estuarine (having water with a salinity of at least 0.5 ppt) and only about 25% are tidal. The most common coastal wetland type is forested and scrub-shrub, which comprises 63% of the coastal wetlands in the continental United States. The next most common coastal wetland type is fresh marsh (16%), followed by salt marsh (15%) and tidal flat (4%).

Ecological Importance

Coastal wetlands are among the most productive ecosystems in the world, comparable to tropical rain forests and coral reefs. An immense variety of microorganisms, plants, insects, amphibians, reptiles, birds, fish, and mammals can be part of a wetland ecosystem. Coastal wetlands can be thought of as "biological supermarkets." They provide large volumes of food that attract and support many animals. The combination of shallow water, high levels of nutrients, and high primary productivity is ideal for the development of organisms that form the foundations of the foodweb, supplying food for many species of fish, shellfish, insects, amphibians, birds, and mammals. A small percentage of wetland vegetation is eaten directly by fish and invertebrates, but most is decomposed by bacteria, producing an organic soup that feeds organisms such as amphipods, shrimp, crabs, snails, shellfish, and finfish. These organisms in turn support a broad food chain that includes a variety of fish, birds, and mammal populations such as deer, muskrat, and manatee.

Coastal wetlands are extremely important to birds, which use them for feeding, resting, and/or nesting. Major migratory flyways follow coastal wetlands along the Pacific and Atlantic Oceans. Many shore birds are wetland-dependent, including gulls, terns, plovers, and sandpipers. Waterfowl such as bay ducks (canvasback, redhead, etc.) and sea ducks (bufflehead, harlequin duck) are dependent on coastal wetlands, and some declines in coastal waterfowl populations are thought to be linked to the decline in coastal wetlands (3).

Coastal wetlands are also important nurseries for juvenile marine organisms. The shallow water and often-abundant plant growth are ideal for sheltering animals from predators until the animals are big enough or fast enough to avoid predators outside the wetland. Some fish, including species of herring and bass, use coastal wetlands as both a spawning area and nursery, whereas others, such as some species of shrimp and the ladyfish (a popular sportfish) spawn in the open ocean, leaving the juveniles to migrate via coastal currents to coastal wetland nurseries. Even adult fish often use coastal wetlands as refuge from larger predators or environmental stresses such as storms or floods.

Coastal marshes and estuaries provide essential habitat for over 75% of the fish caught commercially and recreationally in the United States. Popular species such as spotted seatrout, scup, butterfish, mullet, spot, salmon, gag grouper, Pacific herring, white grunt, summer flounder, menhaden, pink shrimp, spiny lobster, Atlantic croaker, and blue crab all use coastal wetlands as juveniles or adults for feeding and refuge. Bluefish and striped bass, important recreational species, depend on salt marshes for the small fish that are an important part of their diet. Menhaden, one of the most important commercial species landed in the United States, has a particularly strong tie to salt marshes and their detrital food chain. All of these species, and many others too numerous to list here, depend on healthy abundant coastal wetlands to support their populations.

Coastal wetlands are also important for keeping coastal waters clean. Coastal ecosystems receive virtually all the water flowing off the upland landscape — water that may contain fertilizers, pesticides, sewage, sediment, or toxic chemicals. Coastal wetlands filter out sediment and some chemicals, reducing the amount of pollution that washes into bays and the ocean. See also **Coastal Waters**.

Trends

Coastal wetlands are among the most imperiled ecosystems in the world. By the mid-1970s, over half of all salt marshes and mangrove forests present in the pre-colonial United States had been destroyed. California, a large coastal state, has lost over 90% of its wetlands. Florida and Louisiana, two coastal states with the greatest acreage of wetlands, have lost about half of their original wetland area. Louisiana alone is losing between 16,000 and 25,000 acres of wetlands a year, which is the highest sustained wetland loss rate in the country. Most of that loss is occurring in coastal areas.

No long-term national data set is available for coastal wetlands, although some programs, such as the U.S. Fish and Wildlife's National Wetlands Inventory (NWI) http://gis.ca.gov/catalog/showSourceXML.epl?id=1685; style=2, track estuarine wetlands and the U.S. Department of Agriculture's Natural Resources Inventory (NRI) http://www.nrcs.usda.gov/TECHNICAL/NRI/, has been used to estimate loss of tidal wetlands and wetlands in coastal counties.

Many factors are responsible for coastal wetland loss. In the early part of this century, coastal wetlands were drained and used for farming or grazing. More recently, coastal wetlands have been filled or dredged for roads, houses, golf courses, marinas, and other development. In some parts of the world wetlands are being destroyed for aquaculture. In other places, such as Louisiana, wetlands are being lost to open water due to a combination of factors including canals dredged through the marshes, dams on the Mississippi River reducing sediment to the marshes, land subsidence, and sea level rise. Even wetlands that are not actually filled or dredged are becoming degraded due to pollution, changes in water flows, and invasion by weeds or other non-native plants and animals.

Coastal wetland losses can be directly traced to population pressures and other human changes occurring along the coast. Coastal populations have increased steadily since 1970. Currently, over half the population of the United States lives in coastal counties, at densities about five times greater than those of noncoastal counties. This trend of people moving to coastal areas is expected to continue in the coming decades. Expanding populations place enormous pressures on existing natural resources, particularly wetlands, which are very vulnerable to changes in water flow, pollution, and habitat fragmentation. During the period from 1992 to 1997, nonfederal land in coastal counties contained 20% of the wetlands in the continental United States but experienced 31% of the wetland losses. Sixty-six percent of wetlands lost in coastal counties was the result of development while only 41% of wetlands lost in inland counties was due to development.

Coastal wetland loss from anthropogenic factors is magnified by global considerations such as sea level rise. Along much of the U.S. coast, relative sea level is rising at a rate of between a few inches to a foot or more per century. In fairly flat coastal plains, a few inches of rise in sea level can mean that the coastline moves hundreds of feet inland. Coastal wetlands can and do move inland with rising sea level, but in developed areas roads, houses, parking lots, and other human structures interfere with this natural migration of coastal habitats.

Fortunately, the importance of coastal wetlands and their vulnerability have come to the attention of scientists, governments, and nongovernment organizations. Research into the restoration of coastal wetlands and on-the-ground application of this research have yielded promising results, allowing for the restoration of some types of coastal wetlands. Through programs like those funded under the Coastal Wetlands Planning, Protection, and Restoration Act, (CWPPRA) http://www.lacoast.gov/cwppra/index.htm, federal and state agencies in the United States are working together to reduce the loss of wetlands in particularly fragile areas such as coastal Louisiana. And in many places, local governments are developing land use plans to protect coastal wetlands while nongovernmental organizations develop support for these programs and advocate for additional funding for restoration. With these efforts as a starting point and additional protection and restoration efforts in the future, coastal wetlands will continue to provide enormous benefits to the ecology and economy of the world.

COATING AGENTS (Foods). Substances that are used to protect the surface (and penetration through the surface) of various materials that are being processed or in final-product format. Coating agents are widely used in the pharmaceutical and food industries.

For example, in the food field, fresh produce requires very little processing. Some fruits may be dipped in 1–2% citric acid prior to freezing. This removes any residual lye from the peeling process and any further destruction of ascorbate is prevented. However, citric acid alone is not always sufficient to prevent deteriorative effects during freezing and thus a sequestrant/antioxidant may be added. A solution of 0.5% citric acid with 0.02% D-erythroascorbic acid may be used to prevent browning of some fruits during freezing and defrosting. The procedure is also useful with some vegetables. Plain wax coatings are applied to many packaged cheeses.

Dried fruits, such as raisins, prunes, and figs, require a residual moisture content because most consumers do not like a thoroughly dry or crispy product in this category. Residual moisture, of course, encourages mold and yeast growth. Protection can be gained by dipping the fruit in solutions of 2–7% potassium sorbate, this leaving a fine coating of antimicrobial agents on the fruit pieces.

Acetostearin products (di- and triglycerides) solidify into wax-like solids and are used in some protective coatings for food products. Researchers have shown these products to be effective against moisture penetration,

as well as against atmospheric gases. The coating is applied by dipping; spraying in the case of nuts.

For tablet-like confections and pharmaceuticals, sucrose is one of the most common of coating materials. It is transparent, but can be made opaque, and makes an excellent film-like coating. Gums and resins are also used. Some products such as pills and candies can be multicoated by using approved colorants in the coating agents.

The film-forming characteristics of starch have been used for many years. Numerous products can be protectively and decoratively coated with starch. Starch can be added to sugar solutions to provide a less brittle and moisture-sensitive surface. Starch coatings have the advantage of being oil and grease resistant.

Methylcellulose when incorporated into sweet dough products serves to improve adherence of the glaze.

Red meats, poultry, and fish can be coated with a protective film prior to freezing by dipping into successive solutions of 10–15% sodium alginate, 3–5% calcium chloride, and 10–20% glycerol, the latter used as a plasticizer. This coating improves retention of juices upon freezing or thawing. Sodium alginate coating for sausages, alone or with ethylcellulose, prevents salt rust and increases storage stability. Researchers also have studied the effectiveness of carrageenan as a way to prevent oxidative rancidity after freezing. In a Norwegian process, fish are block-frozen in alginate jelly, forming an air-tight coating, preventing oxidative rancidity.

COATINGS. See **Conversion Coatings**; and **Paint and Finish Removers**.

COAXIAL LINE. A type of transmission line in which one conductor completely surrounds the other, the two being coaxial and separated by a continuous solid dielectric or by dielectric spacers with gas as the principal insulating material. Such a line is characterized by negligible external electromagnetic fields and by having essentially no susceptibility to external fields from other sources. It is extensively used for radio-frequency transmission lines and is also used as a multi-channel telephone carrier and television program line. See also **Optical Fiber Systems**.

COBALAMIN. See **Vitamin B_{12} (Cobalamin)**.

COBALT. [CAS: 7440-48-4] Chemical element, symbol Co, at. no. 27, at. wt. 58.9332, periodic table group 9, mp 1495 °C, bp 2870 °C, density 8.832 g/cm^3.

There are two allotropic modifications of cobalt, a close-packed hexagonal form (ε) with space group $P6_3/mmc$, stable at temperatures below 417 °C; and a face-centered cubic form (α) with space group Fm_3m, stable at higher temperatures — up to the melting point. The metal is silvery gray in color. The only naturally occurring isotope, ^{59}Co, is stable, but the other twelve known isotopes are radioactive, their mass numbers ranging from 54 to 64. Half lives range from 0.2 second for ^{54}Co to 5.3 years for the industrially and medically important ^{60}Co. See also **Radioactivity**.

Cobalt was identified and described by Georg Brandt in 1735, but had to wait until the last decade of the nineteenth century before the new sources of metal supply from New Caledonia and Canada stimulated its metallurgical usage.

First and second ionization potentials are 7.86 eV and 17.05 eV, respectively; oxidation potential E° is −0.277 V. Further general specifications are given under **Chemical Elements**.

Occurrence: The cobalt content of the earth's crust is estimated to be within the range 10 to 40 ppm. Economic concentrations of the element are the exception so that supply is governed by its byproduct output from ores mined for the recovery of other elements, particularly copper and nickel. For technical reasons, the sulfides, arsenides and oxidized minerals form almost the entire economic source of the metal. Its production is restricted to a relatively few countries, the most important being the Republic of Zaire and Zambia in Africa, Canada, Finland, Morocco, and the United States. The cobaltiferous deposits in the copper belt of central southern Africa vary in content from 1 to 30 parts of cobalt to 100 parts of copper, with an estimated hundreds of millions of tons containing 2 to 15 parts cobalt to 100 parts copper. Sulfide nickel ores the world over have a cobalt content in the range 2 to 5 (very occasionally as high as 10) parts to 100 parts of nickel; oxide nickel ores vary in cobalt content from 1 to 30 parts per 100 parts nickel, with estimated thousands of millions of tons containing 5 to 15 parts cobalt per 100 nickel. The nickel lateritic deposits in the tropical and subtropical areas of the world represent a large potential future source of both nickel and cobalt.

Manheim (1986) reported that ferromanganese oxides in the open oceans are more enriched in cobalt than any other widely distributed sediments or rocks. Concentrations of cobalt in excess of 1% in ferromanganese crusts on seamounts, ocean ridges, and other raised areas of the ocean have been found. Some experts have observed that these cobalt-rich crusts are among the slowest-growing of any material source on earth, with estimates of an accumulation of only one molecular layer over a period of a few months. As observed to date, most of the cobalt-rich crusts are situated within the exclusive economic zone of the United States. This is in contrast with abyssal cobalt nodules, which occur mainly in international waters and are also difficult to recover. The U.S. Department of the Interior is preparing an environmental impact statement pertaining to the recovery of the ferromanganese crusts.

Mining and Recovery: The economically important cobalt-containing minerals exploited at present are listed in Table 1. The metal extraction processes, following the usual pretreatment of the ore, are varied and complicated because the metallurgical properties of cobalt differ insufficiently from those of the associated metals and because the cobaltiferous raw materials comprise the sulfide, arsenide, and oxide, or a mixture of these. The final refining stage invariably involves electrolysis.

Investigators at the Argonne National Laboratory (1985) reported a two-step process for extracting cobalt and manganese from low- and medium-grade ores normally mined for other metals. The new process provides an important secondary source for these strategically important metals. More detail is given in the entry on **Manganese**.

Uses of Metal and Alloys: The metallurgical applications of cobalt consume approximately 70–75% of the world production; the remainder goes into chemicals. Relatively little use has been made of the pure metal, the most important being as the radioisotope ^{60}Co for teletherapy and industrial radiation processing and gamma radiography. The increasing availability of the metal in various wrought forms will stimulate its applications in those areas where the intrinsic properties of cobalt are advantageous, e.g., magnetic devices, wear resistance and bearing properties at elevated temperatures, and the manufacture of heterogeneous welding rods for hardfacing. Major uses of the metal may be classified as follows:

High-temperature Materials. To meet the demand of the gas turbine industry, alloys capable of reliable performance at high temperature and

TABLE 1. PRINCIPAL ECONOMICALLY IMPORTANT COBALT MINERALS

Group and Name	Ideal Formula	Cobalt Content %	Source Area
Sulfides

Note: See also **Pentlandite**; and **Skutterudite**.

loads have been developed based on cobalt and cobalt-containing nickel and iron-based alloys. The improvement in properties at these very high temperatures (~750–1200 °C) has been brought about by the addition to the oxidation- and sulfidation-resistant cobalt-chromium matrix of varying amounts of refractory metals, mainly tungsten, molybdenum, tantalum, and columbium (niobium) to strengthen the matrix further and promote the formation of stable carbides, which makes a substantial contribution to the high-temperature strength. The application of current techniques of vacuum melting and casting insure optimum material properties and improved component reliability. A new family of alloys based on Co-Fe-Cr is being successfully applied in the exacting conditions that exist in metallurgical furnaces and petrochemical plants.

Magnetic Materials. For the past 50 years, apart from iron, cobalt has been the most important constituent of permanent magnet materials. This is because cobalt additions raise the saturation magnetization and the Curie temperature to higher values than are obtained from pure iron. Present advanced Alnico type cast alloys are the results of 40 years of development and are the most widely used permanent magnet materials. More recently, permanent magnet materials based on cobalt-rare-earth (e.g., samarium, praseodymium) compounds have emerged as the most powerful magnets available.

Hardfacing and Wear-resistant Alloys. These materials, essentially quaternary alloys of cobalt; chromium, tungsten (or molybdenum); and carbon, are widely used for industrial hardfacing purposes. They can be deposited by welding techniques, sprayed on as powders, or produced as separate castings. By using the weld deposition technique, a highly alloyed heat-, wear-, and corrosion-resistant surface can be applied to a much cheaper substrate, e.g., mild steel. Used originally as a component reclamation process, these alloys and techniques are now primary design requirements for many engineering items. The feasibility of electrodepositing composite cobalt-carbide coatings from an agitated slurry of solid carbide particles in a conventional plating bath has been demonstrated. These coatings provide excellent wear protection and are now established in the aerospace industry, while other engineering applications are being evaluated.

The demand for wear resistance allied with a low coefficient of friction has been successfully met by cobalt-molybdenum-silicon alloys. Structurally they conform to the well-proven bearing concept of hard intermetallic phases dispersed through a softer cobalt matrix. They offer outstanding bearing performance in conditions of poor lubrication.

As of the early 1990s the historical importance of cobalt in alloys for reducing wear resistance was markedly diminished by the development of *Norem* alloys, which were derived from stainless steel, particularly the Armco *Nitronic 60*, admittedly one of the few stainless steels that has excellent wear resistance. This is an outgrowth of research conducted by EPRI (Electric Power Research Institute) in an effort to lower equipment costs. Initial uses of the new cobalt-free alloys will be power plant valves and turbines. Also, in nuclear reactor applications, the *Norem* alloys will not become activated (Co does), reducing worker-protection and maintenance costs. Tests have confirmed that the new cobalt-free alloys retain their wear-resistant properties when produced as rods and powders, the most common forms used by welders.

Alloy Steels. The addition of cobalt to high-speed tool steel was one of the earliest uses of cobalt. This application is represented by the super-high-speed tool steel grades, which contain 5–12% cobalt. Two other cutting tool materials, the nonferrous cobalt-chromium tungsten-carbon cast alloy and the cemented carbides also provide a steadily growing outlet for cobalt. Hot work die steels are another group of alloy steels which benefit from the effect cobalt has on the tempering characteristics and consequent hot strength retention. The most significant development in recent years, however, is the advent of the Ni-Co-Mo miraging family of steels, which combine very high strength and toughness properties to an unusual degree. This is still an area of active development and growing engineering utilization.

Toxicity: Cobalt, like most other metals, is not entirely harmless, although it is not in any way comparable to the known toxic metals, such as mercury, cadmium, and lead. Inhalation of fine cobalt dust over long periods can cause an irritation of the respiratory organs, which may result in chronic bronchitis. Complete recovery is usually achieved upon removal from the contaminated atmosphere. Cobalt salts can cause benign dermatoses, either in people new to handling them, or after prolonged exposure, usually several years.

Chemistry of Cobalt: The metal in the massive form is not attacked by air or water at temperatures below approximately 300 °C; above this temperature it is oxidized in air. The metal combines readily with the halogens to form the respective halides. It combines with most of the other metalloids when heated or in the molten state. It does not combine directly with nitrogen but decomposes ammonia at elevated temperature to form a nitride. It reacts with carbon monoxide at 225–230 °C to form the carbide, Co_2C. Cobalt also forms intermetallic compounds with many metals, e.g., Al, Cr, Mo, Sn, Ti, V, W and Zr. Metallic cobalt is readily dissolved in dilute sulfuric, hydrochloric or nitric acids to form cobaltous salts. Like iron, cobalt is passivated by strong oxidizing agents, such as the dichromates. It is slowly attacked by ammonium hydroxide and sodium hydroxide.

Cobalt Compounds: In general the chemical properties are intermediate between those of iron and nickel. The predominant oxidation states of cobalt compounds, except for a large class of organometallic compounds, are 2+ and 3+. Common usage assigns the terms *cobaltous* and *cobaltic*, respectively, to these.

In aqueous solutions and in the absence of complexing agents, cobalt compounds are stable only in the 2+ oxidation (cobaltous) state. In the complexed state the cobaltous ion is relatively unstable, being readily oxidized to the 3+ oxidation (cobaltic) state. An extremely large number of 3+ complex ions have been identified, most of which are quite stable in aqueous media.

Cobalt has an electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^7 4s^2$. The two 4_s electrons are readily removed producing the ordinary Co^{2+} ion. In principle, if the odd $3d$ electron were removed the simple cobaltic ion Co^{3+}, would be formed. This however does not occur; the ion exists only in complex ions or crystal lattices in which cases additional electron orbitals are filled.

Cobalt and oxygen form two stable oxides, cobaltous oxide, CoO, stable below 200 °C and above 900 °C; and cobalto-cobaltic oxide, Co_3O_4, which is stable below 900 °C. Between 200 and 900 °C the CoO oxidizes partially, or completely, to Co_3O_4.

Cobaltous oxide is usually prepared by heating the carbonate. It is insoluble in H_2O, NH_4OH, and alcohol, but dissolves in cold strong acids and in weak acids on heating. Commercial gray oxide, which may contain up to 40% Co_3O_4, is used in the ceramic, glass and enamel industries and also in the production of catalysts. It is also used in the preparation of cobalt metal powder. The Co(III) oxide can also be prepared by calcining oxides, hydroxide and salts. The oxide is insoluble in H_2O and only slightly soluble in acids. The commercial black oxide consists essentially of Co_3O_4 with possibly up to 20% of CoO.

Cobalt(II) hydroxide exists in two allotropic forms, a blue α-Co $(OH)_2$ and a pink β-$Co(OH)_2$. The hydroxide is prepared by precipitation from a cobaltous salt solution by an alkali hydroxide. When the alkali is in excess the pink β-form is produced — the blue α-form is produced when the cobalt salt is in excess. The salt slowly oxidizes in air at room temperature and changes to hydrated cobaltic oxide, $Co_2O_3 \cdot nH_2O$. The hydroxide is practically insoluble in H_2O and in bases, but highly soluble in mineral and organic acids. The commercial salt is used as the starting material in the preparation of drying agents.

Cobaltous halides are formed with the halogen group, but only fluorine forms a stable cobaltic compound. The other cobaltic halides are stable only in complex ions.

Commercial cobaltic fluoride is formed by the reaction of cobalt, its oxides or simple salts with ClF_3 or BrF_5 to yield a brown anhydrous salt. This is a powerful fluorinating agent readily replacing hydrogen in aliphatic and aromatic hydrocarbons. Cobaltous chloride is a pale-blue compound and very hygroscopic. A series of hydrates is known; the hexahydrate is pink but becomes blue on warming. It is extremely soluble in H_2O, and in numerous organic solvents. The commercial salt is used as a starting material in the manufacture of catalysts, in electroplating, agricultural chemicals, and pharmaceuticals. Cobaltous bromide is highly hygroscopic and transforms gradually to the red hexahydrate. The salt is mainly used in the catalysts industry.

A number of sulfides have been reported, the best characterized being Co_4S_3, Co_9S_8, CoS, Co_3S_4, and CoS_2. They are prepared either by metal or salt solution reaction with S or H_2S. The mixed sulfides of cobalt and molybdenum have catalytic properties of hydrogenation and isomerization.

The sulfate, one of the more important industrial salts of cobalt, is usually available as the red heptahydrate, an efflorescent substance. On

heating it converts to the dark-blue monohydrate, and after prolonged heating above 250 °C the red anhydrous salt. It is widely used in the electroplating and ceramic industries, and in the preparation of drying agents and agricultural pasture top-dressing.

Cobalt and nitrogen form three nitrides, Co_3N_3, Co_2N, and CoN, products of metal/ammonia reaction and compound decomposition. All are gray-black or black in color.

In its commercial form cobalt nitrate appears as the red hexahydrate, $Co(NO_3)_2 \cdot 6H_2O$ formed by dissolving the metal oxide or carbonate in dilute HNO_3 and concentrating the solution. The compound deliquesces in moist air and effloresces in dry air. The pink anhydrous cobaltous nitrate cannot be formed by dehydrating the hexahydrate but by treating the salt with nitrogen pentoxide gas (or in solution in concentrated HNO_3). The salt is used mainly in the preparation of catalysts.

Two discrete carbides have been characterized — Co_3C and Co_2C. The former, which has the same structure as Fe_3C, has been prepared by reacting cobalt with coal gas at temperatures between 500–800 °C. Co_2C is formed by the reaction of carbon monoxide at atmospheric pressure on cobalt powder at 225–230 °C.

Cobaltous carbonate, $CoCO_3$, is found almost pure in the mineral sphaerocobaltite in the Republic of Zaire and less extensively in Zambia. The pale-red anhydrous salt is obtained by reaction in solution of an alkaline carbonate and a cobaltous salt under a slight pressure of carbon dioxide (up to 1 atmosphere) and subsequent heating at 140 °C. The commercial salt is violet-red in color, partially hydrolyzed with an indeterminate composition. It is insoluble in H_2O and alcohol, but dissolves easily in inorganic and organic acids, and is often used for the preparation of other salts. According to the thermal conditions it decomposes to the different types of oxides.

Cobaltous acetate, $Co(CH_3CO_2)_2$, is obtained as a pink salt by the dehydration of the tetrahydrate which is prepared by dissolving the hydroxide or carbonate in acetic acid. The tetrahydrate, which is the commercial form, is widely used in the preparation of catalysts, e.g., OXO synthesis, and dryers for inks and varnishes.

Cobaltous oxalate dihydrate, $CoC_2O_4 \cdot 2H_2O$ (pink), is obtained by adding oxalic acid or an alkaline oxalate to a cobaltous salt solution. This is the commercial form of the salt and is important as the starting material in the preparation of cobalt metal powders.

Cobalt(III) coordination compounds are the classics of coordination chemistry, many of the cobalt(III) amines having been prepared in the nineteenth century. They are invariably colored and undergo reaction slowly. Because of this many isomers have been isolated and studied. Much of the knowledge of isomerism, mechanisms of reaction, and general properties of octahedral species are based on cobalt(III) compounds. The important donor atoms (in order of decreasing tendency to complex) are nitrogen, carbon in the cyanides, oxygen, sulfur, and the halogens. The coordination number is invariably six. An extensive class of amines and compounds of the amines is known ranging from hexamine $[CoN_6]^{3+}$ through to monoamines $[CoNX_5]^{2-}$. The compounds are made in several stages by first oxidizing the cobalt(II) species and then various different substituted species are prepared by substitution reactions on the primary cobalt(III) product. When air is drawn through an aqueous solution containing cobalt(II) and ammonia the solution turns brown. From this mixture can be obtained a variety of products which depend on the initial concentrations of reactants, the pH of the solution, the anion present and the presence of heterogeneous catalysts, such as charcoal. The products are invariably colored ranging from blue-violets and green through various shades of red and brown to yellow. The absorption spectra are characteristic of the various structures. Complex cyanides of the types $[Co(CN)_6]^3$- and $[Co(CN)_5X]^{3-}$ are stable and diamagnetic. The anion $[Co(CN)_6]^{3-}$ is pale yellow and is the ultimate product of the reaction when a solution of cobalt(III) cyanide in aqueous KCN is boiled in air. It is very unreactive, being untouched by chlorine, peroxide, alkali, aqueous HCl and H_2S, although it gives CO when treated with concentrated H_2SO_4.

The only cobalt(IV) compound appears to be $Cs_2[CoF_6]$ which is prepared as a yellow powder by the fluorination of Cs_2CoCl_4.

Evidence for cobalt(I) was first obtained from the electrolytic reduction of cyano-compounds and some of the reduced species have been isolated. There are also many cobalt(I) coordination compounds of the organometallic class carbonyl, isonitriles, and unsaturated hydrocarbon derivatives. The oxidation state cobalt(0) may be represented in the cyano-compound which has been formulated as $K_8[Co_2(CN)_8]$. It has been prepared as an air-sensitive brown-violet compound by reducing a liquid ammonia solution of $K_3[Co(CN)_6]$ with an excess of K metal. The only other known cobalt(0) species are organometallic compounds.

COBALT (In Biological Systems). Although cobalt is regarded as an essential element for animals, including humans, the element can perform its essential functions only after it has been incorporated into the vitamin B_{12} molecule. The microorganisms living in ruminants are the major producers of vitamin B_{12} in the food chain. Green plants do not synthesize the vitamin. The normal intake of this vitamin is by way of milk, cheese, meat, and eggs. Persons who follow a strictly vegetarian diet may become deficient in vitamin B_{12} unless supplementary sources are used. Single-stomach domestic and wild animals receive their vitamin B_{12} from animal flesh or from animal fecal material. See also **Vitamin B_{12} (Cobalamin)**.

Cobalt is present in vitamin B_{12} to the extent of about 4%. Lack of cobalt in the soil and feedstuffs prevents ruminants from synthesizing all of the vitamin B_{12} for their needs. Thus, cobalt can be added to feedstuffs as the chloride, sulfate, oxide, or carbonate. Excessive cobalt intakes are toxic, causing a reduction in feed intake and body weight, accompanied by emaciation, anemia, debility, and elevated levels of cobalt in the liver. It is of interest to note that clinical cobalt toxicity closely resembles clinical cobalt deficiency.

Cobalt is required by the microorganisms that live in nodules on the roots of legumes, such as bean and clover. They convert nitrogen from the air into chemical forms that can be used by higher plants. This is possibly the only well established and understood function of cobalt in plant growth. Legumes may grow normally and the microorganisms on their roots fix atmospheric nitrogen, even though the forage does not contain sufficient cobalt to meet the requirements of ruminants.

Areas of low cobalt content in the United States, where clovers and alfalfa are too low in cobalt content to meet requirements of cattle and sheep, include northeastern Maine, all of New Hampshire, Vermont, Massachusetts, Connecticut, and Rhode Island, much of New York with exception of the central portion, the northwestern portion of the lower peninsula of Michigan, a small area in Illinois with Peoria at its approximate center, all but eastern Iowa, and southwestern Minnesota. The low-cobalt soils of New England are primarily sandy and were formed from glacial deposits near and to the south of the White Mountains of New Hampshire. Along the south Atlantic Coastal Plain, legumes with very low concentrations of cobalt are primarily on the sandy soils formed in naturally wet areas. These soils, which are called spodosols, have light-colored subsurface layers overlying a dark-brown or dark-gray hard-pan layer.

Grasses and cereal grains generally contain less than the 0.07 to 0.10 parts per million of cobalt required by ruminants. Cattle and sheep that are not fed any legumes nearly always require cobalt supplementation.

Adding cobalt to soils, either as cobalt sulfate, or as cobaltized superphosphate, can be used to increase the level of cobalt is plants and prevent cobalt deficiency in cattle and sheep. Cobalt fertilization may not

be effective in preventing cobalt deficiency on alkaline soils because in these soils, the added cobalt quickly reverses to forms that are not taken up by plants. Cobalt fertilization is more common in Australia than in the United States. In the United States, cobalt is usually added to mixed feeds, mineral mixes, or salt licks.

Still another method is to place heavy ceramic "bullets" containing cobalt in the animal's rumen. These bullets remain in the rumen and slowly release cobalt to meet the animal's needs for a long period. The diets of hogs and chickens are often supplemented with concentrated forms of vitamin B_{12}.

The relationship of the levels of cobalt in soils and plants to the health of ruminants is one of the striking examples of the importance of a soil and plant relationship to animal health. When some Australian scientists discovered this relationship, new areas in several parts of the world became usable for animal production. The vitamin B_{12} formed within cattle and sheep in these new areas contributed to the vitamin B_{12} nutrition of people, even though adding cobalt to soils does not directly affect human nutrition in the absence of the production of ruminants. Cobalt-deficient grazing soils are found in Australia, New Zealand, and, in the United States, mainly in Florida, although deficient regions are found elsewhere as previously mentioned. Cobalt deficiency can result in a condition known as "pinining disease," where the affected animals are quite listless. The disease is also known as "bush sickness" and "salt sickness."

COBALTITE. The mineral cobaltite is a sulfarsenide (see **Arsenic**; and **Sulfur**) of cobalt, corresponds to the formula CoAsS, crystallizing in the isometric system as cubes or pyritohedrons, also may be massive. Cobaltite has a very good cleavage parallel to the cube faces; uneven fracture; brittle; hardness, 5.5; specific gravity, 6.33; metallic luster; color, silvery-white to reddish, sometimes steel gray or violet to grayish-black; streak, grayish-black. Cobaltite is found with cobalt and nickel minerals deposited commonly by metasomatic processes. It is found in Sweden, Norway, England and the Province of Ontario. It is an ore of cobalt.

COBIA *(Osteichthyes).* Of the order *Percomorphi* and family *Rachycentridae*, characterized as a voracious and fast-moving fish. Three dark stripes on the sides of the body provide identification. Cobia is a large fish, weighing up to slightly in excess of 100 pounds (45.4 kilograms) and achieving a length of nearly 6 feet (1.8 meters). Its primary diet is fish, but it also consumes crab. Occurrence is in tropical and subtropical waters on a worldwide basis. Considered an excellent game fish, but only average for eating. The cobia is very well streamlined.

COBRA. See **Snakes**.

COCAINE. See **Alkaloids**.

COCCIDIOIDOMYCOSIS. Also known as Coccidioidal Granuloma or Valley Fever, this disease is caused by the dimorphic fungus *Coccidioides immitis*. The fungus inhabits desert soils and areas of a semiarid nature, characterized by hot, dry summers, mild winters, and moderate rainfall. These areas are found in parts of California, notably the San Joaquin Valley, in southern Arizona, Utah, New Mexico, Nevada, and southwestern Texas. There are also similar areas in Mexico and Central America where the fungus is found. The parasitic form of the fungus is a spherical cell 30 to 60 micrometers in diameter which does not bud, but divides internally, producing numerous endospores 2 to 5 micrometers in diameter. The mycelial form grows readily in soil, producing a large number of arthrospores, which are easily disseminated by air currents. The disease is not contagious, but is contracted by inhalation of the highly infectious arthrospores.

Some cases have been reported, of persons being infected from spores contained in packages that may have been shipped hundreds of miles from the fungus' natural habitat.

In the endemic region, as many as 80% of the persons residing in the region may contract the disease during their first 5 years of residence. Small children are particularly vulnerable to infection. The primary infection is often mild and passes unnoticed. In the more serious, granulomatous form, the disease may involve bones, joints, skin, subcutaneous tissues, and internal organs. This form occurs rarely and strikes only persons of low resistance.

It is estimated that about 40% of persons who inhale *C. immitis* arthrospores will develop an influenza-like illness within 7 to 28 days after exposure. The other 60% of the persons will show a positive skin test, but no other indication of the infection. A common symptom in children is a rash, particularly on the palms and soles. Marked differences occur in development of progressive and disseminated coccidioidomycosis. About one in 400 males develops a granulomatous disease; in white females, the rate is one-fifth of this, and in black males, the rate is 10 to 15 times greater than in white males. The disease is treated by amphotericin B, an antimicrobial agent used in the treatment of other fungus infections, such as blastomycosis.

ANN C. DEBALDO, Ph.D., University of South Florida, Tampa, FL

COCCIDIOSIS. Coccidiosis is a widespread disease that occurs most often in fowl, such as chickens and turkeys, and other farm animals (cows, sheep, swine, horses, and rabbits). In chickens the disease has caused severe economic losses. Coccidiosis also occurs in ox, water buffalo, zebu, bighorn sheep, wild goat, alpaca, lion, puma, fox, mink, parakeet, Canada goose, snow goose, and camel, among others. It is seen only rarely in humans, and dogs and cats are only occasionally infected.

Coccidiosis in chickens, as with cattle, is frequently caused by a combination of infective *Eimeria* protozoa. *Eimeria tenella* is the most important, but *Eimeria nectrix* is more common. *Eimeria maxima*, *Eimeria acervulina*, and *Eimeria mivati* are moderately pathogenic; *Eimeria brunetti* is highly pathogenic, but relatively uncommon. In chickens, young birds become infected by ingesting with their food oocysts shed in the feces of older birds. Diseased birds exhibit diarrhea, emaciation, and anorexia. The disease results in a marked decrease in the production of eggs, as well as a ca 10% mortality caused by the ingestion of a large number of oocysts. See also **Antiparasitic Agents, Antiprotozoals**.

Anticoccidial drugs are administered in the drinking water or feed of poultry and are primarily prophylactic, rather than curative, in nature. The most common ones in use are salinomycin $C_{42}H_{70}O_{11}$ (**1**, Coxistac [CAS: 53003-10-4]) and monensin (**2**) $C_{36}H_{62}O_{11}$ [CAS: 17090-79-8], a carboxylic acid which is used as its water-soluble sodium salt (Coban, Rumensin). Monensin is also used to treat histomoniasis. See also **Histomoniasis**. These polyether ionophoric antibiotics are capable of complexing and interfacing with specific alkali metal cations to render them lipid-soluble and diffusible across parasite mitochondrial membranes. Related useful polyether antibiotics are narasin [CAS: 55134-13-9] and lasalocid (**3**, Lasalocid A, $C_{34}H_{54}O_8$, [CAS: 25999-31-9]).

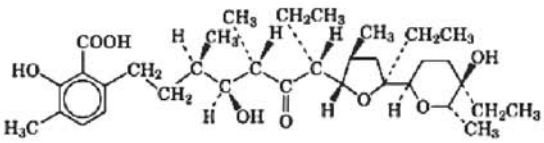
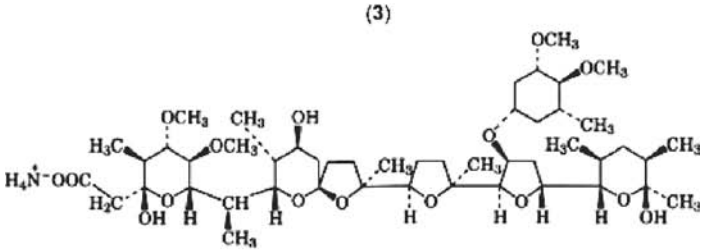
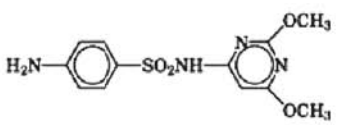
(2)



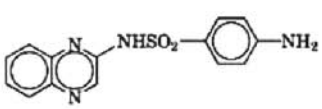
(3)



(4)

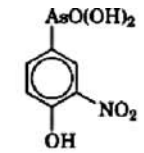


(5)

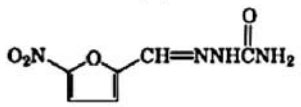


(6)

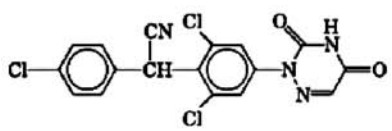
See also **Antibiotic**. The potent ionophoric antibiotic maduramicin (**4**, Cygro, $C_{47}H_{83}NO_{17}$ [CAS: 84878-61-5]) is currently being evaluated as an alternative for use against resistant strains of *Eimeria* inasmuch as resistance to the entire class of ionophoric compounds is presenting serious problems. Strains resistant to all coccidiostats arise rapidly because of the widespread use of these drugs. Sulfa drugs, such as sulfadimethoxine (**5**), $C_{12}H_{14}N_4O_4S$, [CAS: 122-11-2] and sulfaquinoxaline (**6**), $C_{14}H_{12}N_4O_2S$, [CAS: 59-40-5] are members of the first nontoxic class of anticoccidials. Other types of compounds that have been considered treatments for the control of coccidiosis are the arsenicals, such as roxarsone (**7**, 4-hydroxy-3-nitrophenylarsonic acid, $C_6H_6AsNO_6$, [CAS: 121-19-7]); the alkylidene diphenols; 3,3′-dinitrodiphenyl disulfide; the nitrofurans exemplified by nitrofurazone (**8**, 5-nitro-2-furaldehyde semicarbazone, $C_6H_6N_4O_4$, [CAS: 59-87-0], Amifur, Furacin); the triazinones, diclazuril (**9**) $C_{17}H_9Cl_3N_4O_2$, [CAS: 101831-37-2] and toltrazuril (**10**, $C_{18}H_{14}F_3N_3O_4S$, [CAS: 69004-03-1] Hycox, Maxicox); the carbanilide complexes such as nicarbazin [11, $C_{13}H_{10}N_4O_5{\cdot}C_6H_8N_2O$, [CAS: 330-95-0] bis(4-nitrophenyl) urea 1:1 complex with 4,6-dimethyl-2(1*H*)-pyrimidone, Nicarb]; pyrimethamine; clopidol (**12**, $C_7H_7Cl_2NO$, [CAS: 291-90-6] Coyden); robenidine {**13**, $C_{15}H_{13}Cl_2N_5$, [CAS: 25875-51-8],1,3-bis[(*p*-chlorobenzylidene)amino]guanidine}; and halofuginone (**14**) $C_{16}H_{17}BrClN_3O_3$, [CAS: 55837-20-2] and its hydrobromide [CAS: 64924-67-0], Stenorol. Halofuginone is also used to treat theileriasis. See also **Theileriasis**.



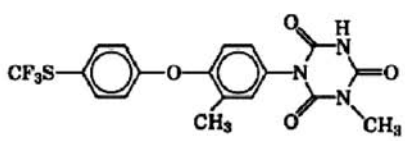
(7)



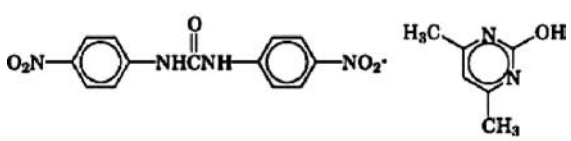
(8)



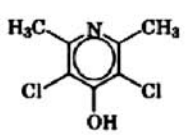
(9)



(10)



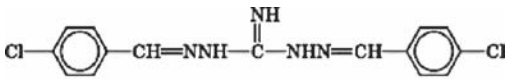
(11)



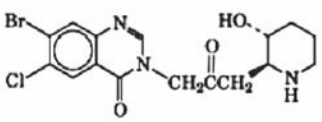
(12)

In cattle, infections by a single species of protozoan are unusual; combinations of the protozoa such as *Eimeria zuernii*, *Eimeria bovis*, and *Eimeria auburnensis* are more typical. Bovine coccidiosis occurs mainly in calves from three weeks to six months old. Adult animals are usually the carriers but tend to be asymptomatic. Infection in calves occurs by ingestion of the oocysts with their feed and/or water. As with poultry, the severity of the disease is a function of the number of oocysts ingested. Small numbers may cause no disease, whereas a large profusion ultimately may cause death. Severe disease is marked by anemia, weakness, emaciation, and anorexia. Monensin (**2**) is effective against coccidia in both cattle and sheep. Clopidol (**12**), halofuginone (**14**), and amprolium (**15**) $C_{14}H_{19}N_4Cl$, [CAS: 121-25-5] are administered as feed additives. Other

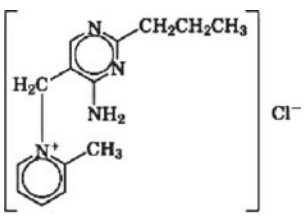
coccidiostats that have been employed are nitrofurazone (**8**), lincomycin (**16**), $C_{18}H_{34}N_2O_6S$, [CAS: 154-21-2] lasalocid (**3**), and salinomycin (**1**). Sulfonamides are only partially effective.



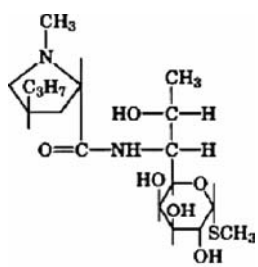
(13)



(14)



(15)



(16)

Coccidiosis is seen frequently in puppies and kittens and is responsible for diarrhea and even death if the animals are maintained in unsanitary conditions. For dogs and cats there exists no satisfactory treatment; however, the disease is self-limiting. Human infections can frequently be traced to these animals.

Cryptosporidiosis, an intestinal infection caused by protozoa of *Cryptosporidium* species is a taxonomically related disease. The disease affects animals, such as calves, lambs, and chickens, and infects humans worldwide, especially infants and children in developing countries. Symptoms range from mild self-limiting diarrhea and abdominal pain to a potentially fatal extreme diarrhea that results in weight loss and poor nutritional absorption. Increasingly, this opportunistic disease occurs in those with a suppressed immune system, especially those with AIDS. The only effective treatment for cryptosporidiosis in AIDS patients who do not respond readily to therapy is spiramycin (**17**) [CAS: 8025-81-8]. Spiramycin is also used to treat toxoplasmosis. See also **Toxoplasmosis**.

COCHRAN'S THEOREM. A theorem in statistics concerning quadratic forms. If $x_1, x_2, \ldots, x_n$ are independent normal variables and $Q_1, \ldots, Q_k$ are quadratic forms in those variables with ranks $n_1, \ldots, n_k$; if $\sum_{i=1}^{k} Q_i = \sum_{i=1}^{n} x_i^2$, then the necessary and sufficient condition for the Q's to be independent χ^2 variables with n_i degrees of freedom respectively is that $\sum_{i=1}^{k} n_i = n$. The theorem is basic to tests of significance in the analysis of variance.

COCKCHAFER *(Insecta, Coleoptera).* A European beetle, *Melo-lontha vulgaris*, related to the May beetles of North America.

COCKLE *(Mollusca, Pelecypoda; Cardium).* Marine bivalve mollusks of several species. Cockles of commercial importance are described in the entry on **Mollusks**.

COCKROACH *(Insecta, Orthoptera).* Flattened oval insects, usually brown in color. The head is almost concealed by the broad margins of the thorax and in winged species the wings overlap above the body. See Fig. 1.

Cockroaches are widely known from a few species that inhabits houses, especially where quantities of food are available. They eat almost anything used by humans as food and often damage other things, such as articles made of cloth containing sizing or paste. They are especially troublesome in restaurants. The two most important pests are the Crotonbug, *Blatella germanica*, and the Oriental cockroach, *Blatta orientalis*. They can be destroyed by sprinkling borax (see also **Boron**), sulfur, or pyrethrum powder liberally about their hiding places or by the use of commercial roach pastes.

The cockroaches gain their greatest development in the tropics, where species with a normal length of more than 2 inches (5 centimeters) are found.

Because the cockroach is such a widespread, persistent, and offensive pest, there has been considerable research over the years toward improving both insecticides and repellants for use against this insect. There has been particular interest shown in repellants during recent years. Some researchers have taken leads from so-called "old wives' tales" to the effect that cockroaches do not like the odors of bay leaves or cucumbers. C.E. Meloan (Kansas State University) has reported experimentation with both of these materials and has found them effective, particularly after

Fig. 1. Cockroach. (*A.M. Winchester*.)

certain substances in them have been isolated or synthesized. For example, six active compounds obtained from bay leaves were found to be effective, but notably a bicyclic compound (*cineole*). Sliced cucumbers were found effective in repelling 80% of roaches in a test area. The active ingredient proved to be trans-2-nonenal, which was found to repel 100% of the roaches in the test area. Further investigation showed that an isopropyl group attached to an oxygen is the active moiety in cineole, while a carbon-carbon double bond attached to a third, electron-rich carbon is the active moiety of trans-2-nonenal. By combining the two groups into one molecule, a very potent synthetic roach repellent resulted. Both diisopropyl ether and diisopropyl fumarate, for example, repel 100% of roaches at concentrations of 30 to 50 ppm. Also effective is 5,5-dimethyl-3-ene-butryolactone and at lower concentrations. Inasmuch as the aforementioned compounds are highly volatile, most likely they would have to be packed in the form of time-release capsules. Incorporating small concentrations of the compounds in the glue used on paper grocery bags and cardboard containers also has been suggested. It is well established that roaches often reach residences and buildings by way of this route.

COCONUT OIL. See **Vegetable Oils (Edible)**.

CODDINGTON EYEPIECE. An eyepiece made from a single piece of glass with a groove cut around its equator to act as a stop. The two convex surfaces are portions of the same sphere. Probably first made by Sir David Brewster.

CODE (Computer System). A code is a system of symbols for representing data or instructions in a computer or data processing machine. A machine language program sometimes is referred to as code.

Alphanumeric Code. A set of symbols consisting of the alphabet characters A through Z and the digits 0 through 9. Sometimes the definition is extended to include special characters, such as $, %, and &. A programming system commonly will restrict the user-defined symbols to only those using alphanumeric characters and for the system to take special action on the occurrence of a nonalphanumeric character. A job currently in progress, for example, may be stopped should the $ character be encountered.

Binary Code. (1) A coding system in which the encoding of any data is done through the use of bits; i.e., 0 or 1. (2) A code for the ten decimal digits, $0, 1, \ldots, 9$ in which each is represented by its binary, radix 2, equivalent; i.e., straight binary.

Biquinary Code. A two-part code in which each decimal digit is represented by the sum of the two parts, one of which has the value of decimal zero or five, and the other the values zero through four. The abacus and soroban both use biquinary codes. An example follows:

DECIMAL	BIQUINARY	INTERPRETATION
0	0 000	$0+0$
1	0 001	$0+1$
2	0 010	$0+2$
3	0 011	$0+3$
4	0 100	$0+4$
5	1 000	$5+0$
6	1 001	$5+1$
7	1 010	$5+2$
8	1 011	$5+3$
9	1 100	$5+4$

Column-binary Code. A code used with punch cards in which successive bits are represented by the presence or absence of punches on contiguous positions in successive columns as opposed to rows. Column-binary code is widely used in connection with 36-bit word computers where each group of 3 columns is used to represent a single word.

Computer Code or Machine Language Code. A system of combinations of binary digits used by a given computer.

Excess-three Code. A binary coded decimal code in which each digit is represented by the binary equivalent of that number plus three; for example:

DECIMAL DIGIT	XS 3 CODE	BINARY VALUE
0	0011	3
1	0100	4
2	0101	5
3	0110	6
4	0111	7
5	1000	8
6	1001	9
7	1010	10
8	1011	11
9	1100	12

Gray Code. A binary code in which sequential numbers are represented by expressions which are the same except in one place and in that place differ by one unit; e.g.,

DECIMAL	BINARY	GRAY
0	000	000
1	001	001
2	010	011
3	011	010
4	100	110
5	101	111

thus in going from one decimal digit to the next sequential digit, only one binary digit changes its value. Synonymous with cyclic code.

Instruction Code. The list of symbols, names and definitions of the instructions intelligible to a given computer or computing system.

Mnemonic Operation Code. An operation code in which the names of operations are abbreviated and expressed mnemonically to facilitate remembering the operations they represent. A mnemonic code normally needs to be converted to an actual operation code by an assembler before execution by the computer. Examples of mnemonic codes are ADD for addition, CLR for clear storage and SQR for square root.

Numeric Code. A system of numerical abbreviations used in the preparation of information for input into a machine; i.e., all information is reduced to numerical quantities. Contrasted with code, alphabetic.

Symbolic Code or *Pseudocode.* A code which expresses programs in source language; i.e., by referring to storage locations and machine

operations by symbolic names and addresses which are independent of their hardware determined names and addresses.

Two-out-of-five Code. A system of encoding the decimal digits 0, 1, . . . , 9 where each digit is represented by binary digits of which 2 are zeros and 3 are ones or vice versa.

CODE EXCITED LINEAR PREDICATION (Celp). See **Data Compression**.

CODEINE. See **Alkaloids**.

CODFISHES *(Osteichthyes).* Along with hakes and rattails, codfishes are of the order Anacanthini and specifically of the family Gadidae. All codfishes are marine with exception of the burbot, *Lota lota*, a species which ranges from the polar regions southward in North America and Eurasia. The marine codfishes prefer cold or temperate water, as contrasted with tropical climes. Their occurrence is much greater in the northern than in the southern hemisphere. Codfishes are among the greatest of world seafood sources.

Included in the codfish family are the pollack, the haddock, and the whiting. Because of certain anatomical differences, some investigators do not consider hakes as members of the family Gadidae, but rather as belonging to a separate family, Merlucciidae.

Atlantic Cod

This is the largest of about 150 species. The Atlantic cod may attain a length of 6 feet (1.8 meters), and weigh up to 210 pounds (95 kilograms). The commercial catch, however, usually averages from 2.5 to 25 pounds (1.1 to 11.3 kilograms). These fish spawn between January and March. A 75-pound (34-kilogram) female may lay as many as 9 million eggs. The eggs first float for a period of up to 20 days. Upon hatching, the larval forms attach themselves to floating plankton for a period of another 60 to 75 days. At the end of this period, they are about 1 inch (2.5 centimeters) in length and sink to the bottom where their subsequent growth is quite rapid. A 2-year-old cod will achieve a length of about 15 inches (38 centimeters). Normally, they are not capable of spawning until about 5 years old.

The most noticeable external characteristics are its 3 dorsal and 2 anal fins, its protruding upper jaw, its almost square tail, and a pale line running along each side of the body from head to tail. There is a fleshy barbel under the lower jaw. In most fish, the upper part of the body is thickly speckled with small, round spots somewhat darker than the body color, which may range from reddish to brown, gray, or greenish. Cod can be found from shallow water near shore, down to 250 fathoms (1500 feet; 450 meters). The cod's usual habitat is within a few fathoms of the bottom, but it also comes to the top of the water in pursuit of small fish or squid. It is most plentiful on the banks and in oceans of moderate depth. The Atlantic cods live chiefly over rocky, pebbly ground, on sand or gravel, and seldom on soft mud. They go in schools, but not in such dense bodies as mackerel and herring. The movements on and off shore and from bank to bank are due chiefly to temperature influence, the presence or absence of food, and the search for proper spawning conditions. Cod prefer temperatures of 32 to 41 °F (0 to 5 °C), but good catches can be made in waters up to 50 °F (10 °C). Cod feed on almost all types of sea life. The most important food is fish, especially herring, capelin, and sand lance, but mussels, crabs, and other bottom animals are also consumed.

The common Atlantic cod is well known on both sides of the north Atlantic Ocean. On the American coast, it is found as far north as Greenland, Davis Strait, and Hudson Strait, and south nearly to Cape Hatteras. In Europe, it is found from Novaya Zemlya, Spitzbergen, and Jan Mayen to the Bay of Biscay. It is also common near Iceland and the Faroe islands.

The cod (*Gadus callarias*), shown in Fig. 1, is caught in large quantities by British fishermen and constitutes about one-third of the total tonnage taken in British fisheries.

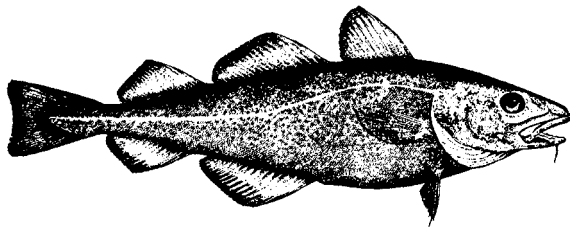

Fig. 1. Cod (*Gadus callarias*.)

Whiting

This fish (*Gadus merlangus*) is essentially a near-shore fish, and occurs in large quantities around the northern coasts of Britain. It figures prominently in the landings at Scottish ports. Less esteemed than the Atlantic cod or haddock, the whiting usually finds a less favorable market.

The whiting is smaller and more short-lived than most other important codfishes. Its meat is quite popular in Great Britain and France, but less so in Germany. Its far-flung distribution extends across the entire northern and western European shelf — from the north polar cap to the Atlantic coast of Spain and the southern coast of Iceland. One subspecies, the Mediterranean cod or *molo*, extends the distribution into the Mediterranean and Black Seas. Whitings are not found in the northwestern Atlantic Ocean. They are most prevalent in the North Sea and off the western coast of England. Whiting resembles haddock somewhat in coloration, and also has a lateral black spot, which is much smaller than that of the haddock and is located at the base of the pectoral fin. As pure shelf inhabitants, whitings are found in more shallow water than haddock and are prevalent in regions with soft, muddy ground at depths of 2 and 5 feet (0.6 and 1.5 meters). Their diet consists mainly of small crustaceans and fishes. Young whitings maintain the same relationship with medusas as to haddock.

Pacific Cod

This fish (*Gadus macrocephalus*) achieves a length up to 4 feet (1.2 meters). It is believed that this species developed from the Greenland cod group, penetrating into the Pacific from the Bering Strait, and is now found on both sides of the Pacific Ocean. It is widely distributed, but, as a coastal inhabitant, it does not migrate. The size and coloration are somewhat similar to those of the Atlantic cod. The maximum age is from 10 to 12 years. The diet is quite diverse, but consists primarily of crustaceans and fishes. Sexual maturity is attained after 5 to 6 years. The spawning season is in late winter. Eggs are laid in enormous numbers (similar to Atlantic cod), but instead of rising, they sink to the floor, an adaptation to the more localized nature of these codfishes.

Haddock

This fish (*Melanogrammus aeglefinus*) ranges in length up to nearly 3.5 feet (107 centimeters). See Fig. 2. Its distribution in the northern Atlantic Ocean is similar to that of the Atlantic cod. However, haddock are not usually found off Greenland, and in the northwestern Atlantic Ocean. Haddock are usually found only off the southern coast of Newfoundland, off Nova Scotia, and in the Gulf of Maine. Haddock differ from all other codfishes by a black spot above the pectoral fin. The lower jaw is very short and the barb is small. Its chief diet consists of invertebrate, bottom-dwelling organisms and herring spawn. As a pure shelf inhabitant, haddock is rarely found below 655 feet (200 meters). The oldest age of this medium-size fish is about 14 years. Like Atlantic cod, haddock undertake periodic migrations between the feeding grounds and the spawning sites. In the northeastern Atlantic Ocean, the chief spawning sites are in the northern North Sea and off the Norwegian coast. Haddock reach sexual maturity after 3 to 4 years, spawning in the spring, somewhat later than

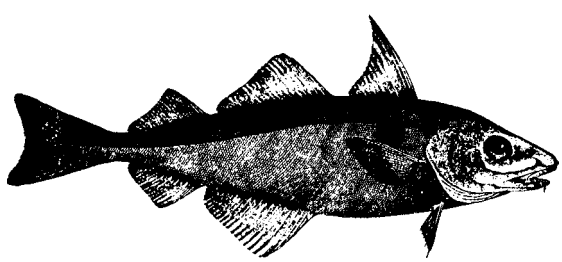

Fig. 2. Haddock (*Melanogrammus aeglefinus*.)

Atlantic cod. The haddock has lower fertility, but the development period of the eggs is shorter than in the Atlantic cod. The initially pelagic young are often found under the umbrellas of large medusas before changing to bottom dwelling in the autumn of their first year of life. Their length at that time is about 4 inches (10 centimeters). Unlike other codfishes, which migrate toward the shallow coastal waters, haddock spend their first years in the open sea. Finnan haddie is smoked haddock.

Silvery Pout

This fish (*Gadiculus*) is the smallest codfish species, ranging in length up to about 6 inches (15 centimeters). Pout is found at greater depths — from 1310 to 3280 feet (400 to 1000 meters) on the continental shelf. The northern species (*Gadiculus thori*) is distributed from Norway and southern Iceland to the Bay of Biscay, while the southern species (*Gadiculus argenteus*) is found from the southernmost part of the distribution of *G. thori*, to the northern Africa coasts and the western Mediterranean.

Pollack

Also known as the *saithe* or *blister-back*, this fish (*Pollachius virens*) has about the same commercial significance as the haddock. In body shape, fin position and size, it resembles the Atlantic cod, but other characteristics clearly distinguish it. See Fig. 3. The lower jaw protrudes somewhat and has a very small barb. The dark-colored mouth is also a distinctive feature. The pollack is a pelagic predator which, as a fast and skilled swimmer, feeds chiefly on schooling fishes, especially herring. However, its extensive migrations follow less well-established routes than those of other codfishes. Its constantly changing life habits make following its growth dynamics difficult, a factor which adds to the difficulties for pollack fishers. The fish can reach an age of 18 to 20 years. The pollack attains sexual maturity in 4 to 5 years and thereafter spawns each spring in practically the same region as haddock. The eggs and larvae drift with the current and the young migrate into coastal waters after their pelagic development period. They spend their first year in coastal waters.

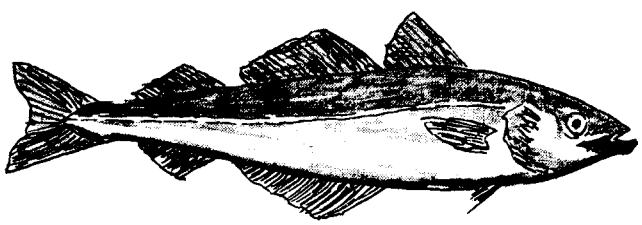

Fig. 3. Pollack (*Pollachius virens.*)

Alaska Pollack

This fish (*Theragra chalcogramma*) is not to be confused with the pollacks just described. The Alaska pollack has the same distribution as the Pacific cod, but is less dependent on being near the coast and may be found at depths as great as 985 feet (300 meters). This species is found in open, warmer (as compared with Pacific cod) water. Its diet consists of plankton and small schooling fishes. In the western Pacific Ocean, isolated populations have developed differences in growth and spawning seasons (October-December versus spring). In recent years, the Alaska pollack has become quite important commercially.

See also **Fishes**.

CODLING MOTH *(Insecta, Lepidoptera).* The moth, *Carpocapsa pomonella*, whose larva lives in apples. An important economic species.

This insect is so serious an enemy of the apple that the successful production of the fruit depends on a program of spraying which has been carefully worked out for all parts of the country. Sprays are effective poisons, but their application must be regulated according to the entrance of the caterpillars into the fruit. Once they have penetrated the surface they are beyond reach of sprays. The principle of spraying is to apply a first spray when the petals of the flowers fall, and a second when the eggs of the next generation of insects are hatching later in the summer. Economic entomologists are prepared to furnish the proper information for various localities, according to the conditions of the year.

The adult codling moth is a grayish brown color, with brown wingtips, and a wingspan from $\frac{1}{2}$ to $\frac{3}{4}$ inch (12 to 18 millimeters). The larva is white to pink, with a brown head, and ranges up to $\frac{1}{2}$ inch (12 to 13 millimeters) in length. The insect overwinters as a larva in a cocoon under bark scales, debris, or litter on the ground. The larva is found in the fruit near the core. The insect occurs wherever apples are grown. Blemish marks called "stings" result when the larva chews into the fruit that has been treated with a slow-acting insecticide, such as lead arsenate. The moth emerges and lays eggs about the time the apple is in bloom. The eggs hatch in about 5 days, after which the small larvae begin to feed. There are four generations per season.

Codling moths lay eggs mostly on the upper and under surfaces of the leaves, although a few may be found on the fruit and branches. Eggs of the codling moth are preyed upon by a minute wasp, *Trichogramma*, and they are attacked by mites. The larvae also have several parasites. Over a dozen species of birds are known to feed on this pest. The downy woodpecker, nuthatch, and chicadee destroy great numbers of hibernating larvae. In spite of the array of natural enemies, the codling moth remains the most destructive insect preying on apple.

Noninsecticidal control methods include the creation of a substitute location for the larvae to spin their cocoons and pupate. This can be accomplished by banding the trunks of trees by tying 6-inch (15 centimeter) strips of burlap or cardboard around them. These bands can be placed around the trunk or around large branches. Insects found in these bands should be collected and crushed immediately. To reduce this insect population further, loose bark should be scraped from the trees and any bark collected on the ground should be removed. All debris in the immediate area that may provide shelter for the insect should be removed.

COEFFICIENT. An algebraic factor. Also a quality or parameter that is characteristic of a substance or a system.

COELACANTHS *(Osteichthyes).* Of the order *Actinistia*, the coelacanth was first discovered in the waters off South Africa in late 1938. The fish measured about 5 feet (1.5 meters) in length and weighed close to 130 pounds (59 kilograms). It previously had been assumed that fishes of this kind had been extinct for some 60 million years. Fossil records had indicated the former existence of coelacanths. Unfortunately, this first *Latimeria chalumnae* had been mounted and the internal organs destroyed before the fervid interest of scientists could intervene. After long and arduous explorations of the waters around the coast of South Africa, Professor J.L.B. Smith landed the second coelacanth. However, it differed from the first in that the first dorsal fin and middle tail fin were missing. Thus, this particular fish was considered a different species. Later the omissions were considered aberrations. The second fish was found some 1900 miles (3057 kilometers) from the site of the first catch, namely, the waters off Anjouan Island, one of a group of islands in the northern end of the Mozambique Channel, which lies between Mozambique and Madagascar.

Fortunately, only 9 months elapsed before the catch of the third coelacanth, also in the same region. Since then a number have been caught. The eighth specimen was the first one that was kept alive for nearly 18 hours. After this scientific "discovery," it was learned that the coelacanth had been known for many years by the inhabitants of Comorro Island. They had named the fish "kombessa." Perhaps many additional species of coelacanths will be discovered.

COELENTERATA. The hydroids, jellyfishes, sea anemones, corals, and related animals. These forms make up a major division of the animal kingdom of simple structure. The body is developed from only two germ layers and is radially symmetrical. The alimentary track is saclike, with a single opening, but sometimes has complex tubular branches. The nervous system is a scattered network of cells connected by their slender processes. Coelenterates have peculiar stinging cells (cnidoblasts) which discharge irritating nematocysts. Most species are marine and all are aquatic.

Two forms of individuals occur in this phylum, the polyp or hydroid and the medusa.

The economic importance of the phylum is limited principally to the corals. Precious coral is sold in considerable quantities and the rock corals have built up many of the oceanic islands. See also **Coral Reef**.

The principal subdivisions of the phylum are the following:

Class Hydrozoa (*Hydromedusae*). Both polyps and medusae occur in these species, usually alternating in a reproductive cycle. Species are often colonial. In colonies individual polyps or hydranths are borne on branches of a common stalk which also gives rise to reproductive individuals or blastostyles from which medusae arise. All individuals are joined by the continuous digestive tract. Polymorphism occurs in some colonial species when polyps are modified to special functions. Most species are small but the Portuguese man-of-war and a few others are large.

Class Scyphozoa (*Scyphomedusae*). The jellyfishes. Usually free swimming species of moderate to large size. All individuals are medusae. Mostly marine.

Class Anthozoa (*Actinozoa*). Sea anemones, sea feathers, corals and allied species. Solitary or colonial marine species. The individuals are polyps. Colonies of some species build up massive hard deposits inside or outside of the body.

COELOM. The true body cavity, formed by the splitting of the middle germ layer of the body (mesoderm) and lined with a definite layer of cells. It is a perivisceral cavity.

The coelom is well developed in annelid worms, where it appears as a series of metameric chambers. It is of limited extent in other invertebrates but in the vertebrates gains great development. Here it is divided into a thoracic and an abdominal cavity and in the terrestrial species the thoracic cavity is further divided into pleural cavities containing the lungs and a pericardial cavity containing the heart. The abdominal or peritoneal cavity contains principally the greater part of the digestive tract.

Excretory organs open from the coelom in the annelids and lower vertebrates, and the liquid which it contains is apparently supplementary to the blood. In all cases the cavity furnishes a space into which developing organs may expand in complex animals.

COELOMATA. Animals which have a coelom. The term embraces the phyla Bryozoa, Brachiopoda, Phoronides, Chaetognatha, Echinodermata, Mollusca, Annelida, Arthropoda, and Chordata.

COELOMODUCT. A tubule opening at one end into the coelom and at the other on the surface of the body. It occurs in a simple form in some annelid worms as an excretory organ and in other species is associated with the nephridial tubule to form a more complex excretory structure. Coelomoducts are regarded as the evolutionary forerunners of the excretory tubules of vertebrates. See **Excretory System**.

COELOSTAT. In many types of astronomical research, it is desirable to have the main instrument stand still. To accomplish this purpose and also allow for the apparent motion of the celestial sphere, it is necessary to reflect the light by a moving mirror from the object in question into the instrument. Such a device is known as a *coelostat*. In the coelostat, a mirror is mounted parallel to the polar axis of an equatorial mounting. The axis is rotated by clockwork from east to west at such a rate that it would complete one rotation in 48 hours of sidereal time. Since the celestial sphere rotates from west to east once in 24 hours of sidereal time, and reflection doubles the angle, this rotation of the polar axis will compensate for the apparent rotation of the celestial sphere. With one single mirror mounted in the manner described, the direction in which the light will be reflected will depend entirely upon the declination of the object observed. To obtain any desired direction of reflection, a second mirror is employed to send the stationary beam from the first mirror in the desired direction.

In case it is desired to hold an image of the sun apparently stationary, the polar axis must be rotated once in 48 hours of solar time. Such an instrument is known as a *heliostat*. Other types of mounting, used for particular purposes, are known as *siderostats*.

COENENCHYME. The middle and outer tissues of certain coelenterates (Alcyonaria); common tissue connecting polyps or zooids of a compound coral.

COENOCYTIC. A condition found in many filamentous fungi and some filamentous algae which have no cross walls to the filaments. Thus, even though the organisms are multicellular, there is no distinct separation into cells. The nuclei flow freely in the cytoplasm within the tube-like outer cell wall.

COENZYMES. A nonprotein substance that is closely associated with or bound to the protein component (*apoenzyme*) of an enzyme. Together, the coenzyme and apoenzyme form the complete enzyme known as the *holoenzyme*. The presence of a coenzyme is necessary for enzyme activity. Coenzymes are organic molecules of a size intermediate between the small-molecule intermediary metabolites, which serve as the substrates of enzymatic reactions, and the macromolecular proteins. Each coenzyme acts usually as acceptor or donor of some specific type of atom or group of atoms to be removed from or added to a small-molecule substrate in a reaction catalyzed by the holoenzyme.

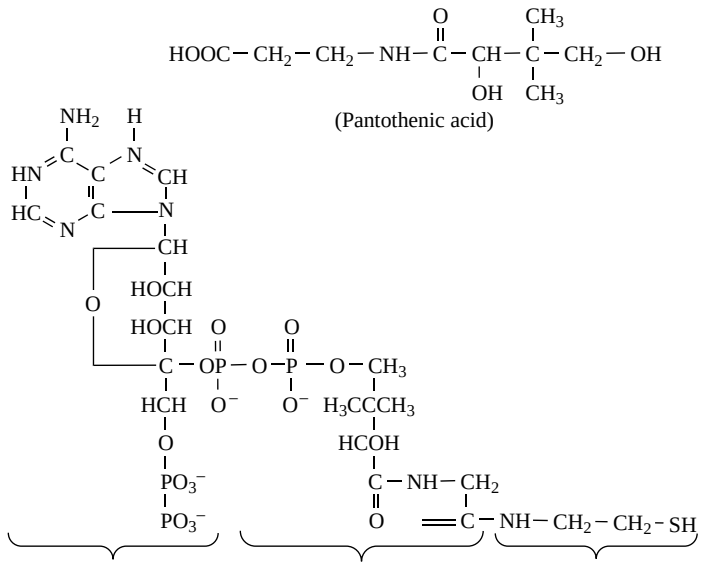

Fig. 1. Structure of CoA, composed of three parts: a nucleotide part derived from 3′-adenosine-5′-phosphate, forming a phosphodiester bond with a 4-phospho derivative of pantothenic acid, and a third part derived from the amino acid, *cysteine*. The side chain −SH group of the latter is free in this compound and is readily acylated, and thus able to act as a carrier for acyl groups in biochemical reactions in which it transfers that group between two substrates.

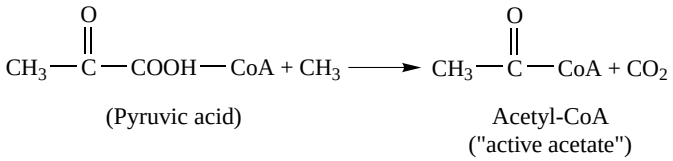
Coenzyme A (CoA). Pantothenic acid is a constituent of coenzyme A, which participates in numerous enzyme reactions. CoA (Fig. 1) was discovered as an essential cofactor for the acetylation of sulfanilamide in the liver and of choline in the brain. It has been established that CoA is involved in many biochemical reactions in the body as an "activator" of normally less reactive carbon fragments and a "transferer" of these fragments to different molecules. CoA is particularly important in the initial reaction of the citric acid cycle of carbohydrate metabolism and energy production. After oxidative decarboxylation of pyruvic acid, CoA combines with the two-carbon acetate fragment to form acetyl-CoA or "active" acetate.



Coenzyme A is necessary for the activation, synthesis, and degradation of fatty acids. Synthesis of cholesterol and ultimately the production of steroid hormones are also coenzyme A dependent.

Nicotinic Acid Coenzymes. Nicotinic acid can be converted to nicotinamide in the body and, in this form, is found as a component of two oxidation-reduction coenzymes (Fig. 2): *nicotinamide adenine dinucleotide*

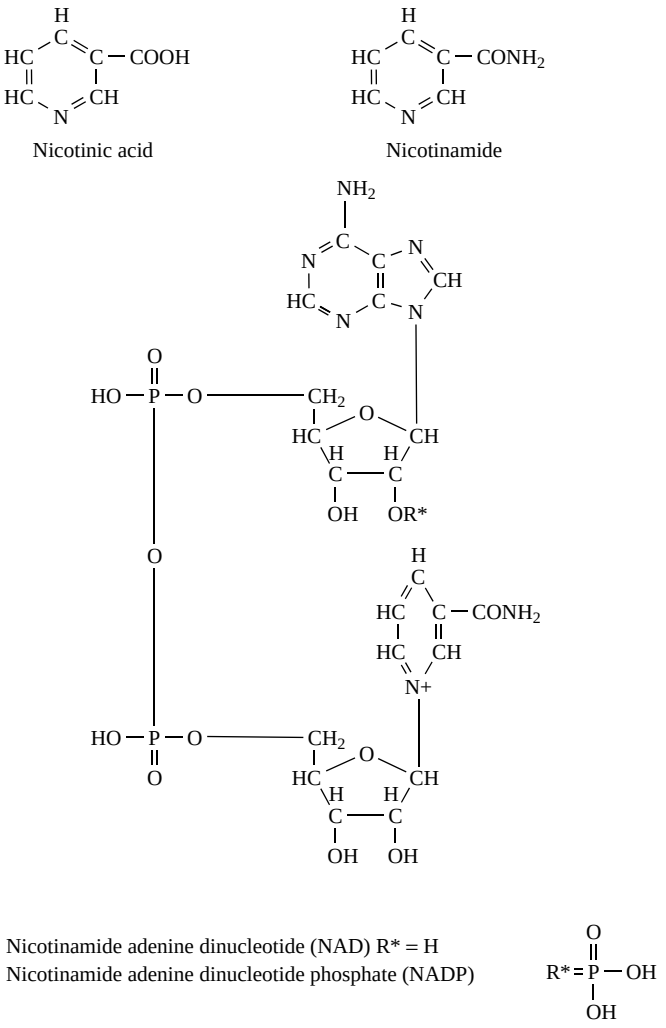


Fig. 2. Structures of nicotinic acid, nicotinamide, and nicotinamide coenzymes.

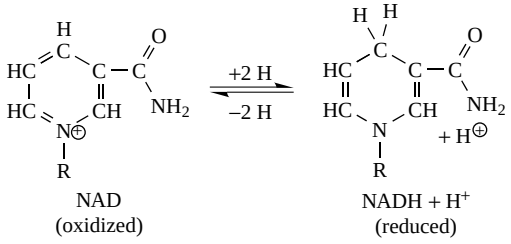

Fig. 3. Oxidized and reduced states of nicotinamide coenzymes as shown in Fig. 2.

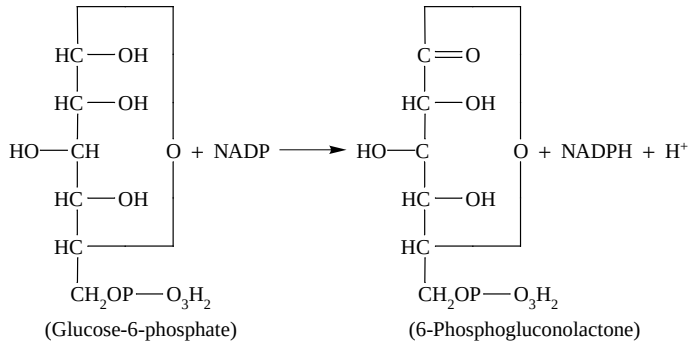
(NAD); and *nicotinamide adenine dinucleotide phosphate* (NADP). The nicotinamide portion of the coenzyme transfers hydrogens by alternating between an oxidized quaternary nitrogen and a reduced tertiary nitrogen. See Fig. 3.

Enzymes that contain NAD or NADP are usually called *dehydrogenases*. In excess of fifty NAD-dependent enzyme systems are known to exist. They participate in many biochemical reactions of lipid, carbohydrate, and protein metabolism. An example of an NAD-requiring enzyme is lactic dehydrogenase, which catalyzes the conversion of lactic acid to pyruvic acid. NADP is an essential coenzyme for glucose-6-phosphate dehydrogenase which catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconic acid. This reaction initiates metabolism of glucose by a pathway other than the citric acid cycle. The alternate route is known as the phosphogluconate oxidative pathway, or the hexose monophosphate shunt. The first step is:



In the biological oxidation-reduction system, reduced NAD (i.e., NADH) is reoxidized to NAD by the riboflavin-containing coenzyme FAD (*flavin-adenine dinucleotide*).

Riboflavin Coenzymes. Riboflavin has been shown to be a constituent of two coenzymes: *flavin mononucleotide* (FMN) and *flavin adenine dinucleotide* (FAD). See Fig. 4. FMN was originally discovered as the coenzyme of an enzyme system that catalyzes the oxidation of the reduced nicotinamide coenzyme, NADPH, to NADP. Most of the many other riboflavin-containing enzymes contain FAD. FAD is an integral part of the biological oxidation-reduction system, where it mediates the transfer of hydrogen ions from NADH to the oxidized cytochrome system. This is illustrated in Fig. 5. FAD can also accept hydrogen ions directly from a metabolite and transfer them, either to NAD, a metal ion, to a heme derivative, or to molecular oxygen. The various mechanisms of action of FAD are probably due to differences in the protein apoenzymes to which it is bound. The oxidized and reduced states of the flavin portion of FAD are shown in Fig. 6.

Decarboxylation Coenzymes. Thiamine, biotin and pyridoxine (vitamin B) coenzymes are grouped together because they catalyze similar phenomena, i.e., the removal of a carboxyl group, −COOH, from a metabolite. However, each requires different specific circumstances. Thiamine coenzyme decarboxylates only alpha-keto acids, is frequently accompanied by dehydrogenation, and is mainly associated with carbohydrate metabolism. Biotin enzymes do not require the alpha-keto configuration, are readily reversible, and are concerned primarily with lipid metabolism. Pyridoxine coenzymes perform nonoxidative decarboxylation and are closely allied with amino acid metabolism.

Folic Acid Coenzymes. The coenzyme forms of folic acid are derivatives of tetrahydrofolic acid, FH_4. See Fig. 7. Folic acid functions as a coenzyme in enzyme reactions which involve the transfer of one-carbon fragments at various levels of oxidation. Vitamin B_2 (*cobalamin*) may be interrelated with folic acid in these reactions. Folic acid and vitamin B_{12} are also considered together since certain clinical anemias can be corrected by administration of either of the two vitamins.

Coenzyme Q. A series of quinones which are widely distributed in animals, plants, and microorganisms, these quinones have been shown to function in biological electron transport systems which are responsible for energy conversion with living cells. The nature and significance of coenzyme Q was first recognized in 1957. In structure, the coenzyme Q group closely resembles the members of the vitamin K group and the tocopherylquinones, which are derived from tocopherols (vitamin E), in that they all possess a quinone ring attached to a long hydrocarbon tail. The quinones of the coenzyme Q series which are found in various biological species differ only slightly in chemical structure and form a group of related, 2,3-dimethoxy-5-methyl-benzoquinones with a polyisoprenoid side chain in the 6-position which varies in length from 30 to 50 carbon atoms. Since each isoprenoid unit in the chain contains five carbon atoms, the number of isoprenoid units in the side chain varies from 6 to 10. The different members of the group have been designated by a subscript following the Q to denote the number of isoprenoid units in the side chain, as in coenzyme Q_{10}. The members of the group known to occur naturally are Q_6 through Q_{10}.

Coenzyme Q functions as an agent for carrying out oxidation and reduction within cells. Its primary site of function is in the terminal electron transport system where it acts as an electron or hydrogen carrier between the flavoproteins (which catalyze the oxidation of succinate

and reduced pyridine nucleotides) and the cytochromes. This process is carried out in the mitochondria of cells of higher organisms. Certain bacteria and other lower organisms do not contain any coenzyme Q. It has been shown that many of these organisms contain vitamin K_2 instead and that this quinone functions in electron transport in much the same way as coenzyme Q. Similarly, plant chloroplasts do not contain coenzyme Q, but do contain *plastoquinones* which are structurally related to coenzyme Q. Plastoquinone functions in the electron transport processes involved in photosynthesis. In some organisms, coenzyme Q is present together with other quinones, such as vitamin K, tocopherylquinones, and plastoquinones; and each type of quinone can carry out different parts of the electron transport functions.

COFFEE TREE AND COFFEE. Of the family *Rubiaceae* (madder family), genus *Coffea*, there are several species of this small tree or shrub, the seeds of which are obtained from a berry-like fruit. The seeds are the

familiar coffee beans of commerce. The green beans are roasted, turning various shades of brown in the process. It is in this form that most people see the coffee bean. Although there are 20 or more species of the coffee tree, two species provide most of the coffee beans of commerce: *C. arabica* and *C. robusta*. The species *C. liberica* is also produced in large quantities. Because *C. arabica* is subject to attacks by insects, the latter two species were developed. The coffee trees mentioned here are unrelated to the Kentucky coffee tree, which is described in a separate entry.

The coffee tree was originally found in Arabia, but is now grown in numerous tropical countries. In addition to a warm climate, the coffee tree requires much rainfall [70 inches (1778 millimeters) or more annually] and it cannot survive droughts. The timing of rainfall also plays an important role, with heavy rain desired early in the season when the fruit is developing and lighter rainfall when the fruit is ripening. *C. arabica* grows best at altitudes of about 2,000 feet (610 meters), whereas *C. liberica* thrives well from sea level up to about 2,000 feet (610 meters). The tree is an evergreen. The blossoms are small and white and the tree appears as covered with a light snow when in full bloom. The berries ripen between 6 and 7 months after flowering. The tree blooms and produces berries once each year, the exact time depending upon species and location. A tree will bear within 5 years from initial seeding and will yield good beans for commercial markets within 8 years. It will produce satisfactory commercial beans for a period of about 20 years thereafter and good beans, but in fewer numbers, for an additional number of years. Although some trees are greater producers, a normal tree will yield from 1 to $1\frac{1}{2}$ pounds (0.45–0.68 kilogram) of green coffee beans each year.

It is recorded that the Arabs cultivated the coffee plant as early as 600 A.D. It is first mentioned in the literature in about 900 A.D. Because of its stimulating qualities, its pleasant flavor and aroma, coffee was first recognized as a food and only later brewed as a beverage. The beverage first became popular in Arabia, gradually spreading into Turkey (circa 1554), thence to Italy (1615) and France (1644). The coffee plants were jealously guarded for many years, but over a period of years, plants were smuggled out of Arabia. The Dutch obtained a few early plants for botanical gardens in the Netherlands. After successful growth under controlled conditions, plants were sent to Java for cultivation and ultimately the coffee plant spread throughout the tropics. The first plants were brought to the Americas in about 1723. The principal countries now exporting it are Brazil, the greatest producer and supplying about 30% of the coffee consumed in the United States, Colombia, Liberia, Ecuador, and other countries of Africa and the Middle East.

The tree averages from 15 to 30 feet (4.5 to 9 meters) in height. The branches start near the base of the trunk. There are wide, long leaves in clusters at the end of each branch. As the tree grows old, branching is less and leaves and berries become less plentiful. The tree is set in rows several feet apart. The native red soil in the environs of São Paulo seems particularly suited to successful coffee production. The berry is dried in large, frequently raked vats in the sun; or oven drying can be used. The ultimate producers of commercial coffees usually blend beans from various sources to obtain the desired, characteristic flavor and aroma of their brand. Mocha and Java coffees are fragrant varieties of Arabian coffee, for example. Medellin coffee from Colombia provides richness of flavor. Brazilian coffee provides an excellent base for blending. Costa Rican coffee is known for fragrance, El Salvadorian coffee for full body, and Mexican *coatepec* for a wine-like flavor. Chicory, the dried, roasted, and ground root of a plant of species *Cichorium intybus*, is frequently blended in European coffees for special flavor. The amount of chicory used may range from 5 to 40%.

The principal coffee-producing regions of the world are shown in Fig. 1.

Coffee Processing. Ripening of the fruit of the coffee tree does not occur within a relatively short time span, as compared with most fruit trees, but extends over a span ranging from a minimum of 3 weeks up to several months. Depending upon the uniformity of planting, mixture of species, and other factors, some trees may be flowering where others are ripening within the same area. The aroma and flavor of coffee are developed during the roasting of the green beans. The most important development in coffee roasters occurred in the early 1940s when a continuous roaster became available. Gas heat temperatures in the roaster range between 450 and 500 °F (232–260 °C). Equipment is designed to provide a continuous tumbling action of the beans throughout their passage in the roaster. Incoming beans lose about 18% of their weight during roasting, most of the weight loss due to expulsion of water, but some occurs from releasing carbon dioxide gas and pyrolysis. For marketing as ground roast, the roasted beans go through a series of size-reduction operations. Great progress has been made in the packaging of ground coffee during the past few decades, with the introduction of freeze-drying and vacuum packaging. Improperly packaged coffee ages within just a few weeks. The aroma changes from a full aroma to flat to brittle to rancid and finally develops a cocoa-like odor, at which time the coffee is quite unfit for brewing. Oxygen is the main deterrent with packaged ground coffee, whereas moisture causes most of the problems with instant coffee.

Instant Coffees. Ground roast is the starting material for instant coffees. Large batteries of percolators of various designs are used to make the liquid coffee extract. In a typical large installation, there may be a battery of up to 8 stainless steel columns, ranging from 1 to 4 feet (0.3 to 1.2 meters) in diameter and from 6 to 20 feet (1.8 to 6 meters) in height. The vessels are designed to operate at pressures ranging from about 10 to 20 atmospheres. The several percolating columns are connected in series. A representative modern soluble coffee plant is diagramed in Fig. 2. See also Fig. 3.

Decaffeinated Coffees. The first coffee decaffeination process was developed in Germany as early as 1908. Since then, scores of patents have been granted for various decaffeination schemes. Earlier decaffeinated coffee (e.g., *Kaffee HAG*, etc.) was available only as decaffeinated ground roast. Once decaffeinated in the green stage, the beans can be subjected to percolation and drying equipment just as any green coffee beans. The first soluble decaffeinated coffee (Sanka) was introduced in 1946. Solvents can be used to extract the caffeine, but growing in preference is the use of water extraction (natural process). This removes up to 98% of the caffeine in a period of about 8 hours of residence time.

Among the volatile compounds contained in regular coffees are aldehydes, ketones, alcohols, esters, pyridine, sulfur compounds, mercaptans, hydrogen sulfide, carbon disulfide, and hydrocarbons. Acetaldehyde, which occurs in fruits, has a pungent fruity aroma and its presence is usually confined to very freshly roasted and ground coffee. The acetaldehyde is retained in spray-dried powders and is more pronounced than in roast ground coffees. Acetone is present in some coffees up to a concentration of about 60 parts per million. The odor is sweet and pungent, and when

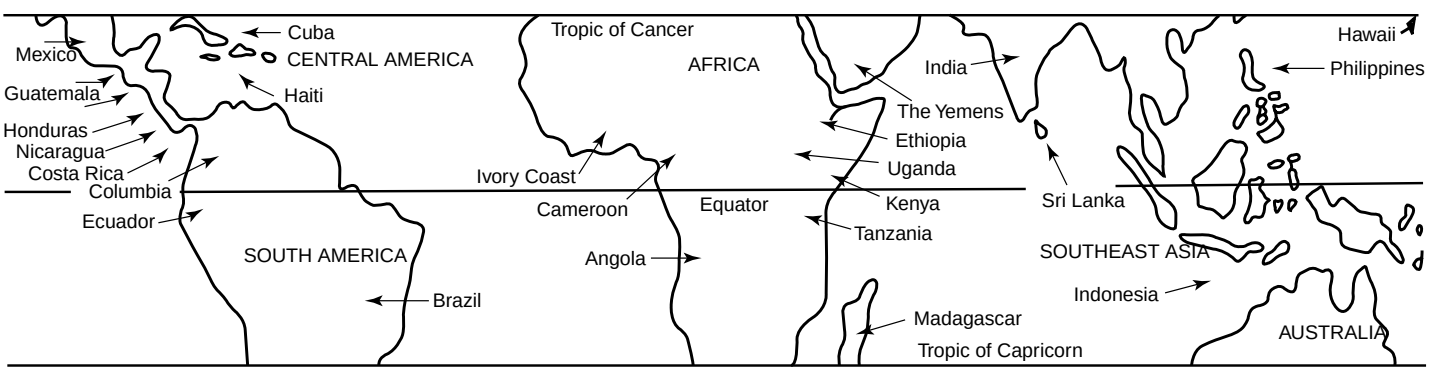

Fig. 1. The principal coffee-producing regions of the world are located within the equatorial band bordered on the north by the Tropic of Cancer and on the south by the Tropic of Capricorn. The altitude of growing locations ranges from sea level to 4000 feet (1220 meters), but is mainly between 1000 feet (305 meters) and 4000 feet (1220 meters).

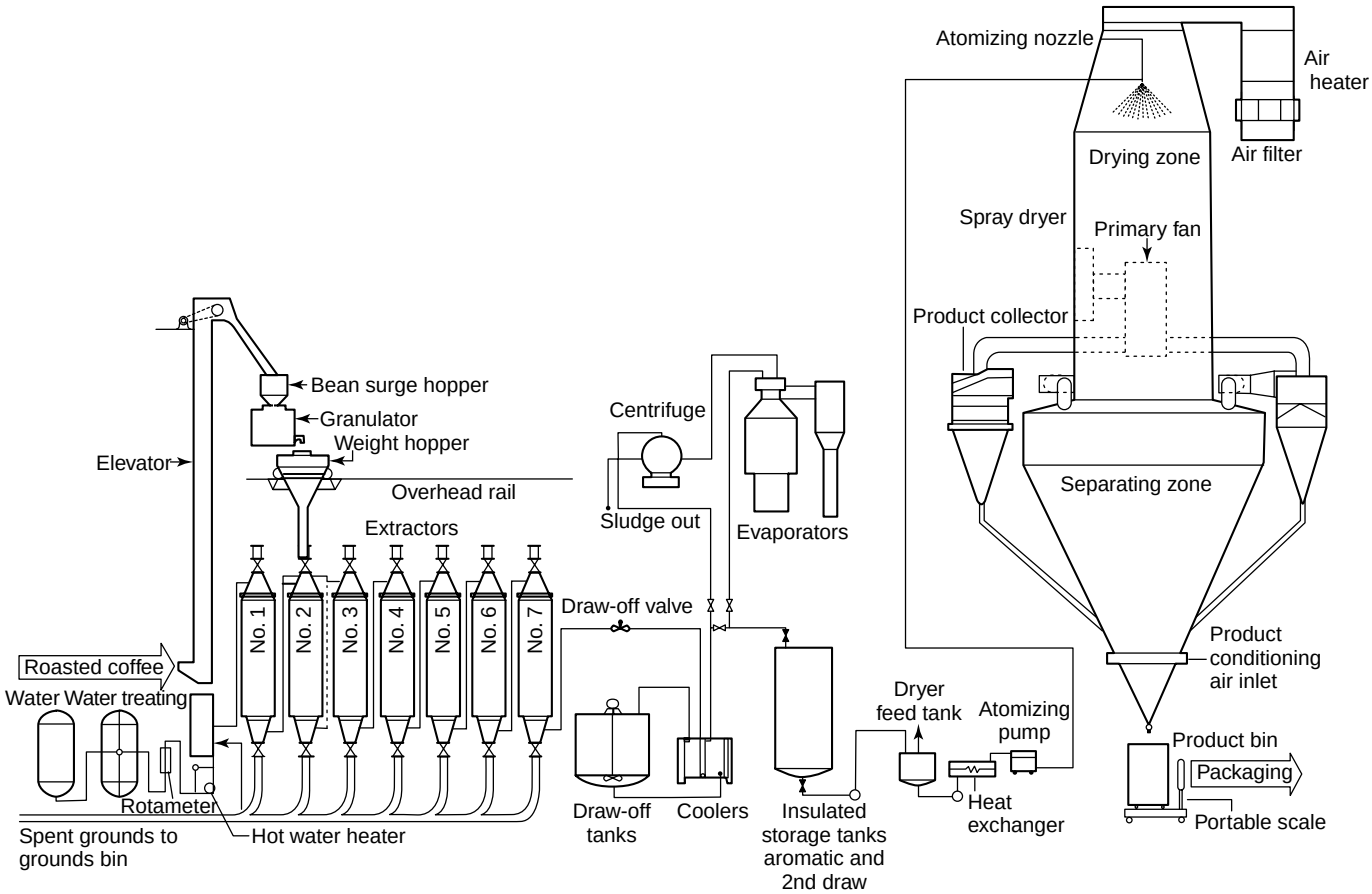

Fig. 2. Representative modern soluble coffee plant. This extraction system is designed to provide two separate product streams. The first is a highly aromatic extract produced by passing water at moderate temperatures through the bed of fresh roasted and granulated coffee. The second stream results from passing high-temperature water through the cells containing the more spent grounds to bring about a maximum recovery of solids from the system. Both product streams are cooled as they leave the extraction system.

The aromatic first-draw product is mixed with the second-draw product after it has been concentrated by thermal evaporation. The combined streams serve as dryer feed. The first-draw product may be used at the concentration leaving the extraction system. In large-capacity plants, it can be concentrated by a freeze-concentration process in which water is removed in the form of ice crystals.

The second draw from each cell is cooled as it leaves the extraction system, clarified and concentrated prior to delivery to the drying system. Clarification of second draw is achieved by holding at approximately 5°C (41°F) for a period of time and then passing it through a continuous desludging type centrifuge. The time period required depends upon such variables as yield and blends used.

At least 3 types of evaporators have been used for the concentration of coffee extracted. Included are the falling-film type, the plate type, and the rotating conical film type. The first two can be designed to reuse the vapors, thereby minimizing energy requirements, but this is at the expense of product hold-up time, in comparison with the rotating conical film type. Heat exchangers, tanks and pumps, plus all interconnecting piping in the processing section, are usually included as part of an engineered package when the system is procured. The product of the process may be used for making either spray-dry or freeze-dry product. (*Stork Bowen Engineering, Inc., Somerville, N.J., member of Vmf-Stork, the Netherlands.*)

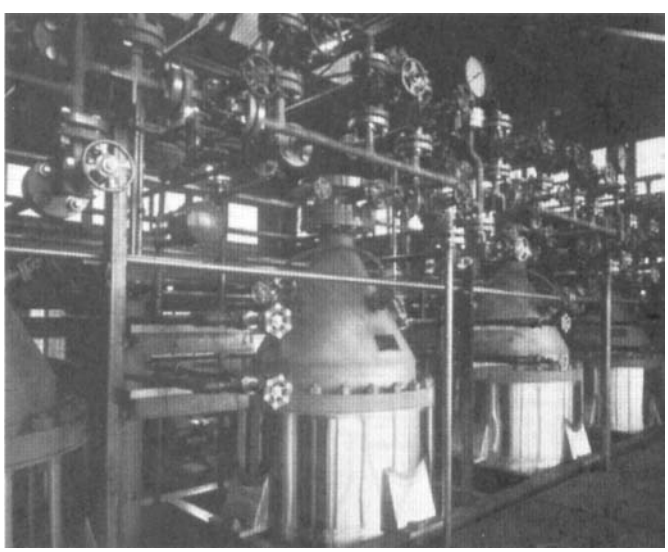

Fig. 3. Close-up of extractors used in soluble coffee products plant. (*Stork Bowen Engineering Inc., Somerville, New Jersy.*)

acetone is not present in excessive amounts, it tends to contribute to the sweetness and smoothness of the coffee aroma. Diacetyl provides a definitely rich note to coffee aroma and may be present up to about 20 parts per million. Esters also are present in coffee up to about 20 parts per million. Methyl acetate contributes most to coffee essence. Pyridine, which can occur in a concentration up to about 200 parts per million, has an undesirable odor and sharp taste. The compound results from the decomposition of trigonelline during roasting. Coffee processors must deal with numerous substances present in parts per million or even parts per billion concentrations. There are surprising combinations of rather foul-smelling (individually) substances that provide pleasant sensations to the taste and odor receptors when in combination. As coffee becomes stale, the original fresh and pleasant odor and taste contributors tend to volatilize at different rates, disturbing the original effects and allowing the less agreeable components to take command. Indicative of the complexities is the fact that an effective, acceptable synthetic coffee still remains to be developed.

Coffee and Health. Studies of the effects of coffee and caffeine on health and, in particular, on the cardiovascular system, have been conducted over many years. The general consensus is that the studies have been too numerous and too inconclusive, which, as one professional has observed, leads to the adage — "do everything in moderation."

The Grobbee et al. study completed in 1990 concludes: "The findings do not support the hypothesis that coffee or caffeine consumption increases the risk of coronary heart disease or stroke." This was a very extensive study of a cohort of 45,589 men in the United States who were 40 to 75 years old (in 1986) and who had no history of cardiovascular disease. The study was critiqued, as is the pattern of studies on this topic, immediately after publication in October 1990.

One frequently voiced complaint of coffee-health studies is the lack of definition of a "cup of coffee," which can vary in terms of strength, method of brewing, and all manner of other factors which do not define coffee intake in terms of precise caffeine "dosage." Home-brewed coffee can range widely in terms of caffeine content, and certainly this is even truer for restaurant coffee.

Unfortunately, it appears that the coffee-health topic will continue to be measured time and time again to fuel the debate among professionals.

COGENERATION (Electricity and Thermal Energy). During the early 1900s, about half of the power generated was located at industrial plant sites — for two reasons: (1) lack of reliable central generating plants; and (2) electrical energy costs billed by central power plants often were higher than plant-generated power and control over those costs was beyond the reach of even the largest of industrial consumers. As the costs of centrally generated electricity went down and as reliability greatly improved, the incentives for industrial plants to self-generate power essentially disappeared for three-quarters of a century. However, in the 1970s these incentives reappeared, notably as the result of very sharp increases in natural gas, oil, coal, and other fuel prices; and the many promises of nuclear power suffered numerous setbacks.

Many industrial facilities, particularly in the chemical and bulk materials processing field, as exemplified by petroleum refineries and petrochemical plants, require lots of energy — in two forms: (1) electricity to power production and handling equipment; and (2) thermal power (heat) in the form of steam and hot air. With *cogeneration*, an industrial plant no longer need operate on the basis of two essentially separate energy systems: (1) electrical energy purchased from a separate utility; and (2) site generation of thermal energy. Cogeneration, which takes advantage of much increased knowledge pertaining to energy utilization and conservation gained during the past decade, gives the industrial energy user better control over the energy system at a given plant site.

Cogeneration may be defined (Benz, 1986) as involving the sequential utilization of energy to produce electric power and a lower level of thermal energy, such as process heat. A petroleum refinery, for example, will use thermal energy extensively, typically the equivalent of 5 to 10% of the crude oil throughput as fuel. Because refineries tend to operate at reasonably steady rates of throughput, they usually are good candidates for cogeneration schemes.

To date, attractive applications of cogeneration in refineries are: (1) integration of cogeneration into the refinery utility plant; (2) utilization of gas turbine exhaust to provide combustion air to a process heater; and (3) utilization of petroleum coke conversion and cogeneration in the production of hydrogen or syngas, a combination that is sometimes referred to as *polygeneration* — because it produces power, process heat, and chemical feedstock. The latter application is an excellent example of energy management and conservation. Once the concept of cogeneration is recognized, there are many alternatives and options, which become evident when the energy requirements of a given plant are audited with energy management in mind. Authorities observe that excellent economic potential for cogeneration exists within a typical refinery, notably when cogeneration facilities are installed as part of a major refinery expansion or modernization program.

As pointed out by Benz et al., at current energy prices one of the most attractive applications for cogeneration is the addition of a gas turbine/HRSG (heat recovery steam generator) to the refinery utility plant.

Where economically feasible, the cogeneration of electricity along with process steam is not limited to any particular prime fuel, such as coal, petroleum coke, syngas, or natural gas. At one large chemical manufacturer in the eastern United States, as reported by Blasius (1985), the fuel is municipal solid waste (MSW), where about 9000 metric tons of MSW per week are converted on a continuous basis to saturated steam (1034 kPa; 150 psig) and 120 MW of electricity to produce various chemical intermediates and products.

In response to the energy crisis of the 1970s, the U.S. Congress enacted the National Energy Act, which includes the Public Utilities Regulatory Policies Act (PURPA). As pointed out by Zambo (1986), the Congress sought to achieve its objective by increasing the efficiency of use of fuel resources and encouraging the use of nontraditional fuels, such as waste heat, garbage, solar energy, and wood. PURPA removed a number of obstacles to cogenerators, such impediments having been developed over many years by the electric utility industry and utility regulators. Under PURPA, cogenerators are exempt from regulation as electric utilities under both federal and state laws; utilities are required to interconnect in parallel with cogenerators; utilities are required to provide electric power to cogenerators at nondiscriminatory rates; and utilities are required to purchase electricity from cogenerators at the utility's "avoided cost," i.e., the cost the utility would otherwise incur if it purchased an equivalent amount of electricity from another source. The situation currently is much debated and is not expected to settle down fully for a number of years. See also **Energy**.

COHEN, STANLEY (1922–). Cohen, the son of Russian Jewish immigrants, was born in Brooklyn, New York on 17 November 1922. He contracted polio as a child and a permanent limp encouraged him to intellectual study. He read chemistry at Brooklyn College and the University of Michigan, Ann Arbor, where, in 1948, he took his PhD on nitrogen metabolism in the earthworm. From then until 1952 he did pediatric work at the University of Colorado. Between 1952 and 1967 he engaged in cancer research at the American Cancer Research Society in St Louis. In 1953

he joined the Department of Zoology at the University of Washington, St Louis. From 1959 until 1986 he was Professor of Biochemistry at Vanderbilt University, Nashville, Tennessee. Following retirement in 1986 he has been continuing as a research professor in biochemistry at the American Cancer Society at Nashville. He was elected to the National Academy of Sciences in 1980.

In the 1950s, while working at the University of Washington, he and the Italian-American cell biologist Rita Levi-Montalcini isolated a 44,000 molecular weight nerve growth factor (NGF) from mouse salivary glands. Chemically this was made up from three proteins. This discovery accelerated research in nerve physiology. While injecting NGF into newborn mice, Cohen noted that it led to precocious development of eyes and teeth. He realized that some additional factor was at work and soon identified a 49-amino-acid peptide in salivary extract, which he named the epidermal growth factor (EGF). This substance aided the healing of corneal wounds and was a factor in the growth of epithelial cells. EGF binds to specific receptors that lie partly on the outside of a cell and partly inside, where it releases enzymes that promote growth. He then went on to identify a similar factor in human saliva and urine, and showed that it was identical with a peptide hormone, urogastrone, found in the stomach. NGF and EGF are hormones that are principally used for growth during embryonic development. In 1986 he was awarded the Nobel Prize in Physiology or Medicine jointly with Levi-Montalcini for "discoveries which are of fundamental importance for our understanding of the mechanisms which regulate cell and organ growth." Cohen's work was of medical significance, especially for research and treatment of cancer, where it is supposed that viral oncogenes mimic EGF at reception sites. It has also had bearings on the treatment of Parkinson and Alzheimer diseases, as well as genetic disorders such as dwarfism, and the healing of skin lesions. In subsequent years he has continued to work on EGF, particularly in the context of cancer research. See also **Levi-Montalcini, Rita (1909–Present)**.

COHERENCE. In radar, a relation between two wave trains such that, when they are brought into coincidence, they are capable of producing interpretable interference phenomena. This is limited to those wave trains, which have fixed or slowly varying phase relationships with each other. In contract are the rapid interference phenomena produced by the superposition of the more or less randomly scattered waves from hydrometeors.

COHERENCY. As applied to metallurgy, this term signifies a continuity between the lattice of a parent crystal and that of a precipitate particle embedded in the former. In general, a state of coherency can only exist as a result of strains set up in both the parent phase and the precipitate. A phase boundary in the ordinary sense does not exist in this case.

COHERENT. 1. Of electromagnetic radiation, being in phase, so that waves at various points in space act in unison, as in a laser producing coherent light. See also **Laser**.

2. Having a fixed relation between frequency and phase of input and output signal.

COHERENT CARRIER. A carrier wave derived from a continuous-wave signal in such a way that its frequency and phase have a fixed relationship to the frequency and phase of the reference signal.

COHERENT DETECTION. The conversion of the intermediate frequency (IF) signal in a Doppler radar or lidar to I and Q channels so that the phase of the echoes is preserved.

Typically two mixers, fed by IF reference signals in phase quadrature, are used to convert the frequency components in the IF signal, centered at the IF frequency, to two video signals with frequency components centered at zero frequency, without modifying the information content.

AMS

COHERENT ECHO. A radar echo whose phase and amplitude at a given range remain relatively constant. Hills, buildings, and slowly moving point targets such as ships are examples of objects chat produce coherent radar echoes. Volume targets (such as clouds and precipitation) give noncoherent echoes. The classification of an echo as coherent or noncoherent is closely related to the spatial resolution (beam width) of the radar or the volume occupied by the radar pulse. Thus, small atmospheric inhomogeneities, which give rise to noncoherent echoes, would give coherent echoes if the radar volume were reduced in size to the order of magnitude of the inhomogeneities themselves.

COHERENT INTEGRATION. The time-domain integration of measurements in a coherent radar over a sequence of pulses or over an observation interval, prior to estimating the signal properties, to improve the signal-to-noise ratio while minimizing signal processing. Also called *coherent averaging or time-domain averaging*.

For such integration to be effective, the integration period must be limited to the time over which the phase of the signal relative to a reference phase does not change substantially (i.e., the coherence time of the signal). The effect of the coherent integration process is to reduce the effective data sampling rate and the Nyquist frequency.

AMS

COHERENT LIGHT. See **Laser**.

COHERENT STRUCTURES. Three-dimensional regions in a turbulent flow with characteristic structures and lifetimes in terms of velocity, temperature, etc., that are significantly larger or longer-lived than the smallest local scales.

Much of the turbulent transport, conversion of mean flow energy into turbulent eddies, nonlinear transfer into smaller scales, and eventual dissipation is associated with coherent structures. Examples include gust microfronts and horseshoe vortices in the surface layer, convective plumes, and longitudinal roll vortices.

See also **Langmuir Circulation**; and **Longitudinal Rolls**.

COHN, FERDINAND JULIUS (1828–1898). Cohn was a German botanist, who developed many of the principal concepts of modern bacteriology.

Ferdinand Julius Cohn was the eldest son of a Jewish merchant in Silesian Breslau. After school he took up his university studies in sciences and mathematics at Breslau University in 1844. Here Christian Nees von Esenbeck and Heinrich Göppert turned his attention to the field of botany, to which he was to make important contributions. His Jewish confession meant that Cohn was, despite various petitions, barred from examinations in Breslau and so he went to Berlin University in 1846. Here the chemist Eilhardt Mitscherlich, the physiologist Johannes Müller and Gottfried Ehrenberg, well known for his work on microscopic organisms and plants, were among his teachers. Cohn took his doctorate in 1847. He was still in Berlin during the 1848 revolution, and he gave a vivid account

of this event in his diary published by his wife in 1901. See also **Plant Sciences (The History)**.

Having returned to Breslau in 1849, Cohn became a lecturer (Privatdozent) in 1850, extraordinary professor in 1859 and ordinary professor of botany in 1872. In 1866 he founded a new institute for plant physiology.

Cohn's initial work was on microscopic algae and fungi, where he was part of a movement headed by the histologist Max Schulze to place more emphasis on the cellular protoplasm instead of cellulose walls in relation to the definition of cells. He incorporated most of this early work into his *Untersuchungen über die Entwickelungsgeschichte der mikroskopischen Algen und Pilze*, published 1854, where he also first wrote about bacteria, the subject that would finally bring him fame. From 1870 onwards, Cohn published his classic work on bacteria in his newly founded journal *Beiträge zur Biologie der Pflanze*. He gave a definition of bacteria as 'chlorophyll-free cells of round, oblong or cylindrical shape that exclusively multiply by transverse division and exist either isolated or in cell-families', developed a taxonomic system of four morphological forms (cocci, bacilli, vibrios and spirilli) and strongly argued that they are form-constant monomorphic organisms. In the course of this work, Cohn provided arguments against pleomorphism and spontaneous generation, most notably by defining a spore stage of increased endurability that could account for the reappearance of certain bacterial species after boiling. See also **Bacteriology (The History)**.

Cohn's concepts of bacterial specificity and the spore stage came to be fundamentalfor medical bacteriology. Robert Koch started his investigations by taking Cohn's concepts from botany to pathology. Cohn was the first to realize the breakthrough that Koch'swork on anthrax marked and had it published in his journal in 1876. See also **Koch, Heinrich Hermann Robert**.

CRISTOPH GRADMANN, University of Heidelberg, Heidelberg, Germany

COIL. This term applies to one or more turns of a conductor when wound as a definite unit of an electrical circuit. Thus there is the choke coil, or, as it is sometimes called, impedance coil, as a number of turns of wire forming a coil used primarily for its reactance effect. The transformer is a unit of one or more coils used for transferring electrical energy by magnetic induction. Coils are particularly important in communications circuits where they serve in the above capacities but also form parts of the tuned circuits that make possible the complex systems. While the coil is ordinarily used for its inductive properties it inherently has both resistance and distributed capacity. The former is because of the resistance of the wire of which it is wound. The latter is due to the potential difference between turns, which are separated by the turn insulation. At high frequencies this distributed capacity becomes extremely important and limits the usefulness of a given coil. Various special winding schemes have been used to minimize this effect. Electrical machines have coils as essential components; for example, field coils, and armature coils.

COINCIDENCE. A term used in counter technology to denote the occurrence of counts in two or more detectors simultaneously or within an assignable time interval. A *true coincidence* is one that is due to the detection of a single particle or of several genetically related particles. An *accidental, chance*, or *random coincidence* is one that is due to the fortuitous occurrence of unrelated counts in the separate detectors. A *delayed coincidence* is the occurrence of a count in one detector at a short, but measurable, time later than a count in another detector, the two counts being due to a genetically related occurrence such as successive events in the same nucleus.

COKITE. The term applied by Lacroix in 1917 to natural coke, the result of the contact metamorphism of coal beds.

COLCHICINE. See **Alkaloids**.

COLD-AIR POOL. See **Meteorology**.

COLD-CATHODE IONIZATION GAGE. A ionization gage (vacuum gage) in which the ions are produced by a discharge between two electrodes, both near room temperature. The discharge usually takes place in the presence of a magnetic field which lengthens the path of the electrons between cathode and anode. One form of gage is a transparent tube in which the color and form of a cold-cathode discharge, without the presence of a magnetic field, give an indication of the pressure and the nature of the gas. The Philips ionization gage, or Penning gage, is a cold-cathode ionization gage in which a magnetic field is used. Various modifications of the Penning gage are named after the inventors, Certain types are referred to as magneton vacuum gages.

See also **Vacuum**.

COLD-FLOW TEST. A test of a liquid rocket without firing it to check or verify the efficiency of a propulsion subsystem, providing for the conditioning and flow of propellants (including tank pressurization, propellant loading, and propellant feeding).

COLD POLE. The location that has the lowest annual mean temperature in its hemisphere. In the Northern Hemisphere the cold pole is usually placed at Verkhoiansk in Siberia (67°33′N, 133°24′E) with an annual mean temperature of −16 °C (3 °F) [January: −50 °C (−59 °F), July: 16 °C (60 °F)], but the country around Verkhoiansk is very mountainous, and lower winter temperatures are found in some of the valleys. At Oimekon, for example, the average January temperature is probably below −51 °C (−60 °F). In the Southern Hemisphere the cold pole is near 80°–85 °S and 75°–90 °E. International Geophysical Year stations located inland on Antarctica have recorded several temperatures well below −73 °C (−100 °F).

COLD-PRESSOR TEST. A test for measuring the response of heart and blood pressure to the stress of plunging an extremity (foot or hand) into ice water. The normal response is an increase in both heart rate and blood pressure.

COLD SEEPS. Cold Seeps occur mostly along continental margins, where gases (methane — sometimes as methane-hydrate ice — and hydrogen sulfide) and oil seep out of the sediments and also provide abundant energy for eubacteria, and archaea, which are the basis of the foodchain. Methane (or natural gas, identical to that used by humans) freezes in cold and high pressure, melting above about 600 m (1,969 feet) depth. There, cold methane seeps out of the bottom in streaming bubbles, sometimes called a *cold vent* instead of a seep. Cold seeps are distinct from hydrothermal vents: the former's emissions are of the same temperature as the surrounding seawater, whereas the latter's emissions are super-heated. Cold seeps constitute a biome supporting several endemic species.

Entire communities of light independent organisms — known as extremophiles — develop in and around cold seeps, most relying on a symbiotic relationship with chemoautotrophic bacteria. These bacteria, both archaea and *eubacteria*, process sulfides and methane through chemosynthesis into chemical energy. See also **Chemosynthesis**. Higher organisms, namely vesicomyid clams and siboglinid tube worms Fig.1 use this energy to power their own life processes, and in exchange provide both safety and a reliable source of food for the bacteria. Other bacteria form mats, blanketing sizable areas in the process.

Unlike hydrothermal vents, which are volatile and ephemeral environments, cold seeps emit at a slow and dependable rate. Likely owing to the differing temperatures and stability, cold seep organisms are much longer-lived than those inhabiting hydrothermal vents. Indeed, recent research has revealed seep tubeworms to be the longest living noncolonial invertebrates known, with a minimum lifespan of between 170 and 250 years.

Cold seeps were first discovered in 1984 by Dr. Charles Paull in the Monterey Canyon, just off Monterey Bay, California, at a depth of 3,200 meters (10,499 feet). Since then, seeps have been discovered in other parts of the world's oceans, including the Gulf of Mexico, the Sea of Japan, and in waters off the coast of Alaska. The deepest seep community known is distributed between the Kuril and Japan trenches and the Kashima seamount in the Sea of Japan, at a depth of 5,000 to 6,500 meters (16,404 to 21,325 feet). The actual discovery of vents and seeps occurred during dives of manned submersibles. Later discoveries of such sites have come about from direct observations of the sea floor using manned or unmanned submersibles (i.e. remotely operated vehicles or ROVs), and we now suspect that cold seeps are a common component of continental borderlands, where fluid flow through the continental crust may be controlled by various processes. See also **Ocean**.

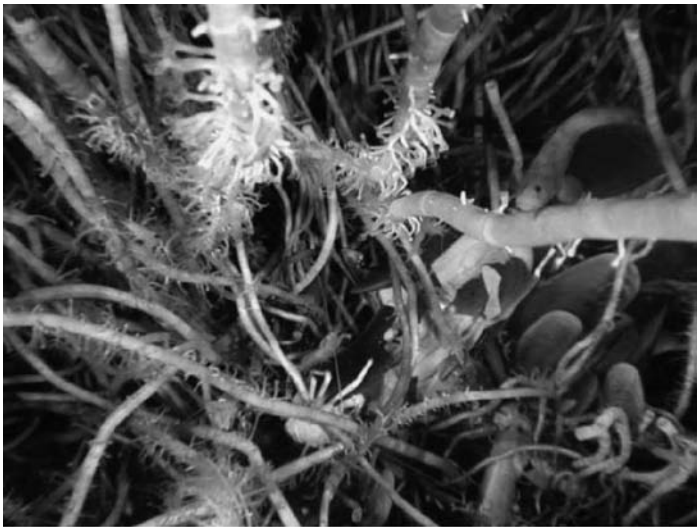

Fig. 1. Tubeworms, soft corals and chemosynthetic mussels at a seep located 3,000 meters (9,843 feet) down on the Florida Escarpment (~100 miles (~161 kilometers) off the west coast of the Florida peninsula). Eelpouts, a Galatheid crab and an alvinocarid shrimp feed on mussels damaged during a sampling exercise. (Image courtesy of NOAA).

Monterey Bay Cold Seeps

In the Monterey Bay region, cold seep communities were first discovered in the axial valley of the Monterey Submarine Canyon during dives in the research submersible ALVIN [Embley et al. 1990]. The presence of seep communities was suspected in Monterey Bay from samples of vesicomyid clams (bivalves associated with seeps) dredged from the bay during research cruises. Seeps have recently been discovered at three more sites under distinctly differing geologic settings using the remotely operated vehicle (ROV) *Ventana*, operated by the Monterey Bay Aquarium Research Institute (MBARI) http://www.mbari.org/. These sites are presently being investigated by scientists from MBARI, Monterey Bay Aquarium, U.S. Geological Survey http://www.usgs.gov/, Hopkins Marine Station http://www-marine.stanford.edu/, and Moss Landing Marine Laboratories http://www.mlml.calstate.edu/. Research topics include the distribution and extent of cold seeps in Monterey Bay, geologic settings under which they exist, and characteristics of biological communities found at seeps.

Studies of the pore water chemistry of seeps indicate that considerable variation exists in the concentrations of sulfide, methane, and other chemical constituents at seeps in the Bay [Barry et al.], and that the mechanisms regulating fluid flow are also vary among sites [Barry et al.]. Fluid seepage at one seep region (Mt. Crushmore) is suspected to result from artesian flow of rainwater which enters a sandstone aquifer (Purisima Formation) in the Santa Cruz mountains and is released along the walls of Monterey Canyon after percolating downslope 1,000 meters (3,281 feet) or more. Analysis of pore fluids from Mt. Crushmore seeps show these fluids to be low in sulfide (~100 μM) and lacking methane. In contrast, fluids at the Clam Flat seep, where fluid flow is thought to derive from tectonic-based sediment compression, had nearly 100 times more sulfide (11,000 μM) and very high methane concentrations (300 μM). Pore fluids at a third site (Clam Field) had high sulfide (6,000 μM), and low methane (10 μM).

COLD SHORT. A metallurgical term to denote a brittle condition in a metal at temperatures below the recrystallization temperature.

COLD-TYPE OCCLUSION. See **Meteorology**.

COLD WALL. The steep water-temperature gradient between the Gulf Stream and (a) the slope water inshore of the Gulf Stream or (b) the Labrador Current. See **Ocean**.

COLD WAVE. 1. As used in the U.S. National Weather Service, a rapid fall in temperature within 24 hours to temperatures requiring substantially increased protection to agriculture, industry, commerce, and social activities. Therefore, the criterion for a cold wave is twofold: the rate of temperature fall, and the minimum to which it falls. The latter depends upon region and time of year.

2. Popularly, a period of very cold weather.

COLD-WORKED METAL. When metals are plastically deformed at a relatively low fraction (frequently <0.5) of their absolute melting temperatures, they are normally said to be *cold-worked*. An increase of *hardness* or strength is normally associated with such deformation. This hardening can be relatively stable as long as the metal is not heated high enough to cause extensive recovery and recrystallization to occur (see **Annealing**). In metals with high melting points, such as the alloys of iron, copper, and nickel, deformation at room temperature is normally considered to be cold-working. On the other hand, room temperature deformation of a low melting point metal such as lead is more properly designated hot-working. In this regard, it is interesting to note that lead is not normally hardened by room temperature deformation.

Cold-working is frequently used for hardening of commercial metal products. Thus, piano wire and the wire used in bridge construction obtain their hardness as a result of the final wire drawing operations. Sheet stock is often supplied in different degrees of hardness obtained by cold-rolling to the desired hardness. Mechanical working is sometimes the only feasible way to harden specific metals and alloys.

COLEMANITE. The mineral colemanite is a borate of calcium corresponding to a formula that is perhaps best represented as $Ca_2B_6O_{11} \cdot 5H_2O$. It occurs either as massive deposits or in monoclinic crystals. It has a subconchoidal fracture; hardness, 4–4.5; specific gravity, 2.42; vitreous to adamantine luster, may be colorless to milky white, grayish or yellowish; transparent to translucent. Colemanite was found originally in Death Valley, Inyo County, California, and has since been found rather widely distributed in San Bernardino, Los Angeles, Kern and Ventura Counties, California, as well as in Clark, Esmeralda and Mineral Counties in Nevada.

Colemanite was, until the discovery of kernite, the chief source of borax. Kernite, $Na_2B_4O_7 \cdot 4H_2O$, because of its easy solubility in water, has displaced very largely other boron-bearing minerals as a source of borax. Colemanite, kernite and inyoite (probably $Ca_2B_6O_{11} \cdot 5H_2O$); are lake deposits associated with other and rarer boron minerals, laid down during periods of volcanic activity or resulting from the leaching of the adjacent Tertiary sedimentary formations. Colemanite was named for Mr. William T. Coleman of San Francisco; kernite and inyoite were named from Kern and Inyo Counties, California.

COLEOPTER. An aircraft having an annular (barrel-shaped) wing, the engine and body are mounted within the circle of the wing.

COLEOPTERA. The beetles. An order of insects usually recognizable by the thickened wing covers, which meet in a straight line down the middle of the back. These wing covers, or elytra, are modified forewings. In most species of beetles they are thickened or horny but in some they are soft. In some species they are divergent and in some they are short, leaving much of the abdomen exposed. The typical condition of the elytra is found outside of this order only in the earwigs. Beetles have biting mouth parts and a complete metamorphosis in which the larval stage is often a grub.

This order of insects is the largest group of its rank in the animal kingdom, with almost 200,000 described species. It embraces almost the entire range of adaptation of the class, although very few beetles are parasitic. Many species are of economic importance.

An excellent reference on the systematics of beetles is "Monographie der Familie Platypodidae, Coleoptera," by Karl E. Schedl, published by Junk, The Hague, 1972.

The main families of Coleoptera include:

Burprestidae	Metallic wood borers
Cantharidae	Soldier beetles
Carabidae	Ground beetles
Cerambycidae	Long-horned beetles
Chrysomelidae	Leaf miners
Cicindelidae	Tiger beetles
Cleridae	Checkered beetles
Coccinellidae	Lady beetles
Cucujidae	Flat bark beetles
Curculionidae	Curculios, weevils, snout beetles
Dermestidae	Skin beetles
Dytiscidae	Predaceous diving beetles
Elateridae	Click beetles
Gyrinidae	Whirligig beetles or lucky beetles
Hydrophilidae	Water scavenger beetles
Lamypyridae	Fireflies or lightning beetles
Lucanidae	Stag beetles
Meloidae	Blister beetles
Mylarbridae (also called *Bruchidae*)	Bean and pea weevils
Ptinidae	Powder-post beetles, deathwatch beetles, drug store beetles
Scarabaeidea	May beetles or June bugs
Scolytidae (also called *Ipidae*)	Bark beetles
Silphidae	Carrion or burying beetles
Staphylinidae	Rove beetles
Tenebrionidae	Darkling beetles

COLEOPTILE. In the seeds of grasses the primitive bud or plumule is enclosed in a protective sheath called the *coleoptile*. During germination of the seed this coleoptile elongates, pushing its way out of the seed and up through the soil. It is very sensitive to light, growing directly toward a beam of light.

COLIC. This is a general term denoting abdominal pain that comes on quickly, is sharp and penetrating in character, intermittent, brief, and cramp-like. Biliary colic is a sharp severe pain that occurs with the passing of gallstones through the bile passages. Lead or painter's colic occurs in lead poisoning and is associated with increased intestinal peristalsis. Renal colic occurs with the passing of a stone through the ureter. Treatment of colic is symptomatic during an attack. Atropine is used to relieve muscle spasm, and morphine may be necessary for severe pain.

Commonly, the term colic is associated with periodic abdominal cramping noted in infants. Colic in a normally developing infant may arise from a variety of causes, including (1) hunger cramps confused with colic, (2) usual feeding periods not geared to the requirements of a particular infant; (3) a tight anal ring that makes it difficult for the infant to expel the stool; (4) sensitivity to certain foods ingested by the mother, in the case of breast-fed infants; and (5) sensitivity to certain kinds of milk, which usually disappears when the child is about six months old, but possibly reappears as allergies in other forms in later years.

COLIIFORMES *(Aves)*. This order of birds which is made up of the (family *Coliidae*) are only a little larger than finches, and are to be distinguished by long, stiff tails, prominent feather crests, and soft ragged plumage. They are extremely skillful climbers, whereby the special structure of their feet stands them in good stead: the first and the fourth toes are reversible; they can be turned forward and backward (pamprodactylous). The coloration of the males and the females is the same and they do not greatly differ in size. The eggs are relatively small and have a strangely rough, coarse-grained shell. The basic color is white. The clutch can number from two to five eggs. There is only one genus (*Colius*) with six species, all of which live exclusively in Africa south of the Sahara.

Probably this order have been given the name mousebirds not just because of their gray and brown feathers, but also because they scurry through the underbrush like mice. These birds are very sociable and can usually be seen in small family groups of 5–7, but occasionally in larger flights of 30 or more. They occur at the edges of forests, along rivers, and in areas with brushwood; they even live in cities in the Sudan and especially in South Africa. See also **Mousebird**.

COLITIS AND OTHER INFLAMMATORY BOWEL DISEASES. These diseases are characterized by inflammation of the bowel. Although similar in many respects, two major diseases have been recognized over the years: (1) *ulcerative colitis* and (2) *Crohn's disease*. Other intestinal diseases are described elsewhere. See **Diarrhea**; and **Diverticulosis and Diverticulitis**.

Ulcerative Colitis. Although the incidence of ulcerative colitis is relatively high, particularly among some races and ethnic groups, the etiology of the disease is not well understood. Attacks of ulcerative colitis range from mild to severe and the disease may recur and frequently worsen over a number of years. Mortality from an acute attack ranges from 0.4% (mild cases) to 15% (severe cases), depending to a large extent on the age and general health of the patient. The risk of colon cancer precipitated by ulcerative colitis increases with both the severity and duration of the disease.

Statistics show that the disease is from 2 to 4 times more prevalent among Jews than non-Jews; and about 4 times more frequent among whites than nonwhites. The disease is found in about 4 people per 100,000 population. Occurrence in females exceeds that in males. Ulcerative colitis is not considered common among persons past 60 years of age, but it is more serious and mortality is higher when it strikes elderly persons. Onset of the disease usually occurs between 25 and 40 years of age.

Early symptoms of ulcerative colitis are constipation and passage of blood or mucus with the stools. Some patients also indicate that an urgency to defecate may produce only small quantities of blood and mucus. This condition may persist for months and even years without diarrhea and any systemic symptoms. Mild ulcerative colitis appears to be limited to the distal (lower end) colon and rectum. The spread of the disease to other parts of the colon occurs only in about 15% of the cases.

In *mild ulcerative colitis* (60% of cases), the patient has intermittent diarrhea with no marked cramping or abdominal pain. There is no fever. Accurate diagnosis is largely dependent upon laboratory examinations and tests. These include sigmoidoscopy and barium-contrast x-ray examination. Tests will confirm presence of the disease, but not always its degree of severity. A general physical examination will normally yield satisfactory health.

In *moderately severe ulcerative colitis* (25% of cases), the patient will pass in excess of 5 stools per day. These will be watery or pasty and will contain significant quantities of blood and mucus. In addition to abdominal cramping, fatigue and intermittent low-grade fever (100.4 °F; 38 °C), some weight loss may be present. A physical examination will show some tenderness over the colon. There may be mild, intermittent anemia and extracolonic complications. The risk of colonic cancer is increased, particularly in a condition that has persisted for several years.

In *severe ulcerative colitis* (15% of cases), hospitalization is commonly indicated. A fever between 100.4 and 104 °F (38 and 40 °C) may be present. The abdomen will be distended and there will be a definite tenderness over the colon. Therapy may commence as mentioned for the less severe attacks of colitis, but antidiarrheal agents are not prescribed.

Crohn's Disease. Similar in some respects and sometimes difficult to distinguish from other forms of colitis, Crohn's disease is also of unknown cause. This disease, also called *granulomatous ileitis*, or simply *ileitis*, has been identified by physicians for about 50 years, but a marked distinction between it and ulcerative colitis just described has surfaced only within the last 20 years. Typical of the disease is inflammation of all layers of the bowel. Usually the disease is first evidenced by persons at about 30 years of age, but is bracketed between the ages of 20 and 40 years. The disease affects females somewhat more frequently than males. The incidence is about half that of ulcerative colitis. So-called regional ileitis (the originally named Crohn's disease) and granulomatous colitis have been identified as variations of the same syndrome.

The onset of Crohn's disease is much more subtle than ulcerative colitis and it is not uncommon for patients to delay reporting to a physician for a number of years. Some authorities have described this condition as a "smoldering" disease. Relatively mild early symptoms include lower abdominal pain, moderate diarrhea (no blood), loss of appetite, and sometimes a mild anemia. Fatigue is a common complaint. Complications may include burning of eyes and blurring of vision due to irititis, burning and urgency of urination, and arthritis, among others. In the findings of sigmoidoscopy examination, granular mucosa are usually found in

Crohn's disease (but not in ulcerative colitis). The spike-like ulcerations are large (0.5–1.0 centimeter) and extend into the submucosa in Crohn's disease, whereas in ulcerative colitis, the pits are small (1 millimeter), superficial, and have been described as "collar buttons." The characteristics of inflammation also differ in the two diseases. Crohn's disease involves the nodular or stenotic distal ileum and right colon, whereas in ulcerative colitis, the sites, as previously mentioned, are the rectum and distal colon. Characteristic of Crohn's disease is the involvement of two or more separate areas (segmentation). Risk of colonic cancer from Crohn's disease (1% of cases) is less than in ulcerative colitis.

Recent Studies. Numerous studies have been directed toward a better understanding of these two diseases — from a statistical, genetic, and laboratory viewpoint. An increased prevalence of Crohn's disease in Western Europe has been reported. In Denmark a sixfold increase during a 25-year period (1962–1987) occurred. In the United States and Western Europe, the incidence of ulcerative colitis and Crohn's disease now is approximately equal. Epidemiological surveys offer support to the conclusion that the two diseases are the result of separate disease processes. Emotional disturbances no longer are considered to be contributing causes of these diseases. Studies have shown no significant relationship between smoking and ulcerative colitis, but Crohn's disease is directly related. A study has shown that ulcerative colitis poses a much greater risk of colon cancer over the population in general.

Recent observations give improved creditability to a familial (genetic) connection in the development of both ulcerative colitis and Crohn's disease. Genetic follow-up studies are in their early phases.

Attempts to sort out differences in the basic causes (pathogenesis) of the two diseases face tremendous complexities. The essential and the less essential factors of each disease have not been determined fully. A major drawback has been the lack of appropriate animal models.

COLLAGEN. The major protein component of connective tissue. In mammals, as much as 60% of the total body protein is collagen. It comprises most of the organic matter of skin, tendons, bones, and teeth, and occurs as fibrous inclusions in most other body structures. Collagen fibers are easily identified on the basis of the following characteristic properties: They are quite inelastic; they swell markedly when immersed in acid, alkali, or concentrated solutions of certain neutral salts and nonelectrolytes; they are quite resistant to most proteolytic enzymes, but are specifically attacked by the collagenases; they undergo thermal shrinkage to a fraction of their original length at a temperature which is characteristic of the collagen from a given animal, but this varies from one species to another; and they are converted in large part to soluble gelatin by prolonged treatment at temperatures above the thermal shrinkage level. Collagen fibers are not unique to mammals; collagen has been identified in the tissues of almost all multicellular animals, ranging from the primitive porifera and coelenterates, through the annelids and echinoderms, and up to the vertebrates.

As a protein, collagen is unusual in both chemistry and structure. Nearly one-third of its residues are glycine, and an additional 20–25% are imino acids (proline and hydroxyproline). In terms of sequence, glycine occurs regularly in essentially every third position, following as a steric requirement of the secondary-tertiary structure.

It appears that specific side-chain interactions between polar residues on adjacent collagen macromolecules are largely responsible for ordering the macromolecules into fibers. Specific cooperative interactions between functional groups on appropriately oriented macromolecules seem to be involved in the heterogeneous nucleation of hydroxyapatite crystals, and thus the initiation and control of mineralization in bones and teeth. As collagen fibers age, *in vivo*, they seem to become progressively more intermolecularly cross-linked, perhaps by the "ester-like" bonds formed. Little or no soluble collagen can be extracted from most mature connective tissue because of this extensive cross-linking, although the material can be converted into soluble gelatin by drastic thermal treatment.

Collagen and gelatin are of commercial importance. As insoluble collagen, this material may be cross-linked further by tanning and thus converted to leather. The soluble gelatins are used in the manufacture of foodstuffs, film emulsions, and glue.

See also **Bone**; and **Scleroderma**.

COLLAR. A fold or ridge of tissue more or less completely encircling the body behind its anterior end. In the snails, cuttlefishes, and related mollusks the ventral edge of the mantle is called the collar and in *Balanoglossus* (Chordata) the region of the body between the proboscis and the trunk is so named.

COLLAR CELL. A cell bearing a flagellum at one end, surrounded by a high membrane. Some of the one-celled animals and the choanocytes of sponges have this form.

COLLATERAL CIRCULATION. Auxiliary vessels for supplying blood to an area of tissue. If an artery is occluded, the collateral vessels expand to take over the task of supplying that area with blood. See also **Circulatory System (Human)**; and **Ischemic Heart Disease**.

COLLATOR. A data processing device used to combine sets or decks of cards or other information-bearing units into a desired sequence. Typically, a card collator has two input feeds so that two ordered sets may enter into the process; and four output stackers so that four ordered sets can be generated by the process. Three comparison stations are used to route the cards to one stacker or the other on the basis of comparison of criteria as specified by the collator controls. Collating is required where data from two or more physically separated files must be combined. Combining a file with names and addresses with another file containing one or more items of personal information is an example. The term *merge* usually signifies the combining of two similarly ordered sets of data into a single ordered set. The order, for example, may be alphabetical or numerical. A data set containing B, H, L, Q, and T may be combined with another set containing C, J, N, and S to produce the ordered set B, C, H, J, L, N, Q, S, and T. The combined set may be referred to as a *unified file*. The four basic operations involved in collating are merging, sequence checking, selection, and matching.

The term is also used for a program or routine that provides similar functions when applied to one or more files stored in a computer storage unit.

COLLECTOR. A class of instruments employed to determine the electric potential at a point in the atmosphere, and ultimately the atmospheric electric field. See also **Atmospheric Electric Field**.

All collectors consist of some device for rather rapidly bringing a conductor to the same potential as the air immediately surrounding it, plus some form of electrometer for measuring the difference in potential between the equilibrated collector and the earth itself. Collectors differ

widely in their speed of response to atmospheric potential changes. When a flame is used to increase the local ion density and thereby facilitate potential equilibration, some advantage over a simple exposed conductor is gained; the relaxation time becomes of the order of one minute. Use of radioactive coatings, preferably emitters of alpha particles, gives a faster response, attaining relaxation times of the order of a few seconds. Certain mechanical collectors have relaxation times of the order of a few hundredths of a second.

COLLEMBOLA. The spring-tails. An order of primitive wingless insects characterized by a forked appendage at the tip of the body used in leaping. This appendage is bent forward beneath the body and when released snaps sharply down and back, projecting the animal into the air. Metamorphosis is absent.

Spring-tails are small and delicate. They are found mostly in moist places on the ground or on bark, though a few species live in dry hot situations. The snow flea, which sometimes appears in large numbers on the surface of snow, is a spring-tail. Some species are found on the surface of water.

COLLENCHYMA. Collenchyma is a specialized plant tissue with thickened primary cell walls. It combines high strength in tension with the ability to grow in length.

Distribution and Mechanical Functions

Function. Plants contain a variety of tissues that are obviously adapted to a mechanical function. One mechanical strategy leads to wood, in which thick, rigid cell walls carry all types of stress. Another strategy relies on turgor pressure inside the cells to bear compressive stresses and distend elastic cell walls, so that these are always in tension. This strategy uses less material and allows rapid growth, but scaling factors restrict it to small plants. Collenchyma is a specialized tissue within such plants. Its thick walls and high tensile strength imply a mechanical role, but in tension only, unlike wood.

Location. Collenchyma is typically found in stems and leaves of dicotyledonous plants; occasionally in fruits and rarely in roots. It is uncommon in grasses, cereals and ferns, where sclerenchyma (woody tissue) occupies similar positions. In stems and petioles, collenchyma is usually located either directly under the epidermis or separated from it by a fewlayers of cortical cells. Collenchyma may form a continuous ring, or discrete strands atribs or angles or outside vascular bundles. The *strings* of celery stalks (Figure 1) are a typical example of collenchyma strands capping ribs, and located as far from the centre of the stalk as its shape allows. This location fits their role in stiffening the stalk against bending, because their contribution scales with the square of their distance from the center. When the stalk is turgid a cut *string* immediately contracts, demonstrating that the collenchyma is under tension. See also **Epidermis (Plant)**; and **Sclerenchyma**.

The pulvini of *Mimosa* and *Robinia* leaves [Moysset and Simon, 1991] are short petiole segments that bend to open and shut the leaves in response to touch or daylight. Uniquely they contain a central collenchyma ring sheathing the thin vascular bundle, surrounded by a thick layer of cortical motor cells that swells asymmetrically to bendthe pulvinus (Figure 1). The collenchyma is stressed in tension by the cortical cells, as in celery and other plants, but its central location facilitates the bending of the pulvinus rather than preventing it.

In leaves, collenchyma strands are located along the veins and around the margin, where tearing stresses are greatest when the leaf flutters. In tomatoes, thin collenchymastrands encircle the fruit just under the skin and strengthen it against bursting. All these locations are consistent with a role in providing tensile strength combined with flexibility and the potential for elongation growth.

Ontogeny, Growth and Anatomy. Collenchyma in the strict sense defined by Esau originates from meristematic activity in the cortex, not in the vascular cambium like wood. It often merges into cortical tissue and elongates in step with it, but with a higher ratio of cell elongation to cell division so that the cells become much longer [Engels and Jung, 1998]. Immature, elongating collenchyma shows irreversible extensibility that is enhanced by auxin or low pH, likegrowing parenchymatous or epidermal tissues but unlike wood [Pilet and Roland, 1974]. The cell walls thicken both during and after elongation growth. Thickening may be restricted to specific parts of the cell circumference, giving anatomically distinct forms of collenchyma (Figure 1). If plant stems are repetitively bent, as by wind, the collenchyma cell walls may become thicker.

Cell Wall Deposition

Cell-Wall Architecture. Immature walls of collenchyma cells are indistinguishable from those of the surrounding parenchyma and the thickened regions of the mature collenchyma wall are similar in structure. Layers of cellulose microfibrils are arranged helicoidally, with a slight change in orientation between each layer and the next [Vian, et al.: 1993]. Between

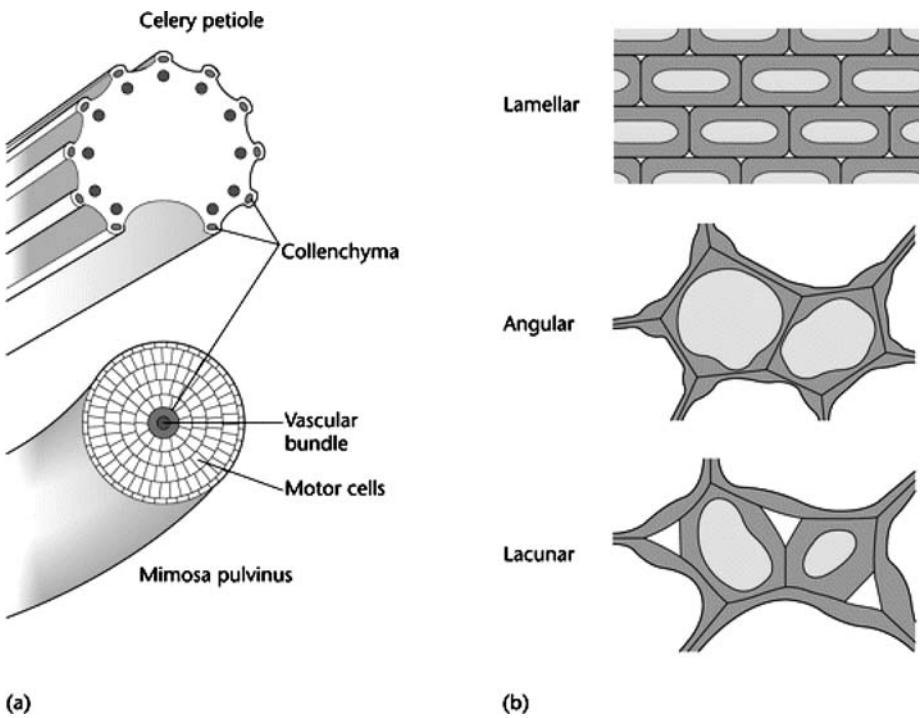

Fig. 1. Location and types of collenchyma. (a) Peripheral location in celery petiole; central location in *Mimosa pulvinus*. (b) Cell-wall thickenings on tangential walls only (lamellar collenchyma); at cell corners (angular collenchyma) and bordering intercellular spaces (lacunar collenchyma).

the layers is a strongly hydrated, flexible pectic gel that can swell or shrink according to the cations present, controlling the thickness of the cell wall and extending across the middle lamella to attach one cell to another. The only known unusual feature of the wall thickenings [Jones, et al.: 1997] is that their pectins lack the β(1,4)-d-galactan side-chains, which are the least rigid components of normal primary walls and interact most strongly with water. With maturity the mean orientation of the microfibrils becomes more longitudinal and the pectins more rigid, dominated by low-ester galacturonan [Fenwick, et al.: 1997]; these characteristics are shared with primary walls of other maturing dicotyledonous cells and especially with epidermal tissue. Rarely, the walls of mature, nongrowing collenchyma cells may become lignified.

Structure-Function Relationships. Collenchyma is well adapted for existence under tension. Its tensile modulus is comparable with that of wood but, unlike wood, it is not normally fused rigidly by lignin into a thick multicellular structure resistant to buckling in compression. Indeed, weaker intercellular bonding may increase the tensile breaking strength of collenchyma by deflecting incipient fractures into a path parallel to the strand. Analogously, within a collenchyma wall the hydrated pectic matrix not only allows flexibility but presumably can deflect transverse cracks and so protect the tensile strength of the individual cellulose microfibrils.

What is Collenchyma? The definition of collenchyma is controversial and needs to be refined, with coherence between structure and function. If collenchyma is defined as a nonepidermal tissue capable of elongation, providing support in tension and having thickened primary cell walls, the semantic problem moves to the distinction between primary and secondary walls. Primary walls are defined elsewhere as walls of growing cells. However, collenchyma does not fit comfortably into this definition: thickening of its cell walls begins during growth and continues without a break when growth ceases. The wall thickenings in collenchyma are deposited inside a preformed primary wall and might logically be considered secondaryto it, but in composition, microfibril architecture and function they resemble the primary wall.

COLLER (Thermoelectric). See **Thermoelectric Cooling**.

COLLES' FRACTURE. A fracture of the arm near the wrist, in which the radius is broken in its lower quarter. It is one of the most common fractures and occurs usually from a fall on the outspread hand, or a direct blow against the wrist.

COLLETERIAL GLANDS. Glands associated with the female reproductive system of insects. They secrete materials that cement the eggs together or form a protective covering over them.

COLLIDER (Particle). See **Particles (Subatomic)**.

COLLIGATIVE PROPERTY. One of four characteristic properties of solutions, namely, the interdependent changes in vapor pressure, freezing point, boiling point, and osmotic pressure, with a change in dissolved matter.

If, under a given set of conditions, the value for any one property is known, the others may be computed. In general, with an increase in dissolved matter (e.g., salt in water), freezing point and vapor pressure decrease, and boiling point and osmotic pressure increase.

See also **Boiling Point**; **Freezing Point**; **Osmotic Pressure**; and **Vapor Pressure**.

COLLIMATOR. An optical apparatus for producing parallel rays of light. A common form consists of a converging lens, at one of whose focal points is placed a small source of light, usually a pinhole or narrow slit upon which light is focused from behind. Rays diverging from this focal point emerge from the objective lens in a parallel beam. See Fig. 1. The slit or other source is viewed through the collimator without parallax, since it appears at an infinite distance. The arrangement is very generally used on spectroscopes and spectrometers. By analogy, any arrangement of slits or apertures which limits a stream of particles to a beam in which all the particles move in the same, or nearly the same, direction is called a collimator.

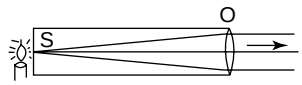

Fig. 1. Divergent rays from slit S rendered parallel by objective O.

COLLISION. As used in physics, this term refers to any interaction between free particles, aggregates of particles, or rigid bodies in which they come near enough to exert a mutual influence, generally with exchange of energy. It does not necessarily imply actual contact. The process is always subject to conservation of momentum, and in an "elastic collision," also to conservation of energy. In the latter case, if the initial velocities are given, the velocities of the bodies after collision can be calculated by applying these two conservation principles. The subject is of special significance in atomic physics, where a collision is defined as a close approach of two or more photons, particles, atoms or nuclei during which an interchange occurs of charge, energy, momentum or other quantities. See also **Impact**.

COLLISION BROADENING. In spectroscopy, the broadening or spreading of an emission line due to the interruption of the radiating process by a collision of the radiator with another particle. In the case of cyclotron radiation, the collision will actually change the phase of the radiation. For many collisions, this has the effect of broadening the observed frequencies by an amount equal to the collision rate.

COLLISION COEFFICIENT. In a two-body collision involving particles 1 and 2, moving in the same straight line, the coefficient of restitution is defined by

$$e = \frac{v_2 - v_1}{u_1 - u_2}$$

where $u_1 > u_2$ are the velocities with respect to a primary inertial system before collison and $v_2 > v_1$ are the corresponding velocities after collision. For a completely elastic collision $e = 1$. For an inelastic collision $d < 1$. See **Impact**; and **Restitution Coefficient (or Collision Coefficient)**.

COLLISION EFFICIENCY. 1. The fraction of all water drops in the path of a falling larger drop that make contact with the larger drop. Calculations using approximate drag forces between large and small cloud drops predict low collision efficiencies (<10%) when the large drop is less than 40 μm in diameter but collision efficiencies approaching 100% when the larger drop is greater than 80-μm diameter. Thus theory indicates that the collision–coalescence process for precipitation formation requires at least a small fraction of cloud drops to be larger than about 40-μm diameter. Because collision between drops does not necessarily result in coalescence, it is important to distinguish between collision efficiency and coalescence efficiency. Their product, termed the collection efficiency, gives the fraction of drops that collide and coalesce.

2. The fraction of drops or aerosol particles colliding with precipitation particles.

COLLISION PARAMETER. 1. In orbit computation, the distance between a center of attraction of a central force field and the extension of the velocity vector of a moving object at a great distance from the center.

2. In gas dynamics and atomic physics, any of several parameters, such as cross section, collision rate, mean free path, etc., which provide a measure of the probability of collision.

COLLISION RATE. The average number of collisions per second suffered by a molecule or other particle moving through a gas. Also called *collision frequency*.

COLLISION THEORY. Theory of chemical reactivity that states that only colliding molecules can undergo chemical reaction and then only if their combined kinetic energy exceeds a critical value.

The maximum value for the rate coefficient for a simple, bimolecular, gas-phase reaction, assuming reaction occurs on every collision, is about 2×10^{-10} cm^3 per molecule per second. Actual rate coefficients are lower due to two effects — the need to overcome an energy barrier during collision in order for reaction to occur, and a "steric factor," which accounts for the fact that reaction can occur only when the collision occurs in a certain geometry.

COLLOID CHEMISTRY. A subdivision of physical chemistry comprising the study of phenomena characteristic of matter when one or more of its dimensions lie in the range between 1 millimicron (nanometer) and 1 micron (micrometer). It thus, includes not only finely divided particles, but also films, fibers, foams, pores, and surface irregularities. Dimension, rather than the nature of the material, is characteristic. Colloidal particles may be gaseous, liquid, or solid, and occur in various types of suspensions (imprecisely called solutions), e.g., solid–gas (aerosol), solid–solid, liquid–liquid (emulsion), gas–liquid (foam). In this size range, the surface area of the particle is large with respect to its volume so that unusual phenomena occur, e.g., the particles do not settle out of the suspension by gravity and are small enough to pass through filter membranes. Macromolecules (proteins and other high polymers) are at the lower limit of this range; the upper limit is usually taken to be the point at which the particles can be resolved in an optical microscope. The first specific observations were made by Thomas Graham in approximately 1860 and were extended by Ostwald, Hatchek, and Freundlich. Though the term is often used synonymously with *surface chemistry*, in a strict sense it is limited to the size range noted in at least one dimension, whereas surface chemistry is not. Natural colloid systems include rubber latex, milk, blood, egg white, etc.

See also **Colloid Systems**; **Fibers**; **Film**, **Foam**; **Emulsions**; and **Surface Chemistry**.

COLLOID SYSTEM. Colloids are usually defined as disperse systems with at least one characteristic dimension in the range 10^{-7} to 10^{-4} centimeter. Examples include: *sols* (dispersions of solid in liquid); *emulsions* (dispersion of liquids in liquids); *aerosols* (dispersions of liquids or solids in gases); *foams* (dispersion of gases in liquids or solids); and *gels* (system, such as common jelly, in which one component provides a sufficient structural framework for rigidity and other components fill the space between the structural units or spaces). All forms of colloid systems are encountered in nature. Products of a colloidal nature are commonly found in industry and are notably extensive in the food field. Foams, widely used in industrial products, but also the causes of processing problems are described in entries on **Foam**; and **Foamed Plastics**.

Early Background. Thomas Graham's investigations of diffusion (1861) led him to characterize as *crystalloids* substances, such as inorganic salts which in water solutions would diffuse through a parchment membrane; and as *colloids* (Greek word for glue) substances, such as starch and gelatin, which would not diffuse through the membrane. Sols with a given weight percent of dispersed material scatter light more strongly than a solution with the same weight percent of dissolved inorganic salt, i.e., a true solution. The Tyndall effect, in which the path of a beam of light through a turbid solution (or through dusty or smoke-filled air) is clearly defined through scattered light, is characteristic of sols. The slow diffusion and strong light scattering, together with the fact that the boiling-point elevation, freezing-point depression, and osmotic pressure caused by a given weight percent of dispersed material in sol form are much less than the corresponding magnitudes caused by the same weight percent of common inorganic salts — these observations indicated to early investigators that the particles dispersed in the sol must be larger than those resulting from dissolving inorganic salts in water.

Development of the ultramicroscope (Siedentopf and Zsigmondy, 1903) permitted particles substantially smaller than the wavelength of light to be observed in scattered light and were thus capable of counting. Invention of the ultracentrifuge by Svedberg (1924) made it possible to cause particles in sols to sediment at observable rates, to measure these rates with reasonable precision, and to infer particle sizes from these rate measurements. The ultramicroscope and ultracentrifuge permitted validation of the early conclusions that colloidal particles are much larger than ions resulting from dissolving metal salts in water.

Svedberg found that in some sols the particles were highly uniform in size. For example, he found that the gram particle weight of insulin (a protein) was 40,900 and that apparently all insulin particles had this gram particle weight. This made it extremely likely that the insulin particles were either single molecules (albeit giant ones), or aggregates of a very definite number of smaller (but still quite large by ordinary standards) molecules. The research of Staudinger (commencing about 1920) and of Carothers (1929) opened up the field of macromolecular chemistry, leading to the recognition that giant molecules were not only abundant in nature, but could be prepared by established principles of chemistry. See also **Macromolecular Science**.

The pioneering work of Svedberg and other early researchers, as continued over the years through the application of much improved instrumentation (scattered laser light, electron microscopy, among other methods for investigating microstructure) are described briefly later in this article.

It is interesting to note that Wolfgang Ostwald, in the late 1800s, stated, "There are no sharp differences between mechanical suspensions, colloidal solutions, and molecular (true) solutions. There is a gradual and continuous transition from the first through the second to the third."

Some colloidal systems are *thixotropic*, i.e., they differ in their fluid behavior from *pseudoplastic* substances in that the flow rate increases with increasing duration of agitation as well as with increased shear stress. When agitation is stopped, internal shear stress exhibits hysteresis. Upon reagitation, generally less force is required to create a given flow than is required for the first agitation. Examples of thixotropic materials include silica gel, most paints, glue, molasses, lard, fruit juice concentrates, and asphalts. By rhythmically shaking or tapping certain thixotropic suspensions, the suspensions will "set" or build up very rapidly. This type of non-Newtonian substance is said to be *rheopectic*. Bentonite sols and suspensions of gypsum in water are rheopectic. *Dilatant fluids* often are termed *inverted plastics* or inverted pseudoplastics. Initial flow under a low shear stress is at a high rate; further increases in shear stress, however, result in lower flow rate. Some liquids may change from thixotropic to dilatant or vice versa as the temperature or concentration changes. Examples of dilatant materials include quicksand, peanut (groundnut) butter, and many candy compounds. For comparison, it should be recalled that a Newtonian substance is a liquid or suspension which, when subjected to a shear stress, undergoes deformation wherein the ratio of shear rate (flow) to shear stress (force) is constant. These varying behavioral patterns of colloidal materials become important considerations in specifying pumps and other process handling equipment. See also **Gold Number**.

Role of Water Molecule — Cluster Theory. Because a very large number of colloid systems involve water, particularly in connection with biological systems, comprehension of the structure and behavior of water is paramount. Notably since the 1950s much progress has been made concerning the physical and chemical nature of water. Long established observations have shown water to be a low-molecular-weight compound, similar in structure and molecular weight to several compounds, such as methane, ammonia, and hydrogen fluoride, among others. However, water has a number of anomalous properties when compared with other structurally similar compounds. Such comparison shows that water has unusually high melting and boiling points, dielectric constant, and density. Water also has a very high surface tension and specific heat, and a high heat of vaporization were this characteristic extrapolated from data on similar substances. That liquid water is a highly structured substance has been

supported for many years through x-ray and neutron diffraction studies, as well as Raman and nuclear magnetic relaxation (NMR) techniques. That water molecules have a V-like structure with an H−O−H bond angle of 104.5° has long been established. Similarly it has been known that the highly electronegative oxygen atom polarizes the O−H bond, thus giving the molecule an unsymmetrical charge distribution. See also **Water**.

The apparent simplicity of structural and behavioral aspects of water disappeared with the observations of Frank and Wen (1957), the first investigators to describe water as a *mixture of monomer and polymerized molecules*. As pointed out by Busk (1984), Frank and Wen found that the formation of a single hydrogen bond enhances the ability of the other hydroxyl groups on the molecules involved to form hydrogen bonds. They described water structure as cooperative in nature. The formation of hydrogen bonds, however, restricts the molecular motion of H_2O molecules and results in a loss of entropy. Initially, the loss in entropy is more than compensated for by the gain in enthalpy of bond formation. The size that a cluster of molecules will grow to is thus a result of a balance between these two forces.

Numerous investigators have contributed to the cluster theory of water and the model proposed (Nemethey-Scheraga Flickering Cluster Model) incorporates the names of some of these investigators. The current description of the model suggests that water is composed of monomeric H_2O molecules, polymeric structures 20−90 molecules in size, and a minor amount of ions, isotopes, etc. Up to 90% of the molecules in liquid water may be in clusters at any one time. The number of clusters increases with temperature; the size decreases. The model predicts the density maximum and some of the other solid-like properties. The model forecasts the lifetime of the cluster to be very short (about 10−11 second) and the bonding forces within each cluster to be quite weak. The latter leads to accurate predictions of the liquid-like characteristics of water. Some molecules (nonbonded monomers) are present only to about 1% of the total. Computer simulations by Del Bene and Pope determined that cyclic water structures are the most stable (e.g., trimers, tetramers, pentamers, and hexamers). This study also indicated that the branching structure needed to support a continuum structure is not entropically favored.

Molecules may interact with water in at least four main ways — hydrogen bonding, ionic bonding, hydrophobic association (nonpolar molecules placed in the polar environment of water), and London dispersion or van der Waals forces.

Inasmuch as water-macromolecule interactions are complex and still not fully understood, other postulations concerning water bonding have been proposed. Fennema (1978), for example has suggested three structural states of water: (1) *constitutional water* (held in interior of folded macromolecules); (2) *interfacial water* (located at or near the surface of a macromolecule); and (3) *bulk phase water* (chemical properties identical to those of free water or water of dilute salt solutions). In making these distinctions, Fennema asserted that the categories do not imply any distinct boundaries between them. Another researcher (Labuza, 1977) proposed two additional types of forces: (1) the effects of trapping water in polymer capillaries, and (2) solute effects due to entropy considerations.

Sols. It is convenient to classify sols into three types: (1) *lyophilic* (solvent loving) colloids, for example, are solutions of gelatin or starch in water; (2) *association* colloids, of which a solution of soap in water at moderate concentration is an example; and (3) *lyophobic* (solvent repelling) colloids, for example, sulfur in water. Both lyophilic and association colloids can be prepared in thermodynamic equilibrium, so that when solvent is removed and then returned to the system, the original properties of the system are regained.

Lyophobic colloids are not (or at most, rarely) equilibrium systems. When solvent is removed and then returned to the system, the original dispersed material fails to redisperse, and it is usually convenient to regard such a system as one in which the dispersed particles are continuously aggregating. A lyophobic sol thus appears to be stable if the aggregation rate is slow; and unstable if it is fast. The terms lyophilic and lyophobic entered the literature before the characteristics of these systems were well understood and thus are somewhat anachronistic; they are nonetheless well-established.

Lyophilic sols are true solutions of large molecules in a solvent. Solutions of starch, proteins, or polyvinyl alcohol in water are representative of numerous examples. Properties of these solutions at equilibrium (for example, density and viscosity) are regular functions of concentration and temperature, independent of the method of preparation. The solvent-macromolecule compound system may consist of more than one phase, each phase in general containing both components. Thus, if a solid polymer is added to a solvent in an amount exceeding the solubility limit, the system will consist of a liquid phase (solvent with dissolved polymer) and a solid phase (polymer swollen with solvent, i.e., a polymer with dissolved solvent).

The foregoing characteristics also are found with solutions of small molecules. But properties of solutions, one of whose components is macromolecular, differ from those having only small molecular components in quite understandable ways. For example, where small molecules are involved, molecular distortion is minor. Quite generally, the shapes of small molecules are little affected by environment unless the small molecules react chemically. In contrast with small molecules, there is a considerable variation in polymer conformation with environment. See also **Molecule**; and **Polymer**.

A polymer dissolved in a good solvent will tend to stretch out, and the resulting entanglement of polymer chains and interference with solvent movement will lead to a high viscosity. If the solvent is a poor one, the polymer molecule will tend to form a small ball, and the viscosity for a given weight percent will be much less. A side group of a polymer may be ionizable. Ionization of this group distributes a charge along the backbone and charge repulsion causes the macromolecule to tend toward a rod shape. If there is a moderate salt concentration in the solution, the backbone charge will be partly shielded by ions from the salt of opposite charge. Thus, the tendency toward rod formation will be less pronounced. The tendency of oppositely charged macromolecules to aggregate is much greater than the tendency of oppositely charged small ions to pair simply because the charges involved are greater in the former case.

The foregoing special properties of solutions of large molecules are relatively easy to describe in qualitative terms, but a difference of a more subtle nature occurs when the system forms two liquid phases. In a macromolecular solution, both phases tend to be rich in the (small molecule) solvent, whereas in systems formed from two molecules of comparable size, one phase is rich in one component, while the other phase is rich in the second component. The formation of two liquid phases from a solvent-macromolecule system is sometimes call *coacervation*; and the phase with the higher percentage of macromolecule is sometimes called the *coaceryate*. See also **Coacervation**.

Association Colloids. These are generally encountered in solutions of soaps and detergents in water. These matters become important, of course, to procedures for cleaning and sterilizing equipment (food processors, biochemical manufacturers, hospitals, etc.), but the principles also apply to other association colloids also encountered industrially, notably in the food processing field. A typical soap, such as sodium stearate, $C_{17}H_{35}COONa$, or a detergent, such as sodium dodecyl benzene sulfonate, $C_{12}H_{25}C_6H_4 \cdot SO_3Na$, consists of a long hydrocarbon tail and a polar (in the examples cited, ionizable) head group. The solubility of the soap in water is largely conferred by the head group. As the soap concentration is increased, the soap molecules tend to cluster in aggregates called *micelles*, with hydrocarbon tails in the interior of the micelles and the polar groups in contact with water. The formation of micelles is favored by the interaction between hydrocarbon tails and is opposed by charge repulsion of the polar group which are placed close together at the micelle surface.

Micelle formation becomes pronounced at soap concentrations exceeding the critical micelle concentration. As hydrocarbon tail length is increased, the interaction of tails is increased, and as salt concentration is increased, the repulsion of head groups is reduced because their charges are partly shielded by ions of the salt. Both of these factors favor micelle formation, causing micelles to be larger and the critical micelle concentration to be smaller. Typically, a micelle might contain about 50 soap molecules. The micelle interior is a hydrocarbon, and as such is receptive to other molecules soluble in hydrocarbons. Hence, a soap solution can 'dissolve' such molecules (taking them up in micelle interiors) even if the molecules are quite insoluble in water. This phenomenon is called *solubilization* and is a factor in detergency.

Lyophobic Sols and Aerosols. These products can be viewed most simply and, in most cases, with sufficient as two-phase systems in which the dispersed particles are steadily and irreversibly aggregating according to a second-order rate law. Thus, where C is the number of particles per cubic centimeter (an aggregate of many primary particles being counted as

one particle) at time t, and where C_0 is the number of particles per cubic centimeter at zero time, and K is a constant, C depends on t according to

$$\frac{C_0}{C} - 1 = KC_0t$$

and will be one-half its value at zero time when $KC_0t = 1$. The time required for this is longer, the smaller K and the smaller C_0. If the time required is weeks, the sol will appear quite stable over a period of days. If there is no barrier to aggregation, so that the particles aggregate as fast as diffusion brings them in contact, the rate constant K can be calculated approximately from diffusion theory and is $8kT/3\eta$, where k is Boltzmann's constant, T is the absolute temperature, and η the viscosity of the medium. Initial sol concentrations (particles per cubic centimeter) giving one-minute half-lives at room temperature are 1.4×10^9 in water; and 2.7×10^7 in air in the absence of aggregation barriers.

Although these numbers may appear large, they correspond to quite small volume percentages of dispersed particles. A particle of radius 5×10^{-5} centimeter is at the upper limit of the colloidal range; and 1.4×10^9 such particles occupy 0.07% of space. The behavior of smokes, fogs, and many dispersions of uncharged particles in water accords well with the rate equation and theoretical rate constant given. In contrast, the dispersed particles in many sols are electrically charged, manifesting this charge through electrophoresis (motion of colloidal particles under the influence of an electric field). In fact, Tiselius developed electrophoresis to a high degree, successfully fractionating and classifying proteins thereby. Evidently like charges on two colloidal particles will contribute to a repulsion between them, which will be greater, the greater the charge on each particle and the smaller the concentration of salts in solution (since ions from the salt will tend to mask the charges on the particle).

The theory of interaction between colloidal particles with a surface electrostatic potential (due to surface charges) surrounded by an electrical double layer (one layer of which is the layer of surface charges, the other a diffuse cloud of charges of opposite sign due to ions from salts in the solution) was developed by Derjaguin and Landau and independently by Verwey and Overbeek, and is generally known as the DLVO theory after the first letters in the names of these scientists. The DLVO theory shows how a barrier sufficient to reduce the rate constant K (and so to increase the half-life at a given initial concentration) by many powers of ten may arise from the interaction of charged particles in a solvent, and the magnitudes calculated agree rather well with experiment.

It is evident why the properties of lyophobic sols depend so critically on the chemistry of the interface between dispersed particle and solvent, for this chemistry establishes the means by which the surface charge can be established or altered. Particles of silver halide dispersed in water will acquire a positive charge if silver ion is in slight excess in the water, because the silver ion can readily add to the silver halide lattice. A negative charge is similarly acquired if the halide ion is in slight excess. The silver ions and halide ions are called *potential-determining ions* for the silver halide sol. They can lose their waters of hydration and adsorb on the particle side of the electrical double layer, conferring a charge on the particle. Hydrogen ion and hydroxyl ion are similarly potential-determining ions for many oxide sols, such as silica and alumina, including particles, such as carbon and many metals, which are ostensibly not oxides, but in fact usually have oxidized surfaces. Finally, charge can be conferred by the adsorption of charged macromolecules, such as gelatin, which are called *protective colloids*. Salts added to the sol form ions, which tend to mask the particle charges and so tend to promote flocculation. The ion whose charge is opposite to the particle charge (the counter ion) is of particular importance, and the greater its charge the lower the concentration at which its flocculating effect is evident.

Emulsions. These are dispersions of one liquid in another. Most commonly, one phase is an oil which is at most slightly miscible with water. The disperse phase can either be oil (an oil-in-water emulsion) or water (a water-in-oil emulsion). For apparent stability, an emulsifying agent is almost invariably required. The emulsifying agent has an oil-soluble tail and a polar head. The emulsifying agent concentrates (adsorbs) at the interface between oil and water, lowering the interfacial tension and frequently conferring a charge on the dispersed droplets. The film of emulsificant thus formed is usually only one molecule thick, but it is essential to emulsification. Mixed emulsificants, such as a mixture of sodium stearate and octadecyl alcohol, may be more effective in emulsification than either component alone, and there is a great deal of art and experience required in the formulation of emulsions. Lecithins and some proteins are effective natural emulsificants, and a mixture of lecithin and cholesterol is an effective natural mixed emulsificant. It should be noted that the difference between solubilization (described in connection with association colloids) and emulsification is not sharp, particularly insofar as large, extensively swollen micelles and ultrafine emulsions are concerned.

Gels. These substances involve the formation of a three-dimensional structure. A gel is a colloidal disperse system in which is contained a dispersed component and a dispersion medium, both extending continuously throughout the system. Further, the system has equilibrium-elastic (time-dependent) deformation. Thus, since they have a shear modulus of rigidity, gels are like solids, but in most other physical respects, they behave like liquids. It is conceived that the three-dimensional network is kept together by bonds or junction points, which essentially have an unlimited lifetime. Junction points may be described as primary valence bonds, attractive forces of long range, or secondary valence bonds, which maintain an association between parts of polymer chains or form submicroscopic crystalline regions. A gel may be defined as a flocculant and gelatinous precipitate. A jelly is a transparent elastic mass. Upon standing, a gel may shrink — a process known as *syneresis*.

In 1861, Thomas Graham first used the term syneresis to describe the phenomenon of exuding small quantities of liquid by gels. By definition, syneresis is the spontaneous separation of an initially homogeneous colloid system into two phases — a coherent gel and a liquid. The liquid is actually a dilute solution whose composition depends upon the original gel. When the liquid appears, the gel contracts, but there is no net volume change. Syneresis is reversible if the colloid particles do not become too coagulated immediately after their formation.

In 1937, Heller classified three types of syneresis as to cause: (1) syneresis of desorption, caused by the particle becoming less hydrophilic with time; (2) syneresis of aggregation, whereby discrete gel particles may unite into a denser gel portion; and (3) syneresis of contraction, where a gel with fibrillar structure contracts and squeezes out the intermicellar liquid. Most commonly, syneresis is the visible manifestation of further slow coagulation that follows the initial setting of the gel, the gel-forming process itself being an enmeshing of the hydrous particles into a network. It may be further explained as the exudation of liquid held by capillary forces between the heavily hydrated particles constituting the framework of the gel. Ostwald noted that the phenomenon is one of the most characteristic of the properties of gels.

A common example of syneresis is found when a mold of gelatin remains under refrigeration for a period. A general shrinkage of the body of the gel occurs and a liquid collects around the edge of the mold. The liquid is a dilute solution of the original composition. Since the total volume of the system remains the same, syneresis should not be considered simply as the opposite of imbibition (absorption). Extending the onset of syneresis in various products, notably foods, is of obvious importance.

Dispersion Processes. 1. The simplest method of accomplishing dispersion is by grinding the solid (or liquid) material with the liquid medium until particles of the required size are ultimately obtained. The colloid mill (Plauson, 1921) is used for such purpose, as in mixing paints and pastes, regenerating milk from milk powder, dispersing cellulose in sodium hydroxide and carbon disulfide for the production of xanthates for viscose, and in emulsifying fats and waxes. See Fig. 1.

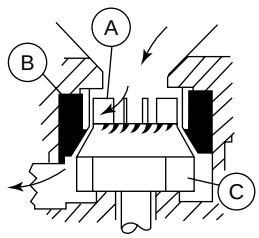

Fig. 1. One type of colloid mill. Rotor blades A break up slurry. Serrations in rotor and stator provide mechanical shear and force material into adjustable gap (0.0005–0.125 inch; 0.013–3.2 millimeters) between rotor and stator B for intense hydraulic shear. Lower part of rotor C adds further whirling action.

2. Zinc sulfide, cupric hexacyanoferrate(II), stannic acid, silver chloride are examples of precipitates which, when washed on the filter paper until the accompanying soluble electrolyte has been removed, form colloidal solutions and pass through the pores of the paper. Since this is usually to be avoided in practice, the washing is then done with an electrolyte, which does not conflict with the treatment to follow. Frequently ammonium nitrate solution is used.

3. A peptizing agent is frequently employed. Tannin is peptized by water, and by glacial acetic acid. Soaps are peptized by water. Gelatin swells in cold water but is not peptized, but is peptized in warm water. Starch, although insoluble in cold water, behaves similarly to gelatin with warm water (63 to 74 °C, depending upon the kind of starch). Cellulose nitrate swells in ethyl alcohol and not in ether, but is peptized in ethyl alcohol-ether mixture. Clay is peptized by ammonium hydroxide, and it is held by some that the action of sodium hydroxide on zinc, aluminum, and chromium hydroxides is one peptization.

4. Water-peptizable colloidal substances such as gelatin, dextrin, gum arabic, and soap peptize many precipitates, and are often called protective colloids. Gelatin in the solution prevents the precipitation of silver dichromate upon mixing silver nitrate and potassium dichromate solutions. (See Condensation Processes, below.)

5. When dilute silver nitrate and dilute potassium bromide solutions are mixed so that there is a slight excess of either solution, silver bromide is peptized. Acheson's oil-dag and aqua-dag are suspensoids of graphite in oil or water containing a protective colloid, tannin. Oil-dag contains about 15% of a "deflocculated graphite," and is used in dilute solution in lubricating oil (about 0.1% graphite). Bearings gradually become coated with a thin layer of graphite.

Sonic methods also are used to create emulsions. Liquids are pumped under pressure through an orifice of special design and impinge on the edge of a blade causing it to vibrate at ultrasonic frequencies. Cavitation takes place continuously in the stream, causing violent pressure changes to be generated locally. The result is a uniform and stable emulsion and a dispersion of a very high order. See also **Cavitation**.

Condensation Processes. 1. When a solution of ferric chloride is poured into a relatively large volume of boiling water, colloidal ferric hydroxide is formed. The ferric hydroxide sol does not react with hydrogen sulfide nor with potassium hexacyanoferrate(II), and like all colloidal substances does not pass readily through animal membranes or parchment.

2. When hydrogen sulfide is passed into a solution of arsenious oxide, arsenious sulfide sol is formed which in the absence of an electrolyte may be made of the high concentration of 60 grams of arsenious sulfide per 100 grams of water. Upon addition of hydrochloric acid, arsenious sulfide coagulates and is precipitated.

3. When hydrochloric acid is added to sodium silicate solution either silicic acid sol or silicic acid gel is formed.

4. When hydrogen sulfide solution is treated with an oxidizing agent, for example, the proper concentration of nitric acid, sulfur sol is formed.

5. When gold chloride very dilute solution (0.01 to 0.001% of gold chloride) is made slightly alkaline (say by the addition of magnesium oxide) and then treated with a reducing agent, for example, formaldehyde or sodium hydrosulfite $Na_2S_2O_4$, red gold sol is formed.

6. Use of a protective colloid in solution prevents the formation of the ordinary and expected precipitate in many cases, and causes the formation of the expected substance as colloidal sol. Silver nitrate (0.6 gram per liter) and potassium dichromate (0.5 gram per liter) to one of which is added 0.1 volume of hot gelatin solution (2 grams per 100 milliliters of water) are mixed with stirring silver dichromate sol is formed.

7. When an electric arc is formed under water between two metallic rods, particles of the metal of colloidal size are formed along with more or less separation of free metal. A protective colloid increases the stability. If the metal vaporizes and then condenses to the colloidal state this is strictly speaking a condensation process, if otherwise, a dispersion process.

The disappearance of the colloidal state of a substance may be accomplished in either of two directions, namely, by the colloid passing into solution or into suspension. Practically, the latter is the more important method. Coagulation, agglomeration or precipitation is readily brought about by discharge of the electric charge on the particles. Ions carrying a charge of opposite sign to that carried by the colloidal particles are active precipitants, and the higher the valency of the ion the more effective (Linder-Picton-Hardy). When the colloidal particles are made neutral the conditions are least favorable to their stability. For colloidal arsenious sulfide, which is negatively charged in water, the coagulating power of potassium iodide K^+I, calcium chloride $Ca^{2+}Cl_2$, aluminum chloride $Al^{3+}Cl_3$ is in the ratio of 1:80:1500 (Svedberg); and for colloidal ferric hydroxide, which is positively charged in water, the coagulating power of potassium chloride KCl^-, potassium sulfate $K_2SO_4{}^{2-}$ is in the ratio of 1:45. The active ion is carried down with the precipitated particles. Oppositely charged colloids, e.g., arsenious sulfide and ferric hydroxide, when mixed, precipitate each other. Other methods of coagulation are by migration of colloidal particles to and their discharge at electrodes, and by heating, as in the case of egg albumin. Coagulation is usually irreversible, especially when caused by electrolytes.

An interesting case, operating on a large scale in nature, of the precipitation of a colloidal system by an electrolyte is that of the action of sea water on the mud and silt of river water entering the ocean. When river water flows into the ocean the former, on account of its lower specific gravity, tends to flow over the latter and spread out in widening range. As the current diminishes some of the suspended mud and silt settles out, but the finer colloidal particles are coagulated by the electrolyte of the sea water and form deltas at the mouths of rivers.

Importance of Colloidal State. All living matter, whether animal or plant, are made up of many colloidal materials and are largely sustained by colloidal processes. Of similar importance is colloidal chemistry in everyday living, in almost all of our foods, such as proteins and starches, in our clothing, whether of natural or synthetic origin, and in our shelter materials, such as wood, bricks, and concrete. When there is added to these, other common things and operations of everyday life, such as pottery and porcelain, paper, rubber and leather, and cooking and washing, where colloidal matter and processes operate, it is evident how broad is the scope and how great is the importance of the field. To these there must also be added other applications in the realm of industry, such as dyeing, printing, photography, water purification, smoke prevention, ore flotation, sewage disposal and soil preparation, paints, varnishes and lacquers, plastics, adhesives, and innumerable other operations and materials.

Advanced Microstructural Analysis. In connection with gelling systems, Davis and Gordon (1984) point out that the *macrostructural* evaluation of a gel usually involves the evaluation of some chemical or physical property of the system as a whole, such as total water and protein or solids content, gel strength, turbidity changes during gelation, pH range at which gelation occurs, and degree of syneresis after gelation and storage. In contrast, in microstructural analysis, the investigator is interested in molecular isolation and characterization of the components of the system. As reported by numerous researchers, molecular changes and interactions result in the association, aggregation, flocculation, coagulation, and gelation of the system. There are three broad areas of microstructural analytical techniques: (1) microscopic, especially electron microscopy, where water must either be removed or immobilized in the gel system prior to viewing; (2) spectroscopic; and (3) thermal analytical. The smallest resolvable size ranges from individual molecules or groups of molecules in differential thermal analysis, differential scanning calorimetry, and thermogravimetric analysis. Light microscopy and ultraviolet microscopy are limited to sizes in the range from 1000 to 3000 angstroms. Resolution of scanning electron microscopy is approximately 150 to 200 angstroms, while transmission electron microscopy has a limit of from 2 to 5 angstroms. The range of resolution of spectroscopic absorption and spectroscopic scattering techniques is from somewhat less than one angstrom to hundreds and even thousands of angstroms. Davis and Gordon report in some detail on the use of the foregoing techniques in gelatinization studies of starch, carrageenan, soy protein isolate, and other similar substances that are encountered in the food processing industries.

COLON. The large intestine, which extends from the cecum to the rectum. It is divided into several parts, although the colon forms a continuous hollow muscular tube. The ascending colon extends from the lower right side of the abdomen at the termination of the small intestine, upward to the under surface of the liver, where it turns to the left and runs across the abdomen to the lower border of the spleen as the transverse colon. Beneath the spleen, it bends downward, descending along the left side of the abdomen as the descending colon. As it enters the pelvis, the colon makes a double curve, similar to the letter S. This portion is known as the sigmoid colon. The end of the sigmoid colon terminates in the rectum.

The functions of the colon are (1) final absorption of the products of digestion, (2) absorption of fluid from the feces so that this material becomes semi-solid, (3) removal of the fecal waste products into the rectum.

COLON CANCER. Colon cancer also called *colorectal cancer*, is a disease of the large intestine which begins at a structure called the *caecum*, located in the right lower quadrant of the abdomen, and continues through all portions of the abdomen to its junction withthe rectum, located in the deep pelvis. The colon is an organ shaped like a question mark (?). See Fig. 1. It is approximately 1.5 meters (5 ft) long and is divided intofour segments based on the vascular supply to each segment.

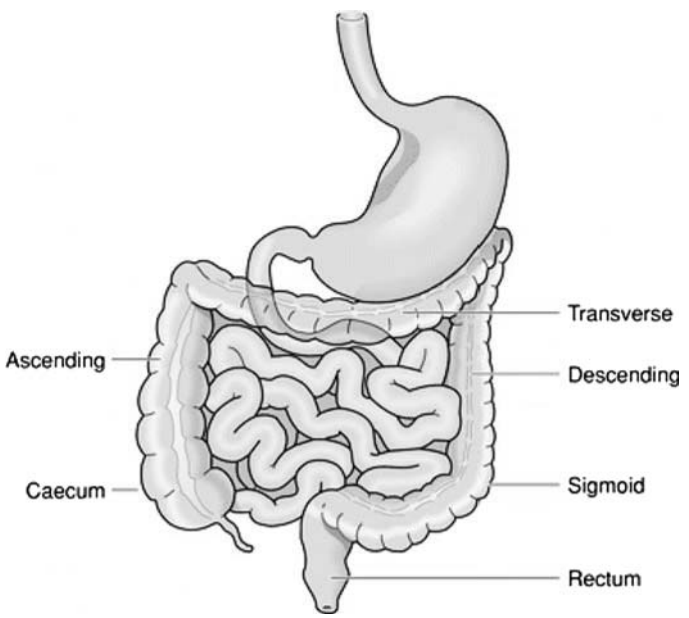

Fig. 1. Anatomy of the large intestine. The colon is divided into four sections: caecum and ascending, transverse, descending, and sigmoid. The rectum forms the most distal portion of the large intestine.

The right colon, otherwise known as the ascending colon, receives its blood supply from the right colic and the ileocolic artery. The most proximal portion of the right colon is termed the *caecum* and is identified by the appendix, which is a small appendage attached to three longitudinal bands of muscle called the *taeniae coli*.

The transverse colon connects the right colon to the left colon. Its blood supply is derived from the middle colic artery and, like the right colic artery; it is derived from the superior mesenteric artery, a branch of the aorta. The juncture at which the right and transverse colon join is termed the *hepatic flexure* and the juncture at which the transverse colon and left colon join is termed the *splenic flexure*. Flexures are points at which the large bowel is tethered and supported in order to prevent excessive twisting that could lead to a condition called *volvulus*. Volvulus is a serious problem that can result in diminished blood supply to the bowel, with subsequent necrosis and perforation. The transverse colon also serves as a tethering point for the greater omentum, which is a large fatty apron of tissue that essentially covers the entire abdomen, separating the small and large bowel from the anterior abdominal wall. The purpose of the omentum is to "police" the abdomen, identifying holes or perforations of the bowel wall and sealing them. In addition, it seems to be an adhesive target for neoplastic cells, which otherwise float free in the abdomen.

The left colon connects the transverse colon to the sigmoid colon, which is named for its S-shaped appearance in the abdomen. The left colon and sigmoid colon are supplied by the left colic and sigmoidal arteries, branches of the inferior mesenteric artery. While the wall of the right colon generally has the largest diameter, the sigmoid colon frequently has a narrow diameter and a thicker wall. It is often the site of formation of diverticula, which are small herniations through the bowel wall and can be sites for faecal impaction, abscess formation and perforation. The colon proper ends at the junction of the sigmoid colon with the rectum, which is marked by its disappearance into the deep pelvis and is covered by visceral peritoneum and perirectal (mesorectal) fat.

Colon cancer is a mucosal disease. In other words, all colon cancers are derived from the mucosal lining of the bowel wall. From the inside out, the bowel wall is composed of multiple layers, which include the mucosa, the submucosa, the muscularis propria (containing circular and smooth muscle layers) and the serosa. The innermost layer of the bowel wall, the mucosa, is a single layer of columnar epithelial cells, some of which produce large amounts of mucus and are thus termed goblet cells. This is the site of the earliest genetic changes that lead to the development of cancer cells. It is a region where normally cells are continuously dividing to replenish those that are shed from the bowel wall into the lumen. This recycling process begins in the crypts of Lieberkühn, at the base of microvilli.

Underneath this mucosal layer lies the submucosa, the strength layer of the bowel. This layer contains blood vessels, lymphatics and terminal nerve fibers. It is an important layer with regards to the genesis of cancer because once a tumor has invaded into this region of the bowel wall it can gain entrance to the blood supply and lymphatic system, permitting distant spread throughout the body. Thus, the earliest stage of colon cancer, termed Dukes' stage A, represents a stage at which cancer is limited to the submucosa and has not spread to lymph nodes or distant organ sites. The likelihood of survival following resection of these early stage cancers is very high. Dukes' B tumors have invaded into and through the muscular layer of the bowel wall and thus carry an increased risk of distant spread; Dukes' C tumors have already spread to regional lymph nodes. See also **Lymphatic System**.

Epidemiology

While the incidence of colon cancer varies widely from country to country throughout the world, colon cancer is a common disease in the United States. In 2007, an estimated 153,760 new cases will be diagnosed, and 52,180 deaths from colorectal cancer will occur (http://www.cancer.org/downloads/STT/CAFF2007PWSecured.pdf). While the mean age of diagnosis is approximately 67 years of age, the incidence rises steadily from age 50 to age 80. Thus fewer than 10% of cancers are diagnosed before age 40. The majority of colon cancers are not inherited but rather are considered sporadic, having developed from an accumulation of mutations throughout the course of a lifetime. Approximately 10% of colon cancers are considered inherited: a genetic mutation in genomic deoxyribonucleic acid (DNA) (involving all cells in the body) has been passed on from one generation to another. In addition to inherited cancers, familial cancer predispositions may exist that are independent of the hereditary nonpolyposis colon cancer (HNPCC) and familial adenomatous polyposis (FAP) diseases. To date, these predisposing factors are not well defined.

Current data suggest that epidemiological risk factors for cancer, other than genetic risk factors, include dietary components, such as the amount of fat and fiber in the diet and perhaps the intake of calcium, vitamins of the antioxidant class, and nonsteroidal anti-inflammatory agents such as aspirin and more specific inhibitors of cyclo-oxygenase. The risk of colon cancer increases with age, the history of previous polyps or cancer, the family history of cancer, and the history of long-standing inflammatory bowel disease, including ulcerative colitis and even Crohn disease.

Genetics

Where as cancer is a genetic disease, only 10% of colon cancers are actually inherited from family members. In fact, the majority of colon

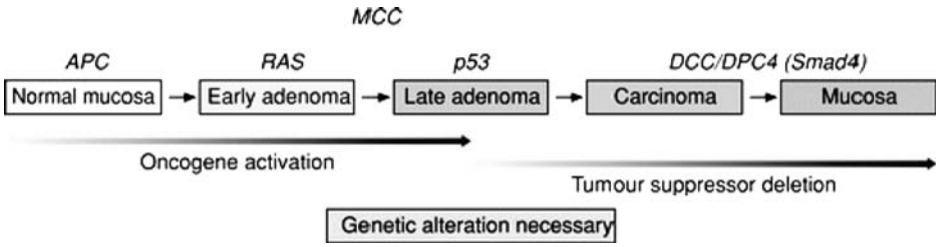

Fig. 2. Multistep model of colon cancer progression includes alterations in both oncogenes and tumour suppressor genes.

cancers are considered sporadic in nature and are derived from accumulated genetic changes. These changes occur within the epithelial cells of the mucosal surface of the bowel wall throughout the lifespan of the person. Once a critical number of genetic changes have occurred (usually 5–6), acancer may develop. A genetic model for the development of colon cancer has recently evolved [Vogelstein and Kinzler, ref.]; this is largely due to extensive gains in our understanding of human genetics, as a direct result of the human genome project (Fig. 2). See also **Human Genome Project (The)**.

Our current understanding suggests that colon cancer is a disease of disrupted growth control. Early genetic alterations occur in the colonic epithelial cells lining the bowel wall. The genetic changes involve mutations or alterations in the genetic code responsible for producing specific proteins. These mutational alterations or deletions result in the production of malformed proteins, which are absent or can no longer function normally. As a result, cells may be 'turned on' to grow without limits and may resist normal mechanisms that result in cell death, a process of cellular suicide called *apoptosis*.

We now know that two basic types of important growth genes are affected in cancer, oncogenes and tumour suppressor genes. Oncogenes represent the mutated forms of preexisting normal genes, called *protooncogenes*, which have normal growth-stimulatory functions in the cell. Only when these genes are mutated in specific regions can they take on constitutively active (always turned on) growth functions. Tumor suppressor genes are the second class of genes that are affected in the genesis of colon cancer. While the specific function and identity of many of these genes in this class are not yet identified, it is clear that specific genes are deleted in the development of cancers and that their absence results directly in tumor formation. In the normal cell, protooncogenes provide growth stimulus and tumour suppressor genes provide growth control. In the tumour cell, mutated protooncogenes and mutated or deleted tumour suppressor genes permit continuous unchecked growth stimuli. See also **Oncogenes**.

Two of the earliest genes affected in the development of colon cancer are the adenomatous polyposis coli (*APC*) gene and the *RAS* gene [Fearon and Vogelstein, ref.]. The *APC* gene was identified in a group of patients with familial colon cancer characterized by hundreds to thousands of adenomatous polyps throughout the colon (familial polyposis), each with malignant potential. In these patients, the *APC* gene represents a tumour suppressor gene. When both copies of this gene are affected or lost, colon polyps will develop, frequently at a very early age. The mechanisms for the formation of polyps and cancer in patients with familial polyposis has been validated by murine models in which the *APC* gene has been mutated or completely knocked out. In these models, mice develop numerous adenomatous polyps throughout the small bowel, with some in the colon. While these polyps generally do not develop into invasive cancers, they frequently bleed and lead to obstruction of the bowel. These mice provide a valuable resource for the testing of new drugs that might prevent polyps or cancer. For example, aspirin and other nonsteroidal agents have been demonstrated to reduce the incidence of polyps in mice, verifying the observation in humans that drugs like these may be beneficial in preventing cancer. Interestingly, this gene is also the most commonly affected gene (up to 95% of cases) in noninherited forms of colon cancer, otherwise known as sporadic colon cancer. Because it is the first gene to be affected in the development of colon cancer, it has been called the *gatekeeper*. Until recently, its role in the development of colon cancer has remained elusive but now there is evidence to suggest that the mutated *APC* gene may activate the transcription of two genes downstream, *MYC* [He, et al.:] and *CYCLIN D* through the action of proteins such as β-catenin and TCF/lef-1. The protein products of these genes, c-Myc and cyclin D, have been implicated in cellular transformation and the growth of cancer.

In common with *APC*, the *RAS* gene is also thought to be involved in the early transition from normal epithelium to premalignant tissue. The *RAS* gene is commonly mutated (up to 50% of cases) in premalignant colon polyps. It is one of the most well understood protooncogenes. We now know that it has a normal function in activating downstream genes in signal transaction cascades through phosphorylation events. When the *RAS* gene is mutated, it is constitutively activated in a guanosine triphosphate (GTP)-locked form, such that it is always capable of phosphorylating downstream targets, targets critical to the growth control of the cell. It results in an activated Ras pathway, whereby Ras activates downstream proteins such as Raf, MEK, MAPK and Erk, with the end result being increased transcriptional activity in the nucleus. This transcriptional activity is presumed to maintain continuous growth characteristic of the cancer cell. More recently, the mechanism by which Ras is attached to the cytoplasmic membrane has been elucidated. A farnesyl group is transferred to the Ras protein by an enzyme called *farnesyltransferase*, which is now the intense target of drug discovery efforts (farnesyltransferase inhibitors, FTIs). FTIs are already in clinical trials that seek to inhibit this enzyme and thus prohibit the interaction of Ras with the cytoplasmic membrane, there by blocking the growth effects of Ras. For signal transduction cascades, location is critical, and without membrane association even mutated Ras becomes inactive without farneslyation.

Once a number of early genetic changes have occurred, additional changes may snowball. This process is termed genetic instability. The predisposition to cellular division results in increased potential for mutational events, and subsequent genetic changes can accumulate. One prominent genetic change occurs in the *p53* gene. The *p53* gene is the most commonly mutated gene in human cancer (up to 50% of all human cancers contain a *p53* mutation) [Koshland, ref.]. Because its deletion results in spontaneoustumor formation in both animal models and in humans, it is thought to represent a tumour suppressor gene where both alleles or genetic copies must be affected to result in a phenotypic change. The normal function of *p53* appears to be related to DNA repair following a toxic insult.

When DNA is damaged, normal or wild-type *p53* signals the cell to self-destruct, a form of cellular suicide called *apoptosis*. When *p53* is mutated, DNA damage may go unrepaired and unrecognized, resulting in the contribution of damaged DNA to subsequent generations of cells. The lack of recognition of abnormal cells, with their associated elimination, is a critical failure common to cancer cells. Mutations spontaneously developing subsequent to the *p53* mutation may theoretically be accumulated rapidly without correction. This is precisely why tumors at advanced stages seem to have accumulated larger numbers of genetic defects, engendering the capacity for advanced rates of growth invasion and distant metastasis or spread.

Other genes and chromosomal defects that have been reported include the *MCC* tumour suppressor gene located on chromosome 5 [Gayther, et al.: and Kopnin, refs.], in the *DCC* [Chen, et al.: Saito, et al.: and Sturlan, et al.:] and *DPC-4* tumoursuppressor genes located on chromosome 18. The *DPC-4* gene is now also known as *Smad-4* and may be regulated in part by the transforming growth factor β(TGFβ) receptor pathway [Korchynskyi, et al.:]. The latter genes appear to be associated with more advanced stages of disease. More recently, a gene such as the *SRC* oncogene has also been identified as participating in the process of advanced tumour growth [Irby, et al.:]. It is believed that mutations in genes such as *SRC*, which are generally uncommon, are possible in a milieu of the tumour cell with multiple mutations capable of continuous unchecked growth and DNA repair. SRC overexpression or activation may be responsible for antiapoptotic activity and increased angiogenesis, both of which may contribute to tumour development and progression.

Familial Adenomatous Polyposis

FAP is a rare inherited disease characterized by the development of hundreds to thousands of adenomatous polyps in the colon by early adulthood. Less than 1% of all colon cancers are secondary to FAP. Without treatment, 100% of patients with this disease will develop invasive colon cancer with the risk of metastatic spread. Recently, the genetic lesion responsible for this disease has been identified. The *APC* gene has been found to be mutated, such that one copy or allele is defective, generally resulting in a shortened protein product. Interestingly, this is the same gene in which a missense mutation has been found in 6% of Ashkenazi Jews[1] (a different, less severe mutation conferring a slightly increased risk of colon cancer) and in most tumors from patients with sporadic or noninherited forms of colon cancer. These common genetic links suggest an important role for the *APC* gene in the development of colon cancer. More recently, a specific role for the *APC* gene product in colon cancer cells has been elucidated. A pathway initiated by the mutated *APC* gene product appears to lead to the increased production of c-Myc, a transcription factor linked to cellular transformation and growth. In addition, the APC pathway may lead to the increased production of cyclin D1, resulting in the stimulation of cell growth via the cell cycle.

Because FAP is an inherited genetic disease associated with mutation of genomic DNA, the entire mucosal surface of the large intestine is at risk for the formation of polyps and cancer. Moreover, these patients carry the risk of developing polyps in the duodenum. In addition, variants of the familial polyposis syndrome include Gardner syndrome and Turcot syndrome, presumed also to be linked to defects of the *APC* gene. Because of this risk, treatment is aimed at the prophylactic removal of the entire colon and rectum at an early age, before the formation of any cancerous changes. Treatment options include total proctocolectomy, with permanent colostomy or with reconstruction by an ileoanal pull-through procedure.

Hereditary Nonpolyposis Colon Cancer

HNPCC is another form of hereditary cancer, accounting for up to 10% of colon cancer cases. It has also been referred to as Lynch syndromes I and II. Patients with this disease tend to have numerous relatives diagnosed with colon cancer, some before the age of 50 — or approximately 10–15 years before the appearance of most colon cancers.

Unlike FAP, this disease has been linked to mutations in proofreading genes coding for mismatch repair enzymes. These genes include *MLH1, MSH2, PMS1, and PMS2*. This disease is also characterized by the replication error phenotype (RER) which results in microsatellite instability. While instability at multiple microsatellite loci can screen for affected individuals, clinical criteria (Amsterdam) [Syngal, et al.:] are now also available for attempting to predict the risk of harboring this disease. The name for this disease is somewhat a misnomer because the majority of patients actually harbor a number of polyps, although many fewer than seen in FAP. This disease may manifest itself in early adulthood and result in the development of invasive cancer. It has also been associated with the formation of tumors in other organs and is predominantly linked to formation of right-sided colon cancers. Genetic testing for the disease is now available for patients meeting specific clinical and family history criteria.

Detection

Because the colon is deep within the abdominal cavity, it is common for a developing cancer to go undetected until significant symptoms develop. Generally, a tumor must bleed, resulting in blood in the stool, or must obstruct the bowel lumen, resulting in abdominal pain, before it can be detected without routine screening measures. It is precisely for this reason that many patients present with large tumors or with advanced disease that has already metastasized to distant organ sites at the time of diagnosis. This is a disappointing fact because the majority of tumors take years to develop, during which time there may be the opportunity for early detection and possible prevention.

[1] The name Ashkenaz was applied in the Middle Ages to Jews living along the Rhine River in northern France and western Germany. The center of Ashkenazi Jews later spread to Poland-Lithuania and now there are Ashkenazi settlements all over the world. The term "Ashkenaz" became identified primarily with German customs and descendants of German Jews. See also http://www.jewishvirtuallibrary.org/jsource/Health/genetics.html.

Early detection by screening is generally the best means of detecting this disease in a curable stage. The concept of screening to reduce cancer mortality has gained significant favor in the management of breast cancer, where routine screening mammography has shifted the identification of the majority of breast cancers to earlier stages than was previously possible. While in the past colon cancer screening was limited to the use of anuncomfortable air-contrast barium enema, current fiberoptic technology has permitted development of flexible sigmoidoscopes and colonoscopes, which can be used to inspect the entire mucosal surface of the large intestine without significant discomfort. Current screening recommendations from the American Cancer Society (Table 1) recommend an annual faecal occult blood test, and sigmoidoscopy every 5 years, starting at age 50, for low-risk adults. For those with a first-degree relative diagnosed with colon cancer, a total colonoscopic examination is recommended, starting at age 40 or 10 years before the age at which the youngest first-degree relative developed cancer.

TABLE 1. AMERICAN CANCER SOCIETY GUIDELINES OF THE EARYL DETECTION OF COLON OR RECTAL CANCER

Starting at age 50, both men and women should have:

- yearly faecal occult blood test, and flexible sigmoidoscopy and digital rectal examination every 5 years
- or
- colonoscopy and digital rectal examination every 10 years
- or
- double-contrast barium enema and digital rectal examination every 5–10 years
- People should begin screening earlier and have it more often if they have any of these risk factors:
- a strong family history of colon or rectal cancer or polyps (mother, father, sisters or brothers)
- a family history of hereditary colorectal cancer syndromes
- a personal history of colon or rectal cancer or chronic inflammatory bowel disease (having already had colorectal cancer)

Tumor markers are generally ineffective in detecting carcinoma of large intestine and are therefore not recommended for screening purposes. Once diagnosed with colon cancer, however, measurements of carcinoembryonic antigen (CEA) may be useful in predicting the presence of distant metastatic disease (serum levels >10 ng ml^{-1} for determining the effectiveness of a surgical resection. Computed tomography is generally not useful for screening purposes but is quite effective in determining the extent of local or metastatic disease.

Treatment

The treatment plan for colon cancer is generally based on the state of the disease, the location of the disease and the functional status of the patient. Thus, attempts atpreoperative staging can be useful in the proper management of the colon cancer patient. The primary treatment modality for colon cancer is surgery. Most surgical procedures are performed via an exploratory laparotomy, although laparoscopic procedures conducted without large systems are also being performed on an experimental basis. Surgical extirpation of the disease is frequently the most important component of treatment and may be the only form of treatment required. These operations are nearly always accomplished without the use of a permanent colostomy, and only rarely are temporary colostomies needed. Wide local excision with resection of associated regional lymphatics and lymph nodes is the underlying principle of all surgical treatment of the colon. In most circumstances, the risk of local recurrence is not related to the extent of a mucosal margin (proximal or distal) but rather it is often related to the extent of a radial margin. This status is justified by the fact that the anastomotic occurrences are actually uncommon. On the other hand, local recurrences and local metastatic spread to the peritoneum and the omentum (termed carcinomatosis) are more common. This problem relates to the frequent full-thickness penetration of the bowel wall by colon cancers. Cancers that invade all layers of the bowel wall may continue to invade adjacent organs and local tissues or spread throughout the abdomen, much like the seeds of a dandelion in the wind. The surgeon faced with local disease will generally attempt to resect it all *en bloc*; even adjacent organs, such as the uterus, ovaries or bladder, may be completely

or partially removed. Once the disease has metastasized to lymph nodes beyond the local basin, or to distant organ sites such as the liver or the lungs, it is rarely curable by surgical intervention alone. Exceptions include limited metastatic disease (fewer than four lesions) to the liver or lungs without extrahepatic or extrapulmonary disease.

Once the disease has spread to lymph nodes or to distant organ sites, chemotherapy is generally incorporated into treatment plans. Adjuvant chemotherapy is generally recommended for patients with nodal disease (Dukes' stage C). Current regimens generally utilize 6 months of adjuvant chemotherapy with S-phase-specific cytotoxic drugs, including 5-fluorouracil and leucovorin. While patients with full-thickness tumors but without evidence of total disease (Dukes' B) carry the risk of distant metastasis, chemotherapy has not been proven to be effective. Recently, however, immune modulation has been demonstrated to have potentially beneficial effects in this subgroup of patients. Modulation may take the form of vaccination with radiated, autologous tumour cells in combination with the immune adjuvant bacillus Calmette–Guérin (BCG). Recent trials are also underway with an antibody called 17-1A directed against tumor cells, which may have some benefitin these stages of disease (Dukes' B and C).

For patients with metastatic disease to distant sites, such as the liver or lungs, systemic chemotherapy is generally indicated and includes drugs such as 5-fluorouracil, leucovorin and ironotecan. While 5-fluorouracil has been the mainstay of colon cancer chemotherapy for 30 years, novel therapeutic interventions are currently in clinical trials. These agents include drugs to inhibit blood vessel formation (antiangiogenesis) and drugs to target specific abnormal proteins within the colon cancer cell, such as Ras. COLONY. A group of individuals of the same species living together for mutual benefit. They may be structurally united or separate and may be alike in form or of different types suited for various functions. See also **Ecology**.

COLOR. This vast subject is complicated by the distinction between the physical basis of colors and the sensations produced by them; and still further by a somewhat confused and unsettled vocabulary. Color consists of those characteristics of light other than spatial and temporal inhomogeneities, light being defined here as that aspect of radiant energy of which a human observer is aware through the visual sensations which arise from the stimulation of the retina of the eye. Color is a broad psychophysiological concept, embracing far more than the psychological sensation of hue. It includes the grays, as well as the chromatic colors; the characteristics of light constituting color may be stated in terms of the appropriate photometric quantity, dominant wavelength and purity — corresponding generally to the attributes of visual sensations, brightness, hue, and saturation.

The practical standard "white" light is direct noon sunlight. A "perfectly white" surface would reflect white light completely without any alteration. No such surface exists. Even snow does not reflect white completely, though it does reflect all visible wavelengths in the same proportion. Its color is one of the "grays" or achromatic colors, of very high "brilliance"; while that of a lead pencil mark is a much feebler achromatic color. A "black" surface would reflect no light at all (see **Black Body**). Most colors, however, are chromatic, that is, they exhibit "hue," because their spectral energy distribution differs so much from that of white or gray that they look "reddish," "bluish," etc. Some colors of the same hue are more "brilliant" than others. Just as snow is of a more brilliant gray than graphite, so bright red is more brilliant than dark red. Further, some colors have greater purity or "saturation" than others; that is, they have more pronounced hue, or are more chromatic, and therefore differ more from a gray of the same brilliance. Thus foliage looks "greener" when freshly washed than when dusty. A chromatic color having little hue but high brilliance is a "tint," e.g., pink; while one of little hue and low brilliance, like brown, is a "shade."

We must now recognize the fact that the same color sensation can be produced by entirely different physical stimuli. Tests of a large number of observers with the spectrometer indicate that, according to the average judgment, the common names of pure spectral hues should be applied to the several wavelength ranges approximately as follows:

	ANGSTROMS		ANGSTROMS
Violet	3900 to 4550	Yellow	5770 to 5970
Blue	4550 to 4920	Orange	5970 to 6220
Green	4920 to 5770	Red	6220 to 7700

But the sensations produced by any of these, or by any of their tints, shades, or mixtures, can also be produced in a variety of other ways. For example, red and green light may be mixed to produce a good imitation of spectral yellow light, though no yellow wavelengths are present in the mixture.

According to the Young-Helmholtz theory, the human vision has three separate color sensations, each capable of stimulation in various degrees. It is thought that, if stimulated separately, they would prove to be the sensations produced by red, blue, and green light, respectively. But they always act together, and every color sensation is the effect of their joint stimulation in some definite proportion. A result of this is that any color can be successfully imitated by adding together red, blue, and green light with suitable relative intensities. These are therefore called "additive primaries." If added in equal intensities, they produce a sensation of white. White may, however, be produced also by adding in suitable proportions various pairs of pure spectral hues, which are "complementary" to each other; thus:

ANGSTROMS	ANGSTROMS
6562 and 4921	5671 and 4645
6077 and 4897	5644 and 4618
5853 and 4854	5636 and 4330
5739 and 4821	

(The third pair, for example, is a certain yellow and a certain blue.)

Color sensations are also commonly produced by removing certain components from white light, as by the use of filters. Pigments such as paint and colored inks act in this way, being selectively reflective. The complementary hues of the three additive primaries are the "subtractive primaries" blue-green (for red), yellow (for blue), and purple (for green).

Maxwell devised an ingenious graphical scheme, called the "color triangle," for representing mixtures of colored lights (not pigments). See Fig. 1. The three additive primaries red, blue, and green are at the vertices of an equilateral triangle, with their complementary subtractives blue-green, yellow, purple on the sides opposite. Each altitude, as PG, is taken as 100%. Any hue is represented by a point H, whose distances r, b, g, from the three sides represent the percentages of the three primaries R, B, G which must be added to imitate it ($r + b + g = 100$). Thus for the point H in the figure, $r = 60$, $b = 10$, $g = 30$, giving a reddish-yellow sensation. The point W, at the center of the triangle, corresponds to the sensation of white.

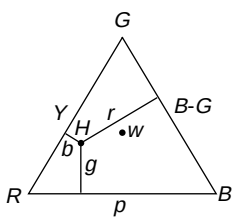

Fig. 1. Color triangle.

COLORADO POTATO BEETLE *(Insecta, Coleoptera).* A leaf-eating beetle, *Leptinotarsa decemlineata*, native to the western United States. Originally it fed on a native plant but about the middle of the nineteenth century it became troublesome in potato fields and rapidly spread across the country. Both larva and adult eat the leaves of potato plants.

COLOR (Animals). The coloration of animals embraces both the colors that appear in their bodies and the patterns in which they are arranged. In many species color appears to be incidental but in others coloration has an important bearing on the life of the individual.

Colors are due in some cases to the presence of compounds that are important for other reasons. The blood of insects, for example, may be green, that of certain mollusks blue, and that of the vertebrates and annelid worms red because of their chemical composition, but these colors have no important bearing on individual life. The black pigment found in eyes is a protection against random light rays but any impervious layer would be as effective; black color is unimportant in itself.

In many animals colors of this kind are supplemented by special pigments located in the superficial layers of tissue and in the vestiture, such as hair, feathers, and scales. Some animals are able to change their color by varying the expansion of the pigment. The surface of the integument in insects is often formed so that it breaks up light rays and reflects only a portion of them. The colors produced in this way are called physical colors and are usually metallic or glassy. All of these colors, whether physical or pigmental, are often arranged in intricate patterns characteristic of the species. In this arrangement details may be observed in some animals which seem to have definite value in relating the individual to its environment.

The white tail patch found in some deer and rabbits has been interpreted as a signal mark. It may serve for ready recognition in poor light and may catch the attention of other members of a group when danger is near.

Warning colors are exemplified by the brilliant red and yellow of the coral snakes. Poisonous or distasteful animals are usually avoided as food and conspicuous appearance makes it all the easier for other animals to see and avoid them. The male sex is frequently advertised by conspicuous coloration.

Concealing colors render the animal less conspicuous in its normal environment, and are essentially the same in the hunter and in the hunted. The white winter coats of the prairie hare and of the weasel are equally inconspicuous against the snow, but the one animal is helped to escape its enemies and the other to catch its prey by this means. Concealing colors may also be in patterns. The black and tawny stripes of the tiger, for example, are said to conceal it admirably in tall grasses lighted by the sun, where vertical shadows are conspicuous. This aspect of coloration, however, merges with protective mimicry, and in mimicry physical form is involved as well as coloration.

See also **Adaptation (Ecology)**.

COLORANTS (Foods). Color, as a component of appearance, is important in the sensory evaluation of a food substance, including beverages. Color affects the degree of acceptability of a food product in the marketplace. Color also is a frequently useful indicator of the degree of wholesomeness of a foodstuff. Many foodstuffs are attractively colored as the result of their naturally occurring pigments. In these instances, a major objective of the food grower and processor is to protect and preserve the natural colors as long as may be required by the distribution network, considering such factors as temperature and humidity to which the food substance may be subjected before reaching the consumer.

Considering the expectations of consumers, particularly in countries that have an advanced food technology, colorants, along with flavorings and texture modifiers, are important. These factors are particularly stressed in connection with modern fabricated foods, substitute foods, and food analogues. Many years have passed since final approval was given to margarine producers to use colorants and artificial flavorings. Even though artificial flavors are used in some products, ice creams and ices, as well as soft drinks, are color matched to their fruit flavors. Yellow colorings provide a note of richness in cake mixes, eggnogs, and other products associated with their content of eggs; cheese snacks are both colored and flavored to simulate cheese; popcorn oil is usually colored; iron oxide can be added to pet foods to simulate the color of meat; the red coloration of cherries is intensified by using red colorants in the processing of maraschino cherries. Caramel colorings are widely used in both alcoholic and nonalcoholic beverages.

Particularly during the past several decades, regulatory agencies in various countries have scrutinized colorants (along with other food additives) against a backdrop of consumer health. Since the early 1900s, several countries have approved colorants for use in foods only after thorough physiological testing. In recent years, analytical instrumentation and research methodologies have become sophisticated and measurements of minute quantities are now practical. With improved analytical tools and a heightened awareness of the effects of foods upon health, a number of colorants that once were considered perfectly safe have come under question. In some countries, most or all synthetic colorants have been banned. Generally, the limitations on the use of colorants have become much more stringent.

In the United States, the first rather complete legislation involving such matters was the Food and Drug Act of 1906. As a result of that legislation, the list of colorants permitted was reduced to only seven dyes. Because the remaining seven dyes did not provide sufficient flexibility in the formulation of food products, considerable research went forth to find additional colors, not only with more desirable hues, but easier to use (solubility in oil/water, less temperature sensitivity, etc.). During the 66-year period from 1906 to 1971, several additional colors were added. In 1938, the Food, Drug, and Cosmetic Act was passed. The common names of dyes previously used were given color prefixes and numbers. For example, Amaranth became FD&C Red No. 2. Under the new act, certification became mandatory.

The color situation in the food industry was relatively without incident until the early 1950s, when, as the result of a few cases of excessive levels of usage in some candies and popcorn, two colors (FD&C Orange No. 1 and FD&C Red No. 32) were delisted. After much controversy and considerable litigation, more colors were delisted. To rectify legal complexities and unworkability of the 1938 Act, the Color Additives Amendments of 1960 were passed. Nevertheless, as pharmacological studies continued, a number of other colors were de-listed during the interim. Much more recently, FD&C Red No. 3 Lake colors were banned in the United States. The foregoing paragraphs relate largely to the use of synthetic colorants. Natural colorants include the anthocyanins, annatto colors, the betalaines, the carotenoids, cochineal, saffron, turmeric, and titanium dioxide. Caramel coloring also falls into this category. Paprika is used in some foods for its coloring attributes.

Anthocyanins are water-soluble pigments that account for many of the red, pink, purple, and blue colors found in higher plants. Most plants contain more than one of these pigments and they occur most prevalently as glycosides. Several hundred different anthocyanins are known. These compounds are most stable at a pH range of 1 to 4, thus limiting the spectrum of usage. As compared with synthetic colorants, the anthocyanins produced to date generally are less stable, have less tinctorial potency, and lack some color uniformity. They are degraded by light, heat, enzymes, and interact with ascorbic acid. They also tend to form complexes with metal ions to produce off-colors. Their main advantage stems from the fact that they are naturally derived and thus not regarded with suspicion as health deterrents as are many synthetic materials. On the other hand, attempts to alter and modify them to make up for their fundamental disadvantages could also move them toward a suspicious category — a factor which researchers on anthocyanins are taking into consideration.

Numerous commercial sources for the anthocyanins have been and are continuing to be investigated. These sources include grape anthocyanins, apparently with good potential in the carbonated beverage field. Roselle plants, native to the West Indies, have been studied and appear to have potential for use in apple and pectin jellies, but not for carbonated beverages, such as ginger ale. Cranberry pomace and blueberries have been investigated. Considerable interest has been shown in the red anthocyanin pigments of miracle fruit (*Synsepalum dulcificum*, Schum), a tropical plant that produces a red berry.

Red cabbage as a colorant source has been studied for many years. As of 1990 at least one firm has introduced San Red RC, the first commercially available food color derived from red cabbage. The color can be used alone or in combination with other colors to create strawberry, cherry, raspberry, and blueberry tones. By way of proprietary technology, the new dye is claimed to be free of flavor and odor defects, which in the past have been associated with red cabbage. The dye is pH dependent. The color tones move toward blue-red as the pH value increases. San Red RC ranks between cochineal and grape juice in percent of color retention.

Betalaines are sometimes referred to as beetroot pigments. They are made up of two main groups: (1) *betacyanins*, the principal component of which is betanin; and (2) *betaxanthins*, the principal component of which is vulgaxanthin-I. The betacyanins contribute a red color, whereas the betaxanthins are yellowish. Another yellow pigment, betalamic acid, derives directly from cleavage of betanin and is probably the key intermediate in the biogenesis of all betalaines.

A factor of concern in connection with the betalaines is the earthy flavor associated with beets. To date, beets have been regarded as the primary source for these substances.

Carotenoids. These yellow-orange colorants are described in entry on **Carotenoids**.

The other natural colorants previously mentioned have been used for many years and are familiar to nearly everyone. Annatto colors are described in a separate entry, **Annatto Food Colors**.

Synthetic Colorants. Perkin, in 1856, synthesized the first synthetic dye, *mauve* or *mauveine*, by the oxidation of crude aniline. In that time and for about 80 years, coal tar was the principal source of aromatic compounds, which, in turn, were the sources of numerous synthesized dyes used primarily in textiles, but some of which were found to be adapted to other uses, including the coloring of food substances. This generally gave rise to the term "coal tar color" used commonly in the food and cosmetics industries for many years. Of course, with the development of more sophisticated organic syntheses and the petrochemical field, the association with coal tar no longer had a direct meaning. The term was finally eliminated from legislation in connection with the Color Additives Amendments of 1960. It is interesting to note, however, that prior to the first Act of 1906, it is estimated that some 80 such dyes were being used in a large number of food products, at a time when there were no regulations regarding the nature and purity of colorants used in foods.

Lakes. In the United States, FD&C lakes were accepted for the approved list of certified color additives for the first time in 1959. As defined by the FDA, a lake is an "Extension on a substratum of alumina, of a salt prepared from one of the water-soluble straight colors by combining such a color with the basic radical aluminum or calcium." Because the substratum of alumina hydrate or aluminum hydroxide is insoluble, the lake provides an insoluble form of the dye, i.e., a pigment. Colors from dyes result from solution in a solvent; whereas colors from pigments result from dispersion of that pigment throughout the food substance. Prior to the acceptance of lakes, insoluble colorants were formed by absorbing them on materials (insoluble), such as cellulose, flour, and starch. Generally, these forms were inadequate because of relatively low coloring power.

When utilized in solid or semisolid vehicles, dyes must be added in solution to achieve effective coloring. Thus, color migration is a problem. Dyes can migrate with the solvent during various drying or processing operations. Because lakes are insoluble, color migration is negligible in applications where distinct interfaces are required. Striped candy pieces provide an example. Where opacity is required, titanium dioxide can be added to lakes. In high-quality lakes, nearly all particles will pass through a 325-mesh screen when wet-tested. Shades of coloration can be produced by blending the various FD&C Lake Colors.

Extending Natural Colors. For some natural foods, such as meat and fish, colorants are not added, but natural colors can be extended over a longer time span by adding various approved chemicals. For example, the bright red color that consumers prefer in fresh meat is due to oxygenated myoglobin, with iron on the heme group in its ferrous state. When oxidation occurs due to exposure, the ferric form is produced which imparts a brown discoloration to the meat. A mixture of tetrasodium pyrophosphate, sodium erythorbate, and citric acid, when combined with modified-atmosphere packaging, will extend the life of the bright red coloration of the meat. Care must be exercised to avoid "masking" microbial problems that develop when meats are held too long.

COLOR BLINDNESS. Color blindness is any abnormality of the color vision system that causes a person to see colors differently than most people or to have difficulty distinguishing among certain colors. The medical term for this condition is color users deficiency.

Color vision deficiency is can be caused by: inherited defects of the color-sensitive pigments of the cone cells, which are concentrated in the macula, the central area of the retina; an abnormality of the cone cells; a reduced number of cone cells; and injury or certain diseases of the retina or optic nerve.

Total color blindness, in which the world is seen only in black, white and gray, is very rare. Most persons with color vision deficiency have vision that is adequate for most purposes, but cannot distinguish certain colors. Reduced discrimination of wavelengths within the middle part of the visual spectrum hinders the person's ability to see green. Reduced discrimination in the long parts of the spectrum results in difficulties seeing the red family of colors. A rarer form is blue deficiency, or tritanopia, which may be inherited but can result from the toxic effects of drugs or poison or deterioration of the retina or optic nerve.

Inherited color vision deficiency usually is gender-based. The majority of sufferers are male. Some women may carry the gene defect and pass it on to their children. The overall incidence of color vision deficiency for whites of European origin is 8% for males and 1% for women. The incidence is lower for Asians and Native Americans and lowest of all for blacks.

Color vision deficiency is detected by tests that use special color plates under daylight conditions. The test usually is conducted during the childhood years. It is also performed when an adult applies for a job in which color vision is essential, such as airline pilot. The exact degree of color vision deficiency can be determined by a test that requires the arrangement of sequences of colored chips or by an instrument called an anomaloscope, which shines a mixture of red and green lights. The person being tested adjusts the mixture until it appears the same as a fixed spot of yellow light. An adjustment that yields a mixture that is too red or too green indicates the presence and severity of color vision deficiency.

Many people with color vision deficiency are not aware of the problem because it does not interfere with everyday living. It can be detected during employment tests for an occupation requiring normal color vision. Such positions include airline pilot, commercial artist, marine pilot, color photographer, or electrician, where the ability to distinguish color-coded wires is important. There is no treatment for the condition. See also **Retina**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

COLOR CENTERS. Certain crystals, such as the alkali halides, can be colored by the introduction of excess alkali metal into the lattice, or by irradiation with x-rays, energetic electrons, etc. Thus sodium chloride acquires a yellow color and potassium chloride a blue-violet color. The absorption spectra of such crystals have definite absorption bands throughout the ultraviolet, visible and near-infrared regions. The term *color center* is applied to special electronic configurations in the solid. The simplest and best understood of these color centers is the F center. Color centers are basically lattice defects that absorb light.

COLORIMETRY. A method of chemical analysis that deals with the measurement of the light absorption by colored solutions. Since light absorption depends upon the concentration of a specific constituent in solution, colorimetry is frequently used by geologists to determine qualitatively the trace quantities of many elements.

The fundamental principle of colorimetry states that the amount of light absorbed by a given substance in solution is proportional to the intensity of incident light and to the concentration of the absorbing species. This is expressed mathematically in the *Lambert-Beer law*:

$$\log I_0/I = abc$$

where I_0 = intensity of incident light
I = intensity of transmitted light
a = absorptivity of the substance
b = light path length
c = concentration of colored substance
I/I_0 = transmittance
$\log I_0/I$ = absorbance

The term colorimetry is generally restricted to the visual comparison and matching of the color of a standard solution with that of an unknown one, whereas *spectrophotometry* involves the use of a photoelectric cell which measures a narrow band of wavelengths for transmittance.

Visual colorimetry is a simple method and is fairly precise. Essentially it requires the matching of the color of a standard solution with that of an unknown sample so that when they become identical, they must contain the same amount of colored substance in columns of equal cross-section. At this point

$$C_x b_x = C_s b_s \text{ and } C_x = C_s b_s / b_x$$

where C_x = concentration of unknown solution
b_x = length of light path of unknown solution
C_s = concentration of standard solution
b_s = length of light path of standard solution

A standard series of solutions is prepared, each with a known concentration, having the same volume as the unknown, and being contained in identical flat-bottomed tubes of equal diameter (*Nessler tubes*). The solutions should be compared in daylight and examined against a white background.

A more refined method uses the Duboscq colorimeter. This instrument features a dual-matched optical system. Uniformly intense light is incident upon both colorimeter tubes and the difference in absorption of the standard and unknown solutions is compensated for by adjusting the thickness of solution through which light passes. When the two colors match $C_x = C_s b_s / b_x$.

Spectrophotometry (q.v.) is the most precise method of measuring light transmittance. It involves the use of a photoelectric cell that measures a narrow band of wavelengths for transmittance, and a prism or grating to give monochromatic light. At each wavelength, three readings are made: (1) sample cell filled with solvent, which gives the value of I_0, (2) the cell filled with standard solution, and (3) cell filled with unknown. The ratio of meter readings of the cell filled with pure solvent and sample is the I_0/I ratio. Spectrophotometry may be used analytically to measure the absorption at a single wavelength, or to determine the whole absorption spectrum of liquids and solutions in the visible and ultraviolet regions.

COLOR INDEX. The human eye is more sensitive to red light than is the photographic plate. Thus, if we have a blue and a red star of the same apparent brightness, i.e., the same visual magnitude, the blue star will appear brighter on the photographic plate, whereas the red star will appear brighter to the eye. Hence, the scale of magnitudes determined photographically for a given sequence of stars will differ from that determined visually. The difference between the photographic magnitude and the visual magnitude for any star is known as the color index of the star. Thus the relation, *color index* $= m_{pg} - m_v$.

Since the spectral type of a star is also a function of the color of the star, we should expect to find a definite relationship between the color index and the spectral type. The "zero point" for this relationship is generally fixed for an AO-type star. Techniques involving color index are quite refined, and the system ofz U, B, V photometry is a good example. If one determines the color indices $B - V$ and $U - B$, one may plot these two coordinates against each other. The main sequence then forms a somewhat skewed curve below the black-body radiation curve. It is then possible, upon obtaining these two indices for any star, to move the star along the curve for a good fit, and, in this way, to determine the spectral type and the absolute magnitude of the star. Fig. 1 illustrates the essential features.

COLOR MIXTURE CURVE. A curve representing the amount of a standard component (usually specified in wavelength) required in a three-color mixture to match a sample color, for unit flux of spectral energy. The variables plotted are usually the amount in lumens of the standard component and the indicated wavelength of the sample color matched.

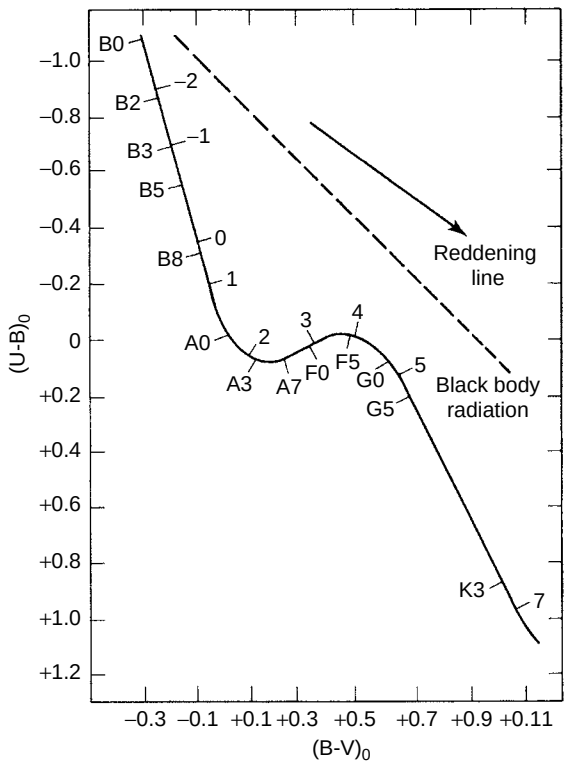

Fig. 1. The relation $(U - B)_0$ and $(B - V)_0$ for main sequence. The broken line represents black-body radiation. Arrow indicates the reddening path for the O stars. (*Becker, "Stars and Stellar Systems," University of Chicago Press.*)

COLOR (Nonspectral). 1. A color not present in the spectrum of white light. 2. A color that can be represented by a point, on the chromaticity diagram that lies on the straight line between the ends of the spectrum locus, or between that line and the achromatic point.

COLOR (Plants). The coloration of plants may be due to pigments in plant surfaces, to the selective scattering of certain wavelengths (colors) of light by small discontinuities in the subsurface structure, to the interference of light beams reflected from interior surfaces, or to a combination of some or all of these effects.

Besides chlorophylls, two other groups of pigments contribute to the color of many plants. They are the carotenoids and the water-soluble group of anthocyanin and anthoxanthin pigments. The carotenoids range in color from yellow to red or purple. Various isomeric forms of carotene are found in carrots and other plants, and one of them is the lycopene that colors tomatoes and rose hips. Various carotenols are found in yellow corn grains and in leaves of many other plants. A carotenone is found in one of the blue-green algae.

The anthocyanins form water-soluble glycosides, which are responsible for scarlet to purple or blue colorations in flowers. Similar compounds of the anthoxanthins are responsible for many pale yellow to ivory white shades. These pigments are also found often in leaves, woody tissues, and fruits.

In the leaves of higher plants, all these pigments add their colors to those of the chlorophylls, the net result depending upon the proportions and types of pigments present. The great variety of green shades observed in any wide expanse of green plants results from the various pigment mixtures modified by structural differences in leaf surfaces. In the fall after frost or following certain diseases or plant food deficiencies, leaf colors may change much due to decomposition of chlorophyll first, followed by carotenoids, permitting the remaining pigments to compose the color values. Thus a single leaf may have various color stages. These pigments all absorb much radiant energy from the sun, as do the chlorophylls, and many of them form vitamin A by changes in the animal metabolism (i.e., after they have been eaten by the animal).

See also **Annatto Food Colors**; **Carotenoids**; and **Pigmentation (Plants)**.

COLOR SATURATION. The attribute of any color perception possessing a hue that determines the degree of its difference from the achromatic color perception most resembling it. This is a subjective term corresponding to the psychophysical term purity. The description of saturation is not commonly undertaken beyond the use of rather vague terms, such as vivid, strong, and weak. The terms brilliant, pastel, pale and deep, which are sometimes used as descriptive of saturation, have connotations descriptive also of brightness.

COLOR TEMPERATURE (Stellar). If a star's radiation is measured at a number of wavelengths, and a black-body curve is fitted through them, the temperature of the star can be estimated from the shape of the curve. This is called a color temperature. Using two standard colors, one can derive a series of temperatures that depend upon the color index.

COLOSTRUM. The fluid secreted by the mother's breasts a few days before and after the birth of a child, before the secretion of true milk begins. It is a thin watery fluid rich in protein, especially globulin, by means of which protein deficiencies in the serum of new-born animals may be made up. In some species there is evidence of transfer of passive immunity to the young animal, by means of antibodies carried in the globulin fraction of the protein, but such evidence for the human species is at present lacking.

COLUMARIN. See **Anticoagulants**; and Furan and Related Compounds.

COLUMBA. A southern constellation found near Canis Major.

COLUMBIFORMES *(Aves).* In this order we combine several very dissimilar families. They are the pigeons (Columbidae), sandgrouse (Pteroclididae) and dodos (Raphidae), of which the last has died out, or rather, has been made extinct by man. Dodos and sandgrouse can at best be considered as very distant relatives of the pigeons.

The largest family in this order is the pigeons (family Columbidae), which are widespread in temperate and tropical regions. They are small to medium-sized birds; the length is about 15–80 centimeters (6–31 inches); they generally have small heads, plump, full-breasted bodies, and soft but very dense plumage. The aftershaft is underdeveloped or missing, but the lower part of the feathers is very downy. Head feathers sit very loosely and easily fall out. Moulting, in contrast to most other birds, is almost completely independent of brooding periods. The bills are slender with a cere at the base and a constriction at the mid-portion. There are 55–59 genera with 302 species.

All birds in this order drink by immersing the bill and sucking, a most unusual method in birds. Vocalizations are usually unmistakable cooing sounds, but also include growls, hisses and whistles. In addition there are flight sounds caused by notches on the primary wing feathers.

Pigeons are monogamous. They build weak and flimsy platform nests of twigs, straw or similar nest materials. The female sits in place and tucks the material around and under her body, while the male collects nesting material and gives it to the female. One or usually two (exceptionally three) eggs are laid, and incubation is shared by both parents. Males sit by day, and the females at night.

Most species of pigeons and doves show only a small degree of sexual dimorphism. Males are slightly larger and have slightly more conspicuous patches of display color on or near the head or anterior parts of the body.

Nearly all species are at least partly arboreal; a few live around rocky cliffs and some are nearly completely terrestrial. Pigeons are found in all parts of the earth but almost completely avoid the Polar regions.

The domestic pigeon is derived from selective breeding in the Rock Dove (*Columba livia*). The length is about 33 centimeters (13 inches), the wing length is about 22 centimeters (7 inches), the wingspan is 63 centimeters (25 inches), the tail length is 11 centimeters (4 inches), and the body weight is 330 grams ($10\frac{1}{2}$ ounces). There are 14 subspecies of the rock doves.

Domestic pigeons that have become wild are difficult to distinguish from rock doves, insofar as they resemble the wild form. They have a larger distribution than the rock dove and thousands of them can be found in large cities in Europe, America, and Asia.

Food of the rock dove consists largely of grains containing meal and oil, available from a variety of plants, corn, and many weeds. In addition,

snails, insects and occasionally worms are eaten. Small stones, sand, clay, lime, and mortar supplement the diet. The salt requirement is satisfied by feeding at dung heaps or areas near toilets or chemical refuse sites.

There are approximately 140 races of domestic pigeons with numerous coloration patterns. Most races have the four basic colors, blue, black, red, and yellow, as well as white. Earlier pigeons were divided into groups with field (hybridized) pigeons together, those of pure race together, and carrier pigeons. Another division was made on the basis of shape, color, markings and other characteristics, from which the following groups were differentiated: 1. runts, Florentine, Maltese, and Modena pigeons; 2. carriers, with well-developed wattles and eye ceres; 3. show pigeons, including German beauty homers; 4. pouters; 5. Silesian, moorheads, and trumpeters; 6. Jacobins, Schmalkalden moorheads, fantails, frillbacks, and Oriental frills; and 7. tumblers and highfliers with flight peculiarities (somersault flight in the former and extensive high and elegant flight in the latter).

Carrier pigeons deserve special mention. Pigeons have been used for sending communications since earliest times. The carrier pigeon of today was created over a century ago in Belgium by breeding various races. This species can cover 800–1000 kilometers (497–621 miles) in a single day.

Pigeon breeding is considered to have begun in Egypt in the fourth century B.C. The first white pigeon was recorded in Greece in 478 B.C. Carrier pigeons came into use a short time thereafter. Innumerable pigeons were sacrificed in the Temple of Jerusalem. Some 5000 pigeons were kept in a pigeon house on the Mount of Olives. Pigeons were regarded with high esteem by the earliest peoples of the Orient. They could nest in the temples and could not be disturbed or killed.

The Mourning Dove (*Zenaidura macroura*) is the common dove of North America. The length is around 30 centimeters (12 inches) and the weight is somewhat more than 100 grams (3.5 ounces). Its predominant color is olive-gray above, shading to pinkish-gray and brownish-gray beneath.

The food of the mourning dove is extremely varied, but is almost completely vegetable matter, chiefly seeds. As is true with most other doves, this species is a feeding opportunist and will take whatever is available. See also **Pigeons and Doves**; and **Poultry**.

COLUMBITE. A mineral oxide of iron, manganese, niobium (columbium), and tantalum; $(Fe,Mn)(Nb,Ta)_2O_6$. Crystallizes in the orthorhombic system. Hardness 6; sp gr 5.20; color, red to brown.

COLUMNAR STRUCTURE. 1. In geology, prismatic columns that develop in basic lava, due to the stress-strain relationships set up by rapid chilling. A relatively frequent phenomenon in basalt flows, such as those of the Giants' Causeway, Ireland. 2. In metallurgy, an arrangement of coarse, parallel, elongated grains in a casting with the grain axes normal to the mold surface.

COLUMN *(Meteorological).* A columnar ice crystal with hexagonal cross section and having aspect ratio (diameter to length) as much as 10 to 1. The column may be either solid or hollow with ends plane, pyramidal, truncated, or hollow. Pyramids and combinations of columns are included in this class. It is one of the common ice crystals found in cirrus clouds. See also **Clouds and Cloud Formation**; and **Hexagonal Column**.

COLUMN (Structural). That part of a structure whose purpose is to transmit, through compression, the weight of the structure and the superimposed loads to the foundation. Other compression members are often termed columns because of the similar stress conditions. The ratio of the length of the column to the least radius of gyration of its cross section is called the slenderness ratio. This ratio affords a means of classifying columns. All the following are approximate values for convenience. A short steel column is one whose slenderness ratio does not exceed 50; an intermediate length steel column has a slenderness ratio ranging from 50 to about 200, while a long steel column may be assumed as one having a slenderness ratio greater than 200. A short concrete column is one having a ratio of unsupported length to least dimension of the cross section not greater than 10. If the ratio is greater than 10 it is a long column. Timber columns may be classed as short columns if the ratio of the length to least dimension of the cross section is equal to or less than 10. The dividing line between the intermediate and long timber columns cannot be readily evaluated. One way of defining the lower limit of long timber columns would be to set it as the smallest value of the ratio of length to least cross-sectional dimension that would just exceed a certain constant K of the material. Since K depends upon the modulus of elasticity and the allowable compressive stress parallel to the grain, it can be seen that this arbitrary limit would vary with the species of timber. The value K is given in most structural handbooks.

If the load on a column is applied through the center of gravity of its cross section, it is called an axial load. A load at any other point in the cross section is known as an eccentric load. A short column under the action of an axial load will fail by direct compression but a long column loaded in the same manner will fail by buckling (bending), the bucking effect being so large that the effect of the direct load may be neglected. The intermediate length column will fail by a combination of direct stress and bending.

In the middle of the eighteenth century a mathematician named Euler derived a formula which gives the maximum axial load that a long, slender ideal column can carry without buckling. An ideal column is one that is perfectly straight, homogeneous and free from initial stress. This maximum load, sometimes called the critical load, causes the column to be in a state of unstable equilibrium, that is, any increase in the loads or the introduction of the slightest lateral force will cause the column to fail by buckling. The Euler formula for columns is

$$P = \frac{K\pi^2 E I}{l^2}$$

in which P = maximum or critical load
E = modulus of elasticity
I = moment of inertia of cross-sectional area
l = unsupported length of column
K = a constant whose value depends upon the conditions of end support of the column. For both ends free to turn, $K = 1$; for both ends fixed, $K = 4$; for one end free to turn and the other end fixed, $K = 2$ approximately, and for one end fixed and the other end free to move laterally, $K = \frac{1}{4}$

Examination of this formula reveals the following interesting facts with regard to the bearing power of columns. First, that elasticity and not compressive strength of the materials of the column determines the critical load. Secondly, the critical load is directly proportional to the moment of inertia of the cross section. The strength of a column may therefore be increased by distributing the material so as to increase the moment of inertia. This can be done without increasing the weight of the column by distributing the material as far from the principal axes of the transverse section as is possible consistent with keeping the material thick enough to prevent local buckling. This bears out the well-known fact that a tubular section is greatly superior to a solid section for column service. Another bit of information that may be gleaned from this equation is the effect of length upon critical load. For a given size column doubling the unsupported length quarters the allowable load. The restraint offered by the end connections of a column also affects the critical load. If the connections are perfectly rigid, the critical load will be four times that for a similar column where there is no resistance to rotation (hinged at the ends).

Since the moment of inertia of a surface is its area multiplied by the square of a length called the radius of gyration, the above formula may be rearranged as follows. Using the Euler formula for hinged ends, and substituting Ar^2 for I the following formula results:

$$\frac{P}{A} = \frac{\pi^2 E}{(l/r)^2}$$

where P/A is the allowable unit stress of the column, and the quantity l/r is the slenderness ratio.

Since the structural column is generally an intermediate length column and it is impossible to obtain an ideal column, the Euler formula has little practical value for ordinary design. Consequently, various empirical column formulae have been developed to agree with test data, all of which embody the slenderness ratio. For design, appropriate factors of safety are introduced into these formulas.

COMAGMATIC. Igneous rocks which have a common set of chemical, mineralogical, and textural features and thus considered to have derived from a common parent magma.

COMA (Optics). One of the five geometrical aberrations of a lens with spherical surfaces. Skew rays from a point object do not meet at the same point on the image plane, but rather in a pear-shaped spot (coma). The Abbe sine condition is a measure of coma. A lens system corrected for both spherical aberration and coma for a single object position is called aplanatic. See also **Aberration (Optical)**.

COMA (Physiology). A state of complete unconsciousness from which the affected individual cannot be aroused even by powerful stimuli. A person in coma is said to be comatose. There are numerous causes of coma — air embolism, brain tumor, cardiopulmonary arrest, cerebral edema, cerebral hemorrhage, cerebral thrombosis, cerebral vasculitis, decompression sickness, diving accidents, drowning, drug overdose, encephalopathy, epidural hematoma, head trauma, heatstroke, hypercalcemia, hyperosmolarity, hyperthermia, hypoosmolarity, infections of numerous kinds, meningeal carcinomatosis, myxedema, narcolepsy, and toxic agents (L-asparaginase, carbon monoxide, cyanide, ethyl alcohol poisoning, ethylene glycol, methyl alcohol poisoning, among others). Treatment, of course, varies with cause. Coma is often present just prior to death and may rise from numerous fundamental causes.

Coma often is a result of a water-related accident. In connection with drowning and near-drowning victims, the Glasgow Coma Scale was developed to assist in prognosis. See Table 1. A score of less than 5 identifies a high-risk situation, where 80% of the victims die or experience permanent neurological sequelae; a score of 6 or higher defines a lower-risk group.

Recovery from complete loss of consciousness is attained by certain stages and will vary with the cause. The entire coma may last but a few minutes, or any of the phases of coma may be prolonged for hours, days, and longer. Deep coma is marked by flaccid paralysis and even loss of involuntary motion. As the coma lightens, the patient passes into stupor, and reflex activity returns. The patient automatically responds to forceful commands, but is unaware of surroundings. The next phase, excitement or delirium, is marked by extreme restlessness and confusion, and sometimes the patient may be violent. The patient gradually becomes quiet, but remains extremely confused mentally. In the next stage, *automatism*, the patient answers questions and performs simple tasks in a fairly orderly but in an automatic manner. The highest functions of the brain, judgment and insight, are usually the last to return. See also **Central and Pheripheral Nervous Systems**.

Oriented	5
Infants (awake, alert, and babbling or crying)	15

COMBINATION. An assignment of a group of objects into two or more mutually exclusive sets. The binomial coefficient $\binom{n}{k}$ is the number of combinations or ways of selecting k objects from a set of n objects. If the k objects are permuted among themselves, no new combinations are formed, but there are $k!$ new arrangements of each combination. See also **Permutation**.

COMBINATION FREQUENCIES. The principle, first recognized by Ritz, that the many frequencies exhibited by the spectrum of a substance can be regarded as differences between a comparatively few terms characteristic of the substance, taken two at a time in their various possible combinations. Ritz's statement was quite empirical, but we now understand that these terms correspond to the different possible energy levels of the atom or molecule, and that the much more numerous spectral frequencies correspond to "jumps" or transitions from one state to another with consequent release or absorption of radiation quanta. For example, if an atom had twenty possible energy states or "levels," the number of possible transitions releasing energy would be theoretically $20 \times \frac{19}{2} = 190$.

It does not follow, however, that all of the corresponding frequencies are actually found in the spectrum; some are not seen because they are forbidden transitions or for other reasons are contrary to the principles of quantum mechanics, or because they occur too seldom to produce observable spectrum lines. When the principle is applied to certain molecular spectra, slight discrepancies are found which may be explained by assuming that some of the energy levels are not single but are close doubles. Such a discrepancy is known as a "combination defect."

COMBINING WEIGHTS. See **Chemical Composition**.

COMBUSTION. The rapid chemical combination of oxygen with the combustible elements of a fuel. There are three combustible chemical elements of major significance — carbon, hydrogen, and sulfur. However, as a source of heat, sulfur is of minor concern. Sulfur is of particular importance in the combustion of several fuels because of the corrosion and pollution problems that its presence creates.

Carbon and hydrogen when burned to completion with oxygen unite according to:

$$C + O_2 = CO_2$$
$$+ 14{,}100 \text{ Btu/pound (7840 Calories/kilogram) of carbon}$$

$$2\ H_2 + O_2 = 2\ H_2O$$
$$+ 61{,}100 \text{ Btu/pound (33,972 Calories/kilogram) of hydrogen}$$

Air is the usual source of oxygen for boiler furnaces. These combustion reactions are exothermic as indicated by the foregoing equations.

The objective of good combustion is to release all of the indicated heat while minimizing losses from combustion imperfections and superfluous air. The combination of the combustible elements and compounds of a fuel with all the oxygen requires *temperature* high enough to ignite the constituents, mixing or *turbulence*, and sufficient *time* for complete combustion. These factors sometimes are referred to as the "three Ts" of combustion.

This description* deals with the basic chemistry necessary for understanding the phenomena of combustion in boiler furnaces. See also **Boiler (Steam Generator)**. Ability to calculate the release of heat in combustion and to determine the amount and nature of the combustion products is essential for the design, for example, of a steam generating plant and determination of its performance characteristics.

Table 1 lists the chemical elements and compounds found in fuels generally used in the commercial generation of heat with their molecular weights, heats of combustion, and other combustion constants. The term "100% total air" used in Table 1 and figures and examples that appear elsewhere in this entry means 100% of the air theoretically required for combustion without excess. Higher percentages indicate the theoretical

* Basic information for this entry from "Steam — Its Generation and Use," copyright The Babcock & Wilcox Co., New York (39th edition, 1978).

plus excess air, e.g., 125% total air means 100% theoretical air plus 25% excess air.

Concept of the Mole. The mass of a substance in weight units equal to its molecular weight is a mole of the substance. For example, carbon (C) has a molecular weight of 12. Therefore, a pound-mole of carbon weighs 12 pounds, a gram-mole of carbon weighs 12 grams, etc. In the case of gases, the *volume* occupied by a mole is called the *molal volume* and this is constant for "ideal" gases. A pound-mole of a gas at 80 °F and atmospheric pressure (1 atmosphere or 14.7 psia or 30 inches of mercury) occupies 394 cubic feet. These concepts of mass and volume are useful in combustion calculations. Pound-moles are commonly used in power plant calculations in the United States and a number of other English speaking countries. Useful metric conversions will be found in the entry on **Units and Standards**.

Fundamental Laws

Several fundamental physical laws apply to combustion calculations. These are reviewed briefly as follows:

Conservation of Matter. This is the familiar statement that "matter is neither destroyed nor created." There must be a weight balance between the sum of the weights entering a process and the sum leaving. In other words, A pounds of fuel combined with B pounds of air will always result in $A + B$ pounds of products. (It should be noted that when a pound of a typical coal is burned, releasing 13,500 Btu, the quantity of mass converted to energy amounts to only 3.5×10^{-10} pound, a loss too small to be measured or considered in conventional combustion calculations. Obviously, this conversion is of significance to nuclear reactions.)

Conservation of Energy. This is the familiar statement that "energy is neither destroyed nor created." The sum of the energy (potential, kinetic, thermal, chemical, and electrical) entering a process must equal the sum of energy leaving, although the proportionate amounts of each may change. In combustion, chemical energy is exchanged for energy in the form of heat. The parenthetical observation made in the prior paragraph also applies to this relationship.

Ideal Gas Law. The volume of an ideal gas is directly proportional to its absolute temperature and inversely proportional to its absolute pressure. The proportional constant is found to be the same for one mole of any ideal gas, so this law may be expressed as:

$$v_M = \frac{RT}{p}$$

where v_M = volume, cubic feet/mole of gas
p = absolute, pressure, pounds/square foot
T = absolute temperature, degrees Rankine = °F + 460
R = universal gas constant, 1545 foot pound/mole

The equation states that one mole of all ideal gases occupies the same volume for the same pressure and temperature conditions — 394 cubic feet at 14.7 psi and 80 °F. Experiments indicate that most gases approach this ideal.

Law of Combining Weights. All substances combine in accordance with simple definite weight relationships. These relationships are exactly proportional to the molecular weights of the constituents. For example, carbon (atomic weight = 12) combines with oxygen (molecular weight = 32) to form carbon dioxide (molecular weight = 44) so that 12 pounds of carbon plus 32 pounds of oxygen unite to form 44 pounds of carbon dioxide.

Avogadro's Law. Equal volumes of different gases at the same pressure and temperature contain the same number of molecules. From the concept of the mole, a pound-mole of any substance contains a mass equal in pounds to the molecular weight of the substance. Thus the ratio of mole weight to molecular weight is a constant, and a mole of a chemically pure substance contains the same number of molecules, no matter what the substance may be. Since a mole of any ideal gas occupies the same volume at a given pressure and temperature (ideal gas law), it follows that equal volumes of different gases at the same pressure and temperature contain the same number of molecules.

Dalton's Law. The total pressure of a mixture of gases is the sum of the partial pressures that would be exerted by each of the constituents if each gas were to occupy alone the same volume as the mixture. In other words, for equal volumes, V, of three gases (A, B, and C) all at the same temperature, T, but at different pressures, P_a, P_b and P_c, when all three gases are placed in the space of the volume, V, then the resulting pressure, P, is equal to $P_a + P_b + P_c$. For gases, each gas in a mixture fills the entire volume and exerts a pressure independent of the other gases.

Amagat's Law. The total volume occupied by a mixture of gases is equal to the sum of the volumes that would be occupied by each of the constituents when at the same pressure and temperature as the mixture. This law is related to Dalton's Law, but considers the additive effects of volume instead of pressure. If all three gases are at pressure, P, and temperature, T, but at volumes V_a, V_b and V_c, then, when combined so that T and P are unchanged, the volume of the mixture, $V = V_a + V_b + V_c$.

Application of Fundamental Laws

Table 2 summarizes the molecular and weight relationships between fuel and oxygen and lists the heat of combustion for the substances commonly involved in combustion. Most of the weight and volume relationships in combustion calculations can be determined by using the information in this table and the seven fundamental laws.

The data for C and H_2 can be expressed as follows:

C	+	O_2	=	CO_2^*
1 molecule	+	1 molecule	→	1 molecule
1 mole	+	1 mole	=	1 mole
		1 cubic foot	→	1 cubic foot
12 pounds	+	32 pounds	=	44 pounds
$2H_2$	+	O_2	=	$2H_2O$
2 molecules	+	1 molecule	→	2 molecules
2 moles	+	1 mole	=	2 moles
2 cubic feet	+	1 cubic foot	→	2 cubic feet
4 pounds	+	32 pounds	=	36 pounds

While there is a weight balance in these equations, there is not a molecular or volume balance; for example, 2 cubic feet of H_2 unite with 1 cu ft of O_2 to form only 2 cubic feet of H_2O. This relationship is based on Avogadro's law and the law of combining weights.

The Mole in Combustion Calculations. Combustion calculations involving gaseous mixtures can be simplified by the use of the mole. Since equal volumes of gases at any given pressure and temperature contain the same number of molecules (Avogadro's law), the weights of equal volumes of gases are proportional to their molecular weights. If M is the molecular weight of the gas, 1 mole equals M pounds. Actual values are available from Table 1, e.g.:

1 mole of O_2 = 32 pounds oxygen
1 mole of H_2 = 2 pounds hydrogen
1 mole of CH_4 = 16 pounds methane

Data from Table 1 can be used to demonstrate that the volume of 1 mole at a given pressure and temperature is approximately fixed and independent of the kind of gas.

At 60 °F and atmospheric pressure (30 inches of mercury), the specific volume of oxygen is 11.819 cubic feet per pound. Therefore, 1 mole of oxygen has a volume of $32 \times 11.819 = 378.21$ cubic feet. Similarly, at 60 °F and atmospheric pressure, the specific volume of hydrogen is 187.723 cubic feet per pound, and 1 mole has a volume of $2.016 \times 187.723 = 378.45$ cubic feet. This volume, usually taken as 379 cubic feet, therefore approximates the volume of 1 mole of gas at 60 °F and atmospheric pressure.

The mole fraction of a component of a mixture is the number of moles of the component divided by the sum of the number of moles of all the components of the mixture. As a mole of every ideal gas occupies the same volume, it follows by Avogadro's law that in a mixture of ideal gases the mole fraction of a component will exactly equal the volume fraction:

$$\frac{\text{Moles of component}}{\text{Total Moles}} = \frac{\text{Volume of Component}}{\text{Volume of Total Mixture}}$$

* When 1 cubic foot of oxygen combines with carbon, it forms 1 cubic foot of carbon dioxide. If carbon were an ideal gas instead of a solid, 1 cubic foot of carbon would be required.

Source: "Steam — Its Generation and Use," 39th edition, The Babcock and Wilcox Company, New York, 1978.

This is a valuable concept, since the volumetric analysis of a mixture of gases automatically gives the mole fractions of the different components.

In power plant practice, the practical source of oxygen is primarily air, which includes, along with the oxygen, a mixture of nitrogen, water vapor, and small amounts of inert gases, such as argon, neon, and helium. Data on the composition of air are given in Table 3.

TABLE 3. COMPOSITION OF AIR

	Composition of Dry Air	
	% by Volume	% by Weight
Oxygen, O_2	20.99	23.15
Nitrogen, N_2	78.03	76.85[a]
Inerts	0.98	—

Equivalent molecular weight of air = 29.0[a]

% Moisture = 1.3% by weight. Standard for boiler industry (ABMA)[b]

Moles air/mole oxygen

$$\text{Cubic feet air/cubic feet oxygen} = \frac{100}{20.99} = 4.76$$

$$\text{Moles } N_2\text{/mole oxygen} = \frac{79.01}{20.99} = 3.76$$

$$\text{Pounds air (dry)/pound oxygen} = \frac{100}{23.15} = 4.32$$

$$\text{Pounds nitrogen/pound oxygen} = \frac{76.85}{23.15} = 3.32$$

[a] It is convenient in combustion calculations to account for inerts as equivalent nitrogen. The equivalent weight percentage of 76.85 and the equivalent molecular weight of 29.0 have been corrected to account for the extra weight of the inerts.

[b] Air containing 0.013 pound water/pound dry air is often referred to as standard air.

Source: "Steam — Its Generation and Use," 39th edition, The Babcock and Wilcox Company, New York, 1978.

The information in Table 2 can be used for air instead of O_2 if 3.76 moles of nitrogen (N_2) are added to both left and right side of each equation for every mole of O_2 involved. For example, the burning of CO in air becomes:

$$2\ CO + O_2 + 3.76\ N_2 = CO_2 + 3.76\ N_2$$

or for methane:

$$CH_4 + 2\ O_2 + 2(3.76)\ N_2 = CO_2 + 2\ H_2O + 7.52\ N_2$$

As indicated by the following example for a fuel gas, molal calculations have a simple and direct application to gaseous fuels, where the analyses are usually reported in percent on a volume basis.

Fuel Gas Analysis (% by Volume)	
CH_4	85.3
C_2H_6	12.6
CO_2	0.1
N_2	1.7
O_2	0.3
Total	100.0

This analysis may also be expressed as 85.3 moles of CH_4 per 100 moles of fuel; 12.6 moles of C_2H_6 per moles of fuel; and so on.

The elemental breakdown of each constituent may also be designated in moles per 100 moles of fuel, as follows:

C in CH_4	$= 85.3 \times 1$	$=$	85.3	moles
C in C_2H_6	$= 12.6 \times 2$	$=$	25.2	moles
C in CO_2	$= 0.1 \times 1$	$=$	0.1	mole
Total C per 100 moles fuel		$=$	110.6	moles
H_2 in CH_4	$= 85.3 \times 2$	$=$	170.6	moles
H_2 in C_2H_6	$= 12.6 \times 3$	$=$	37.8	moles
Total H per 100 moles fuel		$=$	208.4	moles
O_2 in CO_2	$= 0.1 \times 1$	$=$	0.1	mole
O_2	$= 0.3 \times 1$	$=$	0.3	mole
Total O_2 per 100 moles fuel		$=$	0.4	mole
N_2 per 100 moles fuel		$=$	1.7	moles

An analysis of the flue gas produced by burning a gas fuel of the composition given above could be:

Constituent	% by Volume
CO_2	10.4
O_2	2.8
N_2	86.8
Total	100.0

Analyses of flue gases are always reported on a volume basis, *dry*, when an Orsat or other type of gas analysis is used. Flue gases are cooled to room temperature and bubbled through water in most gas analyses, so that the gas becomes saturated with water vapor. This would occur even if no water vapor were formed during combustion. Proportionate parts of the water vapor content of the gas will be absorbed with the different constituents of the gas so that the resulting analysis may be safely assumed to be that of dry gas. These percentages may also be expressed as 10.4 moles CO_2, 2.8 moles O_2, and 86.8 moles N_2; each per 100 moles of dry flue gas.

For each mole of C burned, one mole of CO_2 is formed. From the fuel analysis used there are 110.6 moles C per 100 moles of fuel, and there are also 110.6 moles of CO_2 formed from the 110.6 moles C in the fuel. From the flue gas analysis, there are $100/10.4 = 9.62$ moles of dry flue gas per mole of CO_2. The 100 moles of fuel will then yield $110.6 \times 9.62 = 1{,}064$ moles of dry flue gas. By the application of the mole method, an important value has been quickly determined through knowing only the flue gas analysis and the fuel analysis.

From the flue gas analysis, the molecular weight of the dry flue gas can be easily determined, as follows:

10.4 moles of CO_2 weigh 10.4×44 pounds	=	457.6 pounds
2.8 moles of O_2 weigh 2.8×32 pounds	=	89.6 pounds
86.8 moles of N_2 weigh 86.8×28 pounds	=	2,430.4 pounds
100.0 moles of dry flue gas		2,977.6 pounds

Therefore, 1 mole equivalent of dry flue gas = 29.8 pounds, or the equivalent molecular weight of the dry flue gas = 29.8. Hence, the weight of 1,064 moles of dry flue gas is $1{,}064 \times 29.8 = 31{,}700$ pounds, or 100 moles of fuel yields 31,700 pounds of dry flue gas.

The weight of 100 moles of fuel is the sum of the products of each constituent in the fuel and its molecular weight.

CH_4	85.3	×	16	=	1,365	
C_2H_6	12.6	×	30	=	378	
CO_2	0.1	×	44	=	4.4	
N_2	1.7	×	28	=	47.6	
O_2	0.3	×	32	=	9.6	
	100.0 moles			=	1804.6	pounds

Thus, 1,805 pounds of gas fuel yield 31,700 pounds of dry flue gas, and each pound of gas fuel yields $31{,}700/1{,}805 = 17.6$ pounds dry flue gas.

Heat of Combustion

In a boiler furnace (where no mechanical work is done) the heat energy evolved from the union of combustible elements with oxygen depends on the ultimate products of combustion and not on any intermediate combinations that may occur in reaching the final result.

A simple demonstration of this law is the union of 1 pound of carbon with oxygen to produce a specific amount of heat (about 14,100 Btu, Table 2). The union may be in one step to form the gaseous product of combustion, CO_2, or under certain conditions, the union may be in two steps, first to form CO, producing a much smaller amount of heat (4,345 Btu) and, second, the union of the CO so obtained to form CO_2, releasing 9,755 Btu. However, the sum of the heats released in the two steps equals the 14,100 Btu evolved when carbon is burned in one step to form CO_2 as the final product.

That carbon may enter into these two combinations with oxygen is of utmost importance in the design of combustion equipment. Firing methods must assure complete mixture of fuel and oxygen, to be certain that all of the carbon burns to CO_2 and not to CO. Failure to meet this requirement will result in appreciable losses in combustion efficiency and in the amount of heat released by the fuel, since only about 28% of the available heat in the carbon is released if CO is formed instead of CO_2.

Measurement of Heat of Combustion. In boiler practice, the heat of combustion of a fuel is the amount of heat, expressed in Btu, generated by the complete combustion (or oxidation) of a unit weight (1 pound in the United States) of fuel. *Calorific value* or *fuel Btu value* are other terms used.

The amount of heat generated by complete combustion is a constant for any given combination of combustible elements and compounds and is not affected by the manner in which the combustion takes place, provided that it is complete.

The heat of combustion of a fuel is usually determined by direct measurement in a calorimeter of the heat evolved during combustion. See entry on **Calorimetry**.

The heat of combustion of most gases encountered in boiler practice is given in Table 1. If the content of any gas mixture is known, its heat of combustion can be accurately determined by adding the products of the volume percentage of each constituent times its heat of combustion.

For accurate heat values of solid and liquid fuels calorimeter determinations are required. However, approximate heat values may be determined for most coals if the ultimate chemical analysis is known. Dulong's formula gives reasonably accurate results (within 2 to 3%) for most coals and is often used as a routine check of values determined by calorimeter:

$$\text{Btu/pound} = 14{,}544\text{C} + 62{,}028(\text{H}_2 - \text{O}_2/8) + 4050\text{S} \qquad (1)$$

In this formula, the symbols represent the proportionate parts by weight of the constituents of the fuel — carbon, hydrogen, oxygen and sulfur — as determined by an ultimate analysis; the coefficients represent the approximate heating values of the constituents in Btu per pound. The term $O_2/8$ is a correction applied to the hydrogen in the fuel to account for the hydrogen already combined with the oxygen in the form of moisture. This formula is not generally suitable for calculating the Btu values of gaseous fuels.

High and Low Heat Values. Water vapor is one of the products of combustion for all fuels containing hydrogen. The heat content of a fuel depends on whether this water vapor is allowed to remain in the vapor state or is condensed to liquid. In the bomb calorimeter the products of combustion are cooled to the initial temperature and all of the water vapor formed during combustion is condensed to liquid. This gives the high, or gross, heat content of the fuel with the heat of vaporization included in the reported value. For the low, or net heat of combustion, it is assumed that all products of combustion remain in the gaseous state.

While the high, or gross, heat of combustion can be accurately determined by established (ASTM) procedures, direct determination of the low heat of combustion is difficult. Therefore, it is usually calculated using the following formula:

$$Q_L = Q_H - 1040\ \text{w} \qquad (2)$$

where Q_L = low heat of combustion of fuel, Btu/pound
Q_H = heat of combustion of fuel, Btu/pound
w = of water formed per pound of fuel
1040 = factor to reduce high heat of combustion at constant volume to low heat of combustion at constant pressure

In the United States the practice is to use the high heat of combustion in boiler combustion calculations. In Europe the low heat value is used.

Ignition Temperatures

Ignition temperature may be defined as the temperature at which more heat is generated by combustion than is lost to the surroundings so that the combustion process becomes self-sustaining. The term usually applies to rapid combustion in air at atmospheric pressure.

Ignition temperatures of combustion substances vary greatly as indicated in Table 4, which lists minimum temperatures and temperature ranges in air for fuels and for the combustible constituents of fuels commonly used in the commercial generation of heat. Many factors influence ignition temperature so that any tabulation can be used only as a guide. Pressure, velocity, enclosure configuration, catalytic materials, air-fuel-mixture uniformity, and ignition source are only a few of the variables. Ignition temperature usually decreases with rising pressure and increases with increasing moisture content in the air.

TABLE 4. IGNITION TEMPERATURES OF FUELS IN AIR (APPROXIMATE VALUES AND RANGES AT ATMOSPHERIC PRESSURE)

Combustible	Formula	Temperature, °F
Sulfur	S	470
Charcoal	C	650
Fixed carbon (bituminous coal)	C	765
Fixed carbon (semibituminous coal)	C	870
Fixed carbon (anthracite)	C	840–1115
Acetylene	C_2H_2	580–825
Ethane	C_2H_6	880–1165
Ethylene	C_2H_4	900–1020
Hydrogen	H_2	1065–1095
Methane	CH_4	1170–1380
Carbon Monoxide	CO	1130–1215
Kerosine	—	490–560
Gasoline	—	500–800

The ignition temperatures of the gases of a coal vary considerably and are appreciably higher than the ignition temperatures of the fixed carbon

of the coal. However, the ignition temperature of coal may be considered as the ignition temperature of its fixed carbon content, since the gaseous constituents are usually distilled off but not ignited before this temperature is attained.

Adiabatic Flame Temperature

The adiabatic flame temperature is the maximum theoretical temperature that can be reached by the products of combustion of a specific fuel and air (or oxygen) combination assuming no loss of heat to the surroundings until combustion is complete. This theoretical temperature also assumes no dissociation, a phenomenon discussed later under this heading. The heat of combustion of the fuel is the major factor in the flame temperature, but increasing the temperature of the air or of the fuel will also have the effect of raising the flame temperature. As would be expected, this adiabatic temperature is a maximum with zero excess air (only enough air chemically required to combine with the fuel), since any excess is not involved in the combustion process and only dilutes the temperature of the products of combustion.

The adiabatic temperature is determined from the adiabatic enthalpy of the flue gas as follows:

$$h_g = \frac{\left(\begin{matrix}\text{heat of}\\ \text{combustion}\end{matrix}\right) + \left(\begin{matrix}\text{sensible heat}\\ \text{in fuel}\end{matrix}\right) + \left(\begin{matrix}\text{sensible heat}\\ \text{in air}\end{matrix}\right)}{\text{weight of products of combustion}}$$

where h_g = adiabatic enthalpy (adiabatic heat content of the products of combustion), Btu/pound

Knowing the moisture content of the products of combustion and its enthalpy, the theoretical flame or gas temperature can be obtained from published graphs.*

The adiabatic temperature is a fictitiously high temperature that does not exist in fact. Actual flame temperatures are lower for two main reasons:

1. Combustion is not instantaneous. Some heat is lost to the surroundings as combustion takes place. The faster the combustion occurs the less heat is lost before combustion is complete. If combustion is slow enough, the gases may be cooled sufficiently for combustion to be incomplete with some of the fuel unburned. This is related to the time factor in the "three *T*'s" of combustion mentioned previously.
2. At temperatures above 3,000 °F (1,649 °C), some of the CO_2 and H_2O in the flue gases dissociates, absorbing heat in the process. At 3,500 °F (1,926 °C), about 10% of the CO_2 in a typical flue gas dissociates to CO and O_2 with a heat absorption of 4,345 Btu/pound of CO formed, and about 3% of the H_2O dissociates to H_2 and O_2, with a heat absorption of 61,100 Btu/pound of H_2 formed. As the gas cools, the CO and H_2 dissociated recombine with the O_2 and liberate the heat absorbed in dissociation, so the heat is not lost. However, the effect is to lower the maximum actual flame temperature.

Combustion Calculations

The combustion calculations are the starting point for all design and performance determinations for boilers and their related component parts. They establish (a) the quantities of the constituents involved in the chemistry of combustion, (b) the quantity of heat released, and (c) the efficiency of the combustion process under both ideal and actual conditions.

Combustion Air. Since carbon, hydrogen, and sulfur are the only major combustible elements found in the fuels used for commercial steam generation, the air (pounds) theoretically required for the complete combustion of 1 pound of fuel is:

$$11.53\ C + 34.34\ (H_2 - O_2/8) + 4.29\ S \qquad (3)$$

where C, H_2, O_2 and S represent the fraction by weight (percent/100) of carbon, hydrogen, oxygen and sulfur, and the constants are those given in Table 1. The factor $O_2/8$ in the term $(H_2 - O_2/8)$ is a correction for the hydrogen already combined with the O_2 in the fuel to form water vapor.

With gaseous fuels, instead of breaking down the hydrocarbons into their constituent elements, it is simpler to use the amount of air for the various compounds directly as given in Table 1. For instance, for a gaseous fuel containing the combustible gases indicated in the expression below, the theoretical air required for complete combustion (pounds air/pounds fuel) is:

$$2.47\ CO + 34.34\ H_2 + 17.27\ CH_4 + 13.30\ C_2H_2 + 14.81\ C_2H_4 + 16.12\ C_2H_6 + 6.10\ H_2S - 4.32\ O_2 \qquad (4)$$

Again, the molecular symbols represent the fraction by weight of the gaseous compounds and elements.

If, as is the usual custom, the analyses of gaseous fuels are given on a volumetric basis, the cubic feet of combustion air required as given in Table 1 should be used. Thus for a gaseous fuel containing the combustible gases indicated in the following expression, the number of cubic feet of theoretical air required per cubic foot of fuel for complete combustion is:

$$2.38\ (CO + H_2) + 9.53\ CH_4 + 11.91\ C_2H_2 + 14.29\ C_2H_4 + 16.68\ C_2H_6 + 7.15\ H_2\ S - 4.76\ O_2 \qquad (5)$$

where the molecular symbols represent the fraction by volume of the gaseous compounds and elements. Note that the total air requirement is reduced if oxygen is one of the constituents of the fuel.

The products of combustion can also be determined from the data given in Table 1. Assuming complete combustion with theoretical air of the fuels ordinarily used for commercial steam generation, the products of combustion in pounds (including the nitrogen carried with the combustion air) per pound of fuel are:

$$CO_2 = 3.66\ C$$

$$H_2O = 8.94\ H_2 + H_2O^{**}$$

$$SO_2 = 2.00\ S$$

$$N_2 = 8.86\ C + 26.41\ (H_2 - O_2/8) + 3.29\ S + N_2\dagger$$

The moisture introduced with the combustion air must be added to this theoretical quantity to obtain the total weight of combustion products. The molecular symbols represent the fraction by weight of the constituents in the fuel.

Energy Losses. Not all of the Btu in the fuel are converted to heat and absorbed by the steam generation equipment. Some of the fuel may be unburned, leaving carbon in the ash or carbon may be burned incompletely to form some CO instead of all CO_2. Usually all of the H_2 in the fuel is burned. By far the greatest heat loss is the loss up the stack. Since the heat in the fuel is determined from a base of ambient temperature, all of the products of combustion must be cooled to the same temperature if all of the heat is to be utilized. Higher temperatures then represent a loss, which is the sum of four items: (1) the sensible heat in dry flue gas, (2) the sensible heat in the moisture in the air, (3) the sensible heat in the H_2O in the fuel, and (4) the latent heat of the moisture in the fuel.

It is necessary practically to use more than the theoretical air requirements to assure sufficient oxygen for complete combustion. Excess air would not be required if it were possible to have an ideally perfect union of air and fuel. It is necessary, however, to keep the excess at a minimum in order to hold down the stack loss. The excess air that is not used in the combustion of the fuel leaves the unit at stack temperature. The heat required to heat this air from room temperature to stack temperature serves no purpose and is lost heat. Table 5 gives realistic values of excess air for the fuel-burning equipment which experience has shown is required to assure complete combustion for various fuels and methods of firing.

In most furnaces operating under suction, there is also some leakage of air into the setting and, consequently, the excess air leaving the furnace and the unit is greater than that at the fuel-burning equipment. Another loss that must be considered is the radiation loss from the unit setting.

In summary, there are certain inherent heat losses over which there is no control, and others that are subject to some control. The inherent losses are the result of: (1) the discharge of the products of combustion at a temperature higher than ambient; and (2) the moisture content of the fuel plus the combination of some of the hydrogen with the oxygen in the fuel. The avoidable heat losses, or those that can be controlled by good design and careful operation, can be minimized by: (1) careful control of excess

TABLE 5. USUAL AMOUNTS OF EXCESS AIR SUPPLIED TO FUEL-BURNING EQUIPMENT

Fuel	Type of Furnace or Burners	Excess Air % by Weight
Pulverized coal	Completely water-cooled furnace for slag-tap or dry-ash-removal	15–20
	Partially water-cooled furnace for dry-ash removal	15–40
Crushed coal	Cyclone furnace — pressure or suction	10–15
Coal	Spreader stoker	30–60
	Water-cooled vibrating-grate stoker	30–60
	Chain-grate and traveling-grate stokers	15–50
	Underfeed stoker	20–50
Fuel oil	Oil burners, register-type	5–10
	Multifuel burners and flat-flame	10–20
Acid sludge	Cone and flat-flame type burners, steam-atomized	10–15
Natural, coke-oven, and refinery gas	Register-type burners	5–10
	Multifuel burners	7–12
Blast-furnace gas	Intertube nozzle-type burners	15–18
Wood	Dutch oven (10–23% through grates) and Hofft-type	20–25
Bagasse	All furnaces	25–35
Black liquor	Recovery furnaces for kraft and soda-pulping processes	5–7

COMET. Since ancient times, comets have been noted in the sky as surprise events. They were exceptions to the rigid regularity people had learned to attribute to the movement of the sun, moon, planets, and stars. Thus until the 16th century, comets were regarded by scholars as phenomena of Earth's upper atmosphere. Sometimes they were referred to as "burning vapors." In 1577, the Danish astronomer, Tycho Brahe, noted a bright comet and made numerous measurements of its motions. Although he could not measure its distance from Earth, he produced convincing evidence that the object was well beyond Earth and thus astronomical, not meteorological. In 1682, Edmond Halley (Great Britain) observed what ultimately became known as Halley's Comet or simply Comet Halley. Halley searched prior records of comet appearances and found three prior appearances of a similarly described comet, including that observed in 1682, 76 years apart. He predicted that the comet would return again in 1758 or 1759. Although Halley died in 1742, his prediction was proved to be correct when the comet reappeared in 1758 (first sighted) and in mid-March, 1759 (passed perihelion). Comet Halley returned again in 1834, 1910, and 1986, with next return scheduled for 2062.

Although the general appearance from Earth of comets has been well established for several centuries, including the great bulk of the tail as compared with the head or nucleus, little was understood pertaining to the actual physical make-up of the comet. The technical aspects of comets began to emerge as the result of detailed observations of Comet Kohoutek, which appeared in the spring of 1973. Visually, from Earth, the comet proved disappointing, but much was learned through a variety of instrumental measurements, including optical, UV, IF, and radio astronomy. Included were observations from unmanned satellites. These are described in article on **Kohoutek (Comet)**.

Much more detailed observation was made of Comet Halley in 1986. See also **Halley's Comet**.

Even prior to gaining the aforementioned information, a comet had been suspected by some scientists of being a wispy object of very low mass, but of extremely large dimensions, some comets surpassing by far most other dimensional measurements of the solar system. Some researchers had mentioned that if the tail of Comet Halley were compressed to the density of iron, it could be carried in a small suitcase. At one time, comets were considered to be strictly phenomena of the solar system. Now that cosmologists are envisioning vast numbers of other solar systems in the outreaches of space, comets may encircle thousands or millions of other stars, both larger and smaller than the solar system.

The periods of comets extend from 3.3 years (the shortest known) to many thousands of years. The orbits are elliptical, as are the orbits of the planets, but the cometary orbits generally are highly eccentric (long and narrow).

F.L. Whipple has likened a comet to an enormous "snowball" comprised of frozen gases (carbon dioxide, methane, and water vapor) and containing very little solid matter. This general concept essentially was confirmed as the results of the detailed observations of Comets Halley and Kohoutek. This description, however, does not denigrate the effectiveness of mass in a possible cometary impact with Earth or another planetary body. The mass of solid, frozen gases in the nucleus of a comet can be exceedingly great.

General Structure and Orbits of Comets

A comet consists of three general parts: the nucleus, the coma, and the tail. The relative sizes and appearances of these parts change radically as the comet approaches perihelion. It is believed that the nucleus (or head) of a comet is a mass of more or less condensed material. It looks much like an ordinary star when the comet is a long way from the sun. As the comet approaches the sun, the nucleus increases in brightness and apparently shrinks in size, although this latter characteristic may be an optical illusion, since actual measurements of the diameter of the head are practically impossible. With the approach to the sun, a hazy shell makes its appearance about the nucleus, and the so-called coma increases in size. When quite close to the sun, the coma seems to stretch out in the direction away from the sun and the tail develops in this direction. The real glory of a comet to the naked eye in this tail. See Figs. 1, 2, 3. It should be carefully noted that the tail points in a direction directly away from the sun and does not, in general, trail out behind the comet in its motion. Although many comets apparently never develop a tail at all, the tails that do develop have a variety of shapes and curves, ranging from short, sharply curved tails, to long, straight streamers pointing away from the sun. The tails fall into two distinct classes: those in Class I are composed of ionized molecules; those in Class II are composed of dust. Occasionally, tails are a combination of both types.

The nucleus may have a diameter of up to 16,000 km; the coma, a diameter ranging from 16,000 to 80,000 km; and tails have been observed

Fig. 1. Comet Arend-Roland (1956–1957).

Fig. 2. The Ikeya-Seki comet, as seen over Maryland on November 3, 1965. The length of the comet's tail was estimated at 28 million miles (~45 mil km).

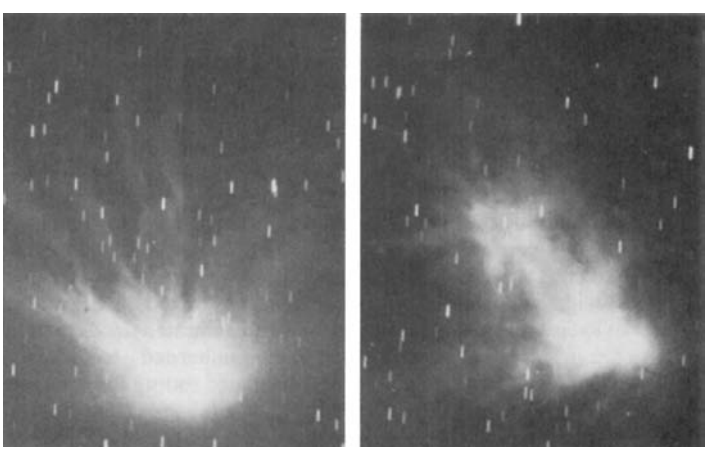

Fig. 3. Comet Humason (August 6 and 7, 1962). The comet was then very active structurally. Its tail extended almost directly away from Earth. (*U.S. Navy photo.*)

with length as great as several hundred thousand km. Hence, the volume of a large comet may be greater than the volume of all other members of the solar system combined. In contrast to the enormous bulk of these objects, their masses are so small that they have never been accurately measured. The only available method for determining the mass of a comet is by means of the perturbations it might produce in the orbits of the planets or asteroids. Many cases of very close approach of comets to objects of known mass have been observed, but while the comet orbit itself may be enormously perturbed, no perturbations have ever been observed in orbits of other objects. The best that can be said regarding cometary masses is that they must be less than one-hundred-thousandth of the mass of the earth.

Orbits of comets differ from orbits of the other members of the solar system in that they are, in general, much more eccentric than the planetary orbits; while the planetary orbit planes are all nearly parallel to the plane of the ecliptic, comet orbits are found inclined through practically every angle. The great majority of the orbits that have been determined are found to be parabolic in character, which means that the objects will not return to visibility again. Two or three comets apparently have hyperbolic orbits, while others are moving about the sun in ellipses, returning to the vicinity of the sun and, hence, visibility, at periodic intervals.

Comet Orbital Classification. The period of their orbital revolution about the sun varies widely among known comets. There are (1) *short-period comets*, with elliptic orbits of moderate eccentricity and small inclination to the ecliptic plane. Periods are usually a few years, but can range upward. Their orbits usually are prograde, i.e., their orbit angular velocities are directed in the same sense as the angular velocities of the planets. (2) *Long-period comets*, the trajectories of which are oriented arbitrarily with respect to the ecliptic and with equal probability of being direct or retrograde. Their orbits are characterized by large eccentricity and, as pointed out by Michels and colleagues (see reference), their orbits are often more conveniently described as parabolas than as ellipses.

An interesting subset of the long-period comets is the group known as the *sungrazers*, so named by H. Kreutz who, in 1882, analyzed the apparition in that year of a spectacular member of this group and reviewed the data on a number of other suspected members. Some authorities believe that these comets originate from the fragmentation of an earlier *protocomet body*, whose nucleus may have fractured under the stresses of a near encounter with the sun. The common orbital path of the Kreutz sungrazers is oriented with respect to the solar system in such a way that they are difficult to observe from the Earth. This is particularly true when perihelion passage occurs during the months from May to August. Only members bright enough to be observed during twilight skies are seen. Some of these comets were discovered only during a total solar eclipse. Thus some astronomers believe that the total number of sungrazing comets is far greater than the number seen and reported. A prominent member of the group is the comet Ikeya-Seki (1965 VIII), which was well observed by astronomers.

Under viewing conditions comparable to those of a total solar eclipse, a brilliant comet (1979-XI: Howard-Koomen-Michels) was discovered in data from the Naval Research Laboratory's (U.S.) orbiting SOLWIND coronagraph. As observed by Michels, an extensive sequence of pictures, telemetered from the P78–1 satellite, showed the coma, accompanied by a bright and well-developed tail, passing through the coronagraph's field of view at a few million kilometers from the sun. Calculations based on the observed motion of the comet's head and morphology of the tail indicated that this previously unreported object was a sungrazing comet and a member of the group of Kreutz sungrazers. It appeared from the data that the perihelion distance was less than one solar radius, so that the cometary nucleus encountered dense regions of the sun's atmosphere, was completely vaporized, and did not reappear after the time of closest approach to the sun. It was observed, however, that after this time cometary debris, scattered into the ambient solar wind, caused a brightening of the corona over one solar hemisphere and to heliocentric distances of 5 to 10 solar radii. The foregoing observations were made on 30 and 31 August 1979, but they did not become available to analysts until a few years later. The data, which essentially have not been challenged, substantiate that this comet was the first to be discovered from a spacecraft and the first to be observed colliding with the sun. See Fig. 4.

Spacecraft Encounters with Comets

The decade of the 1980s proved to be very enriching for cometary astronomy, largely because of the appearances of two important comets, Giacobini-Zinner and Halley, within range of observation as they orbited around the sun.

Comet Giacobini-Zinner. As reported by Tycho T. von Rosenvinge, John C. Brandt, and Robert W. Farquhar (Goddard Space Flight Center,

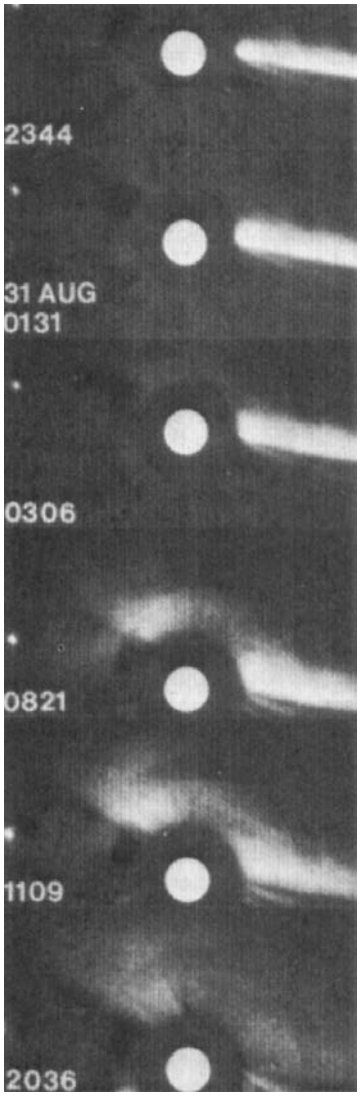

Fig. 4. Sequence of frames made by SOLWIND coronagraph in late-August 1979 of a previously undiscovered object (Comet Howard-Koomen-Michels) as the comet approached the sun (top views) and as it encountered the sun (bottom views), where scattering of cometary debris is believed to have altered the solar corona. (*E.O. Hulbert Center for Space Research, Naval Research Laboratory, Washington, DC.*)

Greenbelt, Maryland), on 11 September 1985, the International Cometary Explorer (ICE) spacecraft passed through the tail of comet Giacobini-Zinner and made in-situ measurements of particles, waves, and fields.* The primary goal of this encounter was to study the interaction between the solar wind and the comet. This interaction was expected to be unlike any previously observed because the cometary atmosphere is not constrained by gravity. Neutral water molecules, sublimed from the comet nucleus by sunlight, freely escape at speeds of about 1 km sec^{-1} and are eventually ionized on a time scale of 10^6 second, leading to an extensive region of interaction millions of kilometers in diameter. Once ionized, the ions interact with the magnetic field of the solar wind and are carried radially outward from the sun. The acceleration of the "pick-up" ions causes the solar wind to slow significantly. The nature of this process was studied in situ and was found to be stronger than had been anticipated.

From information gained by ICE, a number of important findings have been reported. See references at end of this article.

(1) *Plasma*. S.J. Bame and colleagues http://www.lanl.gov/worldview/science (University of California, Los Alamos National Laboratory, New Mexico) reported that a strong interaction between the solar wind and comet Giacobini-Zinner was observed on 11 September 1985, using the Los Alamos plasma electron experiment aboard the ICE spacecraft. As ICE approached an intercept point 7800 km behind the nucleus from the south and receded to the north, upstream phenomena due to the comet were observed. Periods of enhanced electron heat flux from the comet as well as almost continuous electron density fluctuations were measured. These effects are related to the strong electron heating observed in the cometary interaction region and to cometary ion pickup by the solar wind, respectively. No evidence for a conventional bow shock was found as ICE entered and exited the regions of strongest interaction of the solar wind with the cometary environment.

(2) *Energetic Ions*. R.J. Hynds (Blackett Laboratory. Imperial College, London) and associates reported that during the encounter with the comet, an *energetic particle anisotropy spectrometer* on the spacecraft observed large fluxes of energetic ions, believed to result mainly from ionization of the cometary atmosphere followed by pickup and acceleration by the ambient flow of the solar wind. These heavy cometary ions were observed from about 1 day before closest approach to about $2\frac{1}{2}$ days afterward. Three regimes of differing ion characteristics were identified — an outer, middle, and inner region. F.M. Ipavich (University of Maryland), D. Hovestadt (Max Planck Institut für Extraterrestrische Physik, Germany) *http://wave.xray.mpe.mpg.de/* and other researchers reported conclusive evidence for the existence of energetic ($\sim$35,000 to 150,000 eV), heavy ($\gtrsim$12 atomic mass units), singly charged cometary ions within $\sim 1.5 \times 10^6$ km of the comet. These observations were made with an *ultralow-energy charge analyzer* on the spacecraft. Because of the extremely low gravity of the cometary body, neutral molecules and atoms evaporated from the surface can escape freely into space from the collision dominated inner region of the comet with a velocity generally assumed to be $\sim$1 km sec^{-1}. These molecules are subjected to complex chemical reactions in the inner coma and, farther out, a variety of photo-dissociative and ionizing processes. As a result, a few types of parent molecules, such as H_2O, CO_2, NH_3, CH_4, and CO, of direct cometary origin, produce a variety of molecular and atomic ions. Spectroscopically identified ions include OH^+, H_2O^+, C^+, CO^+, CO_2^+, CH^+, CN^+, N_2^+, H_2S^+, and Ca^+. The source density of these ions is determined by the gas production rate and the cross sections for dissociation and ionization.

(3) *Magnetic Field*. Magnetic field measurements near comets are of scientific interest because they represent an important aspect of the interaction of the comet with the solar wind and should reveal how the comet becomes magnetized. As observed by E.J. Smith (Jet Propulsion Laboratory, California Institute of Technology) and other associates, when an active comet is observed, it has already developed a structure that is dependent on the presence of magnetic fields derived from the solar wind. In the absence of direct observations, competing theories often provide several possible answers to issues such as: the existence of a bow shock that accompanies the comet through the solar system; the number, character, and length scales of different plasma regimes surrounding the comet; and the strength of the magnetic field in the coma and tail. A vector helium magnetometer on ICE observed the magnetic fields induced by the interaction of the comet with the solar wind. A magnetic tail was penetrated $\sim$7800 km downstream from the comet and was found to be $\sim 10^4$ km wide and consisted of two lobes, containing oppositely directed fields with strengths up to 60 nanoteslas, and separated by a plasma sheet $\sim 10^3$ km thick containing a thin current sheet. The magnetotail was enclosed in an extended ionosheath characterized by intense hydromagnetic turbulence and interplanetary fields draped around the comet. A distant bow wave, which may or may not have been a bow shock, was observed at both edges of the ionosheath. Weak turbulence was observed well upstream of the bow wave.

Information of the foregoing kind gained from Comet Giacobini-Zinner will help in the continuing molding and refining of cometary theory.

* As detailed in the Goddard Space Flight Center Report, at the time of launch in August 1978, the ICE spacecraft was known as the International Sun-Earth Explorer Number Three (ISEE-3). Little thought had been given to the possibility of its encountering a comet. Rather, ISEE-3 was part of a collaboration between the European Space Agency and NASA to study the interaction between the solar wind and Earth's magnetosphere. The first mission phase came to a close in the summer of 1982 when it was decided that two additional missions could be undertaken: (1) exploration of the deep magnetic tail of Earth, and (2) crossing the tail of comet Giacobini-Zinner. The craft was retargeted for the comet mission and, at that time, was renamed ICE (*International Cometary Explorer*). At the time of the encounter. ICE was about 50 times farther from Earth than it was designed to go. This confronted the Deep Space Network with a challenging task for recovery of data.

TABLE 1. SPACECRAFT ENCOUNTERS WITH COMET HALLEY

Date of Encounter	Vehicle	Sponsor	Distance to Nucleus (Sunward) (km)	Distance from Sun (km)	Distance from Earth (km)	No. Experiments Aboard
3/6/86	VEGA-1	Russia	10,000	1.185×10^8	1.74×10^8	13
3/7/86	SUISEI	Japan	2×10^5	1.20×10^8	1.71×10^8	1
3/8/86	SAKIGAKE	Japan	4×10^6	1.215×10^8	1.665×10^8	3
3/9/86	VEGA-2	Russia	3,000	1.245×10^8	1.635×10^8	13
2/13/86	GIOTTO	European Space Agency	605	1.335×10^8	1.470×10^8	10

Comet Halley. In the spring of 1986, Comet Halley was encountered by 5 spacecraft launched from Earth in late 1984 and the first half of 1985. See Table 1. The NASA-Kuiper Airborne Observatory also made measurements of Halley in December 1985. It is also interesting to note that NASA's Pioneer Venus Orbiter, which had been circling Venus since 1978, conducted an investigation of Halley a month before the five spacecraft flew by the object. The Orbiter was delicately repositioned with precise commands from Earth to observe the comet at its closest point to the sun, a distance of about 55 million miles (88.5 mil km). The spacecraft measured changes in the comet caused by intense solar heating and also provided an ultraviolet image of the comet. These data gave scientists leads on the gas composition, rate at which water vaporized, and the ratio of gas to dust in the comet. See also **Halley's Comet**.

Early Cometary Theories

The comet Bennet was discovered at Riviera, South Africa by J.C. Bennett on December 28, 1969, and was visible to the naked eye in the spring of 1970 when it displayed a straight narrow plasma tail and a huge moderately curved dust tail. By using photographic plates sensitive only in certain parts of the spectrum (notably in the red region) and with appropriate filters, the plasma tail can be completely suppressed. Finson and Probstein, using this technique, were able to derive significant information concerning the nature of the dust and gas production mechanisms in comets. In the Finson-Probstein model of dust comets, it is assumed that there is essentially continuous emission of solid particles of various sizes from the nucleus into the atmosphere brought about by the drag forces of the outgoing gas. Shortly after the ejection of solid particles, the solar gravity and solar radiation pressure are considered to be the only two forces that control the motion of the dust particles in the cometary tail. The trajectory of any individual particle depends upon its size and on the time, velocity, direction, and other circumstances of ejection. The observed photometric profile of the tail at any time depends upon the size distribution of the ejected particles, their emission rate as a function of time before the time of observations, and variations in the initial particle velocity with time and size. The photometric profile also depends upon the geometrical configuration of the sun, earth, and comet in space.

This hypothesis now competes to some extent with the "dirty snowball" hypothesis previously described.

Origin of Comets

One argument against origination of comets in interstellar space is that, to date, no comet has been observed which approached the sun on a very hyperbolic orbit with velocity far above the velocity required to escape from the solar system. But if comets do not originate in interstellar space, from whence do they come? A general assumption is that comets originated as a part of the solar nebulae (gaseous cloud from which solar system condensed) and at a location either among the outer giant planets or even further from the sun (Pluto and beyond). Some scholars have suggested that there may be billions of comets in "cold storage" some 1000 times farther from the sun than Pluto. It is further believed that the long-period comets originate in this reservoir. This assumes that comets may have been formed from relatively small accumulations of grains of substance left over from planetary formation. Thus, it is further suggested that the interior of comets may contain some of the most primitive of solar system matter, matter that has remained unchanged by temperature, pressure, melting, resolidifying, and so on. The mechanism required, periodically, to release cometary material from such a reservoir and cause it to become a long-period comet is probably some kind of perturbation. But of what nature? Perhaps by an occasional passing star?

The spectra of comets have been studied for a number of years. From these observations, it has been found that comets shine partly by reflected sunlight and partly by radiation from gases. Band spectra that have been identified in the coma include those of the radicals CH, C_2, OH, NH, and CN, among others. These are transformed into stable molecules, such as CO, CO_2, and N_2, as they are driven into the tail. The first direct observation of cometary water was the detection of H_2O^+ ions in the comet Kohoutek. In 1974, radio astronomers reported molecules of water in the comet Bradfield. There is, however, no preponderance of evidence that there is consistency among the compositions or behavior of various comets. There have been a number of examples of marked departures from the "predictable" behavior of comets. Comet Tuttle-Giacobini-Kresak, in May 1973, suddenly flared to a brightness by about 9 magnitudes (factor of 4000) in less than 5 days. The comet Schwassmann-Wachmann 1 also has displayed spectacular outbursts several times per year. See also **Kohoutek (Comet)**.

Halley's comet has made 29 passages since its first appearance in recorded history. The material exposed in 1986 was once buried deep within the nucleus, far below the original surface layer where significant chemical modification by long-term cosmic ray exposure could have occurred. As pointed out by M.J. Mumma (Goddard Space Flight Center), the material currently being evolved from the nucleus is thought to be primordial, unmodified since condensing from its natal cloud of gas and dust, possibly the presolar neubla or an interstellar cloud. The composition of the nucleus is the fingerprint of that nebula, a "Rosetta stone," from which we can determine its physics and chemistry. With reference to observations of the coma of comet Halley in December 1985 from the NASA-Kuiper Airborne Observatory, Mumma observed that the identification of these parent molecular ices and quantitative measurements of their abundances are central problems in cometary research. In the aforementioned observations, gaseous neutral H_2O was detected.

Cometary Enrichment of Earth with Organic Molecules

A relatively recent school of philosophers observes that the high content of organic molecules (including, in addition to frozen water vapor, carbon dioxide, and methane, such substances as hydrogen cyanide and formaldehyde) in the nuclei of carbonaceous comets (asteroids as well) may have nurtured the early Earth with the substances necessary to the chemistry of life. This hypothesis is described in considerable detail by C.F. Chyba (Cornell University) and a team of researchers. However, as early as 1908, T.C. and R.T. Chamberlain proposed in *Science* (28, 897, 1908), "that infalling 'planetisimals' may have been an important source of prebiotic organic material on early Earth." (See Chyba reference listed.)

Comets and Mass Extinctions. In recent years, scientists have been converging on a plausible explanation of the causes of mass extinction of various life species on Earth during the course of the planet's development. Two general kinds of hypothesis have emerged, and each may be appropriate for specific extinctions: (1) sudden impact of Earth by massive external forces, such as huge meteorites, asteroids, or comets, and (2) more gradual deterioration of Earth environments, as the result of regression of the seas, numerous volcanic eruptions, and the production of oxygen-deficient waters. The latter sometimes is referred to as the "world went to hell" hypothesis, as the result of an unusual convergence of events that ultimately destroyed various life forms on Earth over a prolonged period of time.

Disappearance of the dinosaurs some 65 million years ago (boundary of the Cretaceous and Tertiary periods) generally has been attributed to a sudden impact type of event. There is some evidence from craters to support this view. Another, even more powerful event or period of

devastation of life on Earth is estimated to have occurred some 250 million years ago (boundary of the Permian and Triassic periods) at which time from 80 to 95 percent of marine species were destroyed.

Recent studies of two craters (Manson crater located in Iowa, which is estimated to have been formed some 65–66 million years ago; and the Chicxulub crater located in Yucatan, which is estimated to be of similar age) have given rise to a proposal by E. Shoemaker (U.S. Geological Survey) of a "splattering" hypothesis. Essentially, this concept envisions an initial impact of Earth by a comet which, upon impact, broke up and showered the planet with masses of debris over a period of years. Thus, an initial, large impact caused subsequent impacts of a catastrophic nature in other locations. See also **Mass Extinctions**.

Particularly, during the last few years, and as mentioned under **Asteroid**, probably more attention by researchers has been given to asteroids than to comets as probable causes of past impacts with Earth.

Cometary Collision with Jupiter. In March 1993, the comet Shoemaker-Levy 9 was discovered and noted to be on a collision course to Jupiter, with which it is predicted to collide in mid-1994. Unlike the usual comet, this object is made up of a string of some 20 nuclei, as compared with a single nucleus. Measurements have indicated that this *compound comet* is traveling at about 60 km/sec. Some researchers have postulated that the comet was strongly influenced by Jupiter's gravitational pull when it passed by the planet in July 1992. At that time, the comet came within 100,000 km of Jupiter. Prior to current predictions that the comet will collide with the planet, it had been speculated that Shoemaker-Levy would become a permanent neighbor (satellite) of the planet. Orbital calculations have confirmed that the comet is circling Jupiter and not the sun, the latter being the common mode for comets.

According to estimates as of early 1994, there was to be a series of impacts (because of the comet's beaded nature) sometime near mid-1994. Calculations indicated that these impacts would occur on the side of Jupiter not facing Earth. However, astronomers predicted that the flashes would be reflected toward Earth from the planet's satellite, Io, and that these would be visible to low-power instruments from Earth. The flashes also should have been visible from the Galileo probe, which was scheduled to rendezvous with Jupiter in 1995.

Some astronomers, who are following this possibly catastrophic scenario, suspect that repercussions, such as the formation of a huge storm system (comparable to Jupiter's Great Red Spot) later may be observable from Earth with comparatively low-power instruments.

Although scientists were prepared worldwide to observe Jupiter at the proposed time of impact, it must be stressed that even minor errors in calculating the comet's orbit could have voided the foregoing expectations.

According to a current hypothesis, Jupiter from the time of its formative eons, has been involved in some manner with comets. One theorist has observed that Jupiter could have gained its current size only if it acquired sufficient mass from the gas in the nebula surrounding a young star. According to a model developed by the esteemed astronomer, G.W. Wetherill (Carnegie Institution of Washington), "if Jupiter had failed to form in the solar system, many more comets would have remained in orbits that could eventually bring them into collision with the earth." Without this partial clearing of comets from the solar system, the model indicates that impacts with Earth would have occurred at a rate some 1,000 times the rate which history records. These could have caused major extinctions every 100,000 years as compared with the comparatively few extinctions Earth has experienced thus far.

Comet Machholz. On May 12, 1986, an unusual *short-period* comet was discovered by amateur astronomer, Donald Machholz, when using a large pair of binoculars. This comet, Machholz 1986 VIII (1986c) has been found to travel closer to the sun than any known planet. The comet has an orbital period of less than 150 years. As reported by D.W.E. Green (Harvard Smithsonian Center for Astrophysics) and a team of investigators, comet Machholz should provide a unique object for studying cometary evolution. Calculations made after its discovery indicate that the comet is spiraling closer to the sun — from a perihelion distance of $q \simeq 0.9$ astronomical units at about A.D. 700 to $q \simeq 0.13$ AU at presents. The present orbital period is $\simeq$5.25 years and it is estimated that the comet may impact the sun at about the year 2450.

As part of a detailed report, the aforementioned investigators (reference listed) observe, "Some researchers have found that observations of comets previously recorded as minor planets were, in fact, prediscovery observations of short-period comets. With this in mind, Green searched for such possible observations back to the turn of the 20th century, with no success."

Naming of Comets

Comets take their names from their discoverers. Normally, a preliminary designation will be used. This consists of the year followed by a letter assigned in order of discovery during that year. A few years later, if all preliminary data are confirmed, a given comet will receive a permanent designation. This states the year of the comet's perihelion passage, followed by a Roman numeral giving the order of passage during that year. However, the literature will continue to identify them as well by discoverer names.

Only a very small proportion of the comets that are discovered ever become visible to the naked eye, and there must be many comets that are never discovered at all. From a study of ancient records, there has been, on the average, about one comet visible to the naked eye per year. The year 1911, in which four such objects were seen, apparently holds the record for maximum number, and there are years in which no comet at all is visible to the unaided eye.

COMFORT CHART. As used by the American Society of Heating and Air Conditioning Engineers, a diagram showing curves of relative humidity and effective temperature superimposed upon rectangular coordinates of wet-bulb temperature and dry-bulb temperature. Upon this chart (one for each chosen rate of air movement) may be indicated comfort zones bounded by relative humidity and effective temperature curves; these zones may be determined for various conditions (different seasons, different nations, different races, different clothing, etc.).

Web Reference

American Society of Heating and Air Conditioning Engineers: www.ashrae.org/

COMFORT ZONE. The ranges of indoor temperature, humidity, and air movement, under which most persons enjoy mental and physical well-being. As represented on comfort charts of the American Society of Heating and Air Conditioning Engineers, comfort zones are areas bounded by curves of effective temperature and relative humidity. See also **Comfort Chart**. The limiting conditions vary somewhat according to season and to the native climate of the person or group. In the United States the comfort zone with normal ventilation lies between air temperatures of about 17° and 24°C (63° and 75°F) at a relative humidity of 70%, and 19°C (67°F) at a relative humidity of 30%, giving an effective temperature within a few degrees of 19°C (67°F). The limits, however, vary with the season, being higher in summer than in winter. In the United Kingdom, the comfort zone is centered on an effective temperature of about 16°C (60°F). In the Tropics the comfort zone lies between the same limits of relative humidity, but at air temperatures around 26°C (78°F).

COMMAND CONTROL. A system whereby functions are performed as the result of a transmitted signal.

COMMAND DESTRUCT. A command control system that destroys a flightborne test rocket, actuated on command of the range safety officer whenever the rocket performance indicates a safety hazard.

COMMAND GUIDANCE. The guidance of a spacecraft or rocket by means of electronic signals sent to receiving devices in the vehicle.

COMMIPHORA TREE. Of the family *Burseraceae* (torchwood family), genus *Commiphora*, the *C. abyssinica* is a small, low, thorny tree that is found in the southern part of Saudi Arabia, on the island of Socotra in the Indian Ocean south of the Arabian Peninsula, and in eastern Africa. The commiphora contains a yellow-to-brown aromatic resin known as myrrh. It is postulated that the myrrh mentioned in the Bible was a mixture of this resin and labdanum, obtained from various species of the rockrose. Long before the time of Christ, the Arabians used myrrh for barter and trade with other peoples. At that time, it is believed that the commiphora tree grew in large numbers and that the trade in myrrh and of the wood of the tree was quite extensive. History records that the Romans used it, the Greeks honored Zeus by burning the resin, and that Chaldean priests used it profusely on the alters to Baal. The Egyptians also used the resin as an embalming medium.

The fruit of the tree, somewhat resembling a small cedar, is yellow, smooth, egg-shaped, and about the size of a current. The leaves are small and relatively sparse. The flower is mildly fragrant. The boswellia tree, the source of frankincense, is also of the torchwood family — so named because of the high resinous content and hence flammability of the tree. See also **Boswellia Tree**.

COMMISSURE. A transverse nerve cord or fiber tract connecting paired components of the nervous system.

COMMON COLD. Sneezing, scratchy throat, runny nose — everyone knows the first signs of a cold, probably the most common illness known. Although the common cold is usually mild, with symptoms lasting a week or less, it is a leading cause of doctor visits and of school and job absenteeism. In the course of a year, individuals in the United States suffer one billion colds, according to some estimates. Colds are most prevalent among children, and seem to be related to youngsters' relative lack of resistance to infection and to contacts with other children in day-care centers and schools. Children have about six to ten colds a year. In families with children in school, the number of colds per child can be as high as 12 a year. Adults average about two to four colds a year, although the range varies widely. Women, especially those aged 20 to 30 years, have more colds than men, possibly because of their closer contact with children. On average, individuals older than 60 have fewer than one cold a year.

The economic impact of the common cold is enormous. The National Center for Health Statistics (NCHS) estimates that 66 million cases of the common cold in the United States required medical attention or resulted in restricted activity. There are approximately 45 million bed days annually associated with the common cold and 22 million days lost from school, according to NCHS.

The term *cold* is not to be confused with the professional use of the acronym COLD, which stands for the much more serious respiratory diseases, collectively known as *chronic obstructive lung disease*.

More than 200 different viruses are known to cause the symptoms of the common cold. Some, such as the rhinoviruses, seldom produce serious illnesses. Others, such as parainfluenza and respiratory syncytial virus, produce mild infections in adults but can precipitate severe lower respiratory infections in young children.

Rhinoviruses (from the Greek rhin, meaning "nose") cause an estimated 30–35% of all adult colds, and are most active in early fall, spring, and summer. More than 110 distinct rhinovirus types have been identified. These agents grow best at temperatures of 33°C (about 91°), the temperature of the human nasal mucosa.

Coronaviruses are believed to cause a large percentage of all adult colds. They induce colds primarily in the winter and early spring. Of the more than 30 isolated strains, three or four infect humans. The importance of coronaviruses as causative agents is hard to assess because, unlike rhinoviruses, they are difficult to grow in the laboratory.

Approximately 10–15% of adult colds are caused by viruses also responsible for other more severe illnesses: adenoviruses, coxsackieviruses, echoviruses, orthomyxoviruses (including influenza A and B viruses), paramyxoviruses (including several parainfluenza viruses), respiratory syncytial virus and enteroviruses. The causes of 30–50% of adult colds, presumed to be viral, remain unidentified. The same viruses that produce colds in adults appear to cause colds in children. The relative importance of various viruses in pediatric colds, however, is unclear because of the difficulty in isolating the precise cause of symptoms in studies of children with colds.

Although many people are convinced that a cold results from exposure to cold weather from getting chilled or overheated. NIAID grantees have found that these conditions have little or no effect on the development or severity of a cold, nor is susceptibility apparently related to factors such as

exercise, diet, or enlarged tonsils or adenoids. On the other hand, research suggests that psychological stress, allergic disorders affecting the nasal passages or pharynx (throat), and menstrual cycles may have an impact on a person's susceptibility to colds.

In the United States, most colds occur during the fall and winter. Beginning in late August or early September, the incidence of colds increases slowly for a few weeks and remains high until March or April, when it declines. The seasonal variation may relate to the opening of schools and to cold weather, which prompt people to spend more time indoors and increase the chances that viruses will spread from person to person. Seasonal changes in relative humidity also may affect the prevalence of colds. The most common cold-causing viruses survive better when humidity is low — the colder months of the year. Cold weather also may make the nasal passages' lining drier and more vulnerable to viral infection.

Cold Symptoms

Symptoms of the common cold usually begin two to three days after infection and often include nasal discharge, obstruction of nasal breathing, swelling of the sinus membranes, sneezing, sore throat, cough, and headache. Fever is usually slight but can climb to 102 °F (38.9 °C) in infants and young children. Cold symptoms can last from two to 14 days, but two-thirds of people recover in a week. If symptoms occur often or last much longer than two weeks, they may be the result of an allergy rather than a cold.

Colds occasionally can lead to secondary bacterial infections of the middle ear or sinuses, requiring treatment with antibiotics. High fever, significantly swollen glands, severe facial pain in the sinuses, and a cough that produces mucus, may indicate a complication or more serious illness requiring a doctor's attention.

How Cold Viruses Cause Disease

Viruses cause infection by overcoming the body's complex defense system. The body's first line of defense is mucus, produced by the membranes in the nose and throat. Mucus traps the material inhaled: pollen, dust, bacteria and viruses. When a virus penetrates the mucus and enters a cell, it commandeers the protein-making machinery to manufacture new viruses which, in turn, attack surrounding cells.

Cold symptoms: the body fights back. Cold symptoms are probably the result of the body's immune response to the viral invasion. Virus-infected cells in the nose send out signals that recruit specialized white blood cells to the site of the infection. In turn, these cells emit a range of immune system chemicals such as kinins. These chemicals probably lead to the symptoms of the common cold by causing swelling an inflammation of the nasal membranes, leakage of proteins and fluid from capillaries and lymph vessels, and the increased production of mucus.

Kinins and other chemicals released by immune system cells in the nasal membranes are the subject of intensive research. Researchers are examining whether drugs to block them, or the receptors on cells to which they bind, might benefit people with colds.

How Colds are Spread

Depending on the virus type, any or all of the following routes of transmission may be common:

- Touching infectious respiratory secretions on skin and on environmental surfaces and then touching the eyes or nose.
- Inhaling relatively large particles of respiratory secretions transported briefly in the air.
- Inhaling droplet nuclei: smaller infectious particles suspended in the air for long periods of time.

Research on rhinovirus transmission. Much of the research on the transmission of the common cold has been done with rhinoviruses, which are shed in the highest concentration in nasal secretions. Studies suggest a person is most likely to transmit rhinoviruses in the second to fourth day of infection, when the amount of virus in nasal secretions is highest. Researchers also have shown that using aspirin to treat colds increases the amount of virus shed in nasal secretions, possibly making the cold sufferer more of a hazard to others.

Prevention

Handwashing is the simplest and most effective way to keep from getting rhinovirus colds. Not touching the nose or eyes is another. Individuals with colds should always sneeze or cough into a facial tissue, and promptly throw it away. If possible, one should avoid close, prolonged exposure to persons who have colds.

Because rhinoviruses can survive up to three hours outside the nasal passages on inanimate objects and skin, cleaning environmental surfaces with a virus-killing disinfectant might help prevent spread of infection.

A cold vaccine? The development of a vaccine that could prevent the common cold has reached an impasse because of the discovery of many different cold viruses. Each virus carries its own specific antigens, substances that induce the formation of specific protective proteins (antibodies) produced by the body. Until ways are found to combine many viral antigens in one vaccine, or take advantage of the antigenic cross-relationships that exist, prospects for a vaccine are dim. Evidence that changes occur in common-cold virus antigens further complicate development of a vaccine. Such changes occur in some influenza virus antigens and make it necessary to alter the influenza vaccine each year.

Treatment

Only symptomatic treatment is available for uncomplicated cases of the common cold: bed rest, plenty of fluids, gargling with warm salt water, petroleum jelly for a raw nose, and aspirin or acetaminophen to relieve headache or fever.

A word of caution. Several studies have linked the use of aspirin to the development of Reye's syndrome in children recovering from influenza or chickenpox. Reye's syndrome is a rare but serious illness that usually occurs in children between the ages of three and 12 years. It can affect all organs of the body, but most often injures the brain and liver. Although most children who survive an episode of Reye's syndrome do not suffer any lasting consequences, the illness can lead to permanent brain damage or death. The American Academy of Pediatrics recommends children and teenagers not be given aspirin or any medications containing aspirin when they have any viral illness, particularly chickenpox or influenza. Many doctors recommend these medications be used for colds in adults only when headache or fever is present. Researchers, however, have found that aspirin and acetaminophen can suppress certain immune responses and increase nasal stuffiness in adults.

Nonprescription cold remedies, including decongestants and cough suppressants, may relieve some cold symptoms but will not prevent, cure, or even shorten the duration of illness. Moreover, most have some side effects, such as drowsiness, dizziness, insomnia, or upset stomach, and should be taken with care.

Nonprescription antihistamines may have some effect in relieving inflammatory responses such as runny nose and watery eyes that are commonly associated with colds.

Antibiotics do not kill viruses. These prescription drugs should be used only for rare bacterial complications, such as sinusitis or ear infections, that can develop as secondary infections. The use of antibiotics "just in case" will not prevent secondary bacterial infections.

Does vitamin C have a role? Many people are convinced that taking large quantities of vitamin C will prevent colds or relieve symptoms. To test this theory, several large-scale, controlled studies involving children and adults have been conducted. To date, no conclusive data has shown that large doses of vitamin C prevent colds. The vitamin may reduce the severity or duration of symptoms, but there is no definitive evidence. Taking vitamin C over long periods of time in large amounts may be harmful. Too much vitamin C can cause severe diarrhea, a particular danger for elderly people and small children. In addition, too much vitamin C distorts results of tests commonly used to measure the amount of glucose in urine and blood. Combining oral anticoagulant drugs and excessive amounts of vitamin C can produce abnormal results in blood-clotting tests.

Inhaling steam also has been proposed as a treatment of colds on the assumption that increasing the temperature inside the nose inhibits rhinovirus replication. Recent studies found that this approach had no effect on the symptoms or amount of viral shedding in individuals with rhinovirus colds. But steam may temporarily relieve symptoms of congestion associated with colds.

Interferon-alpha has been studied extensively for the treatment of the common cold. Investigators have shown interferon, given in daily doses by

nasal spray, can prevent infection and illness. Interferon, however, causes unacceptable side effects such as nosebleeds and does not appear useful in treating established colds. Most cold researchers are concentrating on other approaches to combatting cold viruses.

Thanks to basic research, scientists know more about the rhinovirus than almost any other virus, and have powerful new tools for developing antiviral drugs. Although the common cold may never be uncommon, further investigations offer the hope of reducing the huge burden of this universal problem.

COMMON ION EFFECT. The reversal of ionization which occurs when a compound is added to a solution of a second compound with which it has a common ion, the volume being kept constant. The degree of ionization of the second compound then is lowered, i.e., it retrogresses. The common ion effect also can markedly affect solubility.

COMMON-MODE REJECTION RATIO. A parameter used to express the ability of a differential subsystem or instrument or reject the effect of a common-mode voltage applied at its input terminals. An idealized model of the common-mode rejection ratio (CMRR) is shown in Fig. 1. Voltage V_{CM} is the common-mode voltage, V_{in} is the equivalent differential-input voltage due to V_{CM}, V_0 is the output voltage (in the case of a digital measurement subsystem or instrument, the output value), the G is the gain or conversion factor of the differential subsystem or instrument. See also **Common-Mode Voltage**; and **Differential-Mode Voltage**.

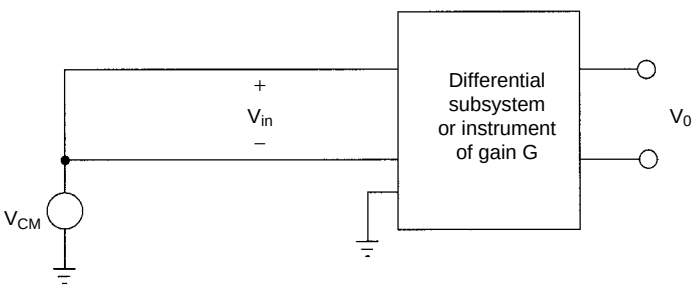

Fig. 1. Model of common-mode rejection ratio (CMRR).

The $\text{CMRR} = V_{CM}/V_{\text{in}}$. Inasmuch as it is difficult to measure V_{in} directly, the equivalent definition, $\text{CMRR} = V_{CM}G/V_0$ may be used as the basis of measurement.

If the common-mode voltage is ac, the measurement of the CMRR is based upon the ac component in the output. Where a digital output is involved, this is the increase in the repeatability or spread in output values. Consistent units must be used, i.e., if peak-to-peak values are used for V_{CM}, then the peak-to-peak increase in the spread of output readings must be used.

Frequently, the CMRR of an instrumentation subsystem ranges from 100 to 140 dB or, when expressed as a ratio, from 10^5:1 to 10^7:1, with 120 dB being the most common. Definition of CMRR in decibel units follows the formula: $\text{CMRR (dB)} = 20 \log(\text{CMRR})$. A specification of 10^6:1 signifies that every volt of common-mode voltage results in the equivalent of 1 microvolt of normal-mode voltage at the input of the subsystem. Since the CMRR of most subsystems depends upon the resistive source unbalance and, often, on the value of the common-mode voltage, a CMRR specification should include these parameters. A complete specification of the CMRR would be: $\text{CMRR} = 10^6 : 1$ at up to 1,000 ohms source unbalance and 200 V dc.

THOMAS J. HARRISON.

COMMON-MODE VOLTAGE. A voltage that is common to both inputs of a differential subsystem or instrument when measured with respect to a system reference point (usually ground) is termed the *common-mode voltage*. A differential subsystem used to measure a signal voltage V_s is shown in Fig. 1. The point G_1 is the ground reference point for the measurement subsystem. It will be noted that the signal voltage is referenced to G_2. The latter may or may not be at the same potential as G_1. Voltages at input terminals A and B are $V_A = V_S + V_{CM}$ and $V_B = V_{CM}$. The voltage common to both A and B is V_{CM}, the common-mode voltage. Common-mode voltage sometimes is defined as the average value of V_A and V_B, namely $(V_A + V_B)/2$. Inasmuch as common-mode voltages generally are of concern only when $V_{CM} \gg V_s$, there is little practical difference between the two definitions.

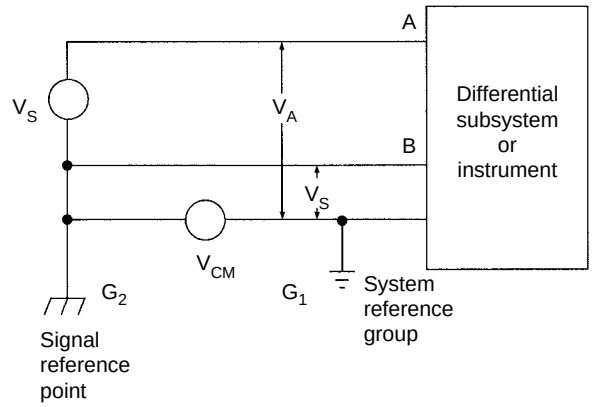

Fig. 1. Common-mode voltage.

Common-mode sources cause problems in differential-measurement systems inasmuch as they can cause measurement error due to common- to normal-mode (or differential-mode) conversion. See also **Differential-Mode Voltage**. In a perfect differential-measurement system, only the value of the signal voltage V_s would be measured — with no contribution arising from the presence of a common-mode voltage V_{CM}. However, in practice some common-mode voltage usually appears as a signal voltage.

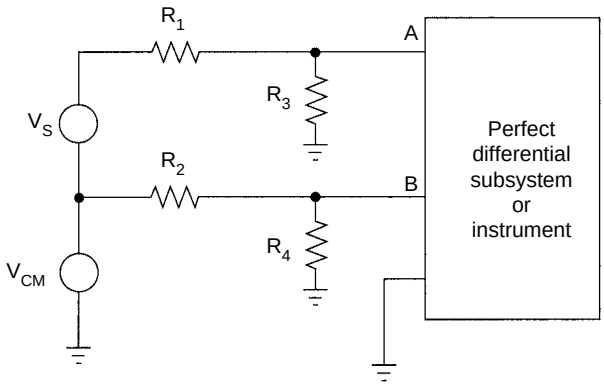

Fig. 2. Model of common-to-normal-mode conversion.

Conversion can occur as shown in Fig. 2. Resistance R_1 and R_2 are respectively representative of the input-line resistance and the source impedance of V_s. Resistances R_3 and R_4 are leakage resistances to ground in both the input lines and the differential measurement subsystem. Resistances R_1 and R_3 comprise a voltage divider, as do resistances R_2 and R_4. If the input impedance of the instrument is neglected, the differential- or normal-mode voltage, $V_A - V_B$ is

$$V_A - V_B = V_S \frac{R_3}{R_1 + R_3} + V_{CM}\left(\frac{R_3}{R_1 + R_3} - \frac{R_4}{R_2 + R_4}\right)$$

If one assumes that $R_3 \approx R_4 \gg R_2$, R_2, the expression becomes

$$V_A - V_B \approx V_S + V_{CM}\left(\frac{R_2 - R_1}{R_3}\right)$$

The desired measurement result is the value V_s. Consequently, the second term in the foregoing expression represents the error arising from common- to normal-mode conversion, commonly referred to as the *common-mode error*. The common-mode rejection ratio, which is a measure of the ability of a system to reject the effect of common-mode voltage, is the inverse of the coefficient of V_{CM}, namely, $|R_3/(R_2 - R_1)|$.

The situation shown in Fig. 2 is only one possibility whereby common-mode voltage can be converted into a normal-mode signal. Where the common-mode source is ac, resistance R_3 and R_4 usually can be neglected. However, the leakage capacitance from input terminals A and B to ground must be considered. The diagram of Fig. 2 represents an idealized version of the actual phenomenon. Lumped parameters are assumed, but in an actual situation, the resistances and capacitances will be distributed along the length of the input lines.

Common-mode voltage can result from the way a system is used, or from entirely unintentional causes. Bonding of a thermocouple to a current-carrying conductor or use of a subsystem to measure the voltage drop across an ungrounded resistor in a circuit are representative of error arising from the manner in which the system is used. Where the signal source is grounded, and where ground potential differs from that at the measurement point, the source of common-mode voltage error could be considered unintentional. Needless to say, however, the system does not differentiate between the two causes.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

COMMUNAL ENTROPY. The contribution to the entropy of a system arising from the disorder when the molecules are sufficiently free to change positions frequently. See also **Entropy**.

COMMUNICATIONS. (**See alphabetical index**)

COMMUTATION RELATIONS. Physical quantities are represented in quantum mechanics by linear operators. Two linear operators A and B do not commute in general, $AB \neq BA$. The commutation relations give an expression for the commutator $AB - BA$. Canonically conjugate dynamical variables q, p satisfy the commutation relations $qp - pq = i\overline{h}$, where $\overline{h} = h/2\pi$ and h is Planck's constant. Components M_x, M_y, M_z of an angular momentum operator satisfy the commutation relations

$$M_x M_y - M_y M_x = ihM_z$$

$$M_y M_z - M_z M_y = ihM_x$$

$$M_z M_x - M_x M_z = ihM_y$$

See also **Commutator (Mathematics)**.

COMMUTATIVE LAW. Arithmetic or algebraic quantities obey this law when the result of some operation is independent of the order in which it is performed. Thus, if $(a + b) = (b + a)$ or $ab = ba$, the processes are commutative. An operator or matrix is often noncommutative.

COMMUTATOR (Electric). See **Electric Power and Energy Measurement**.

COMMUTATOR (Mathematics). If A and B are two noncommutative operators, their commutator is

$$[A, B] = AB - BA$$

According to quantum theory, if the commutator vanishes for two operators that represent dynamical variables, then the measurement of one of these variables does not interfere with that of the other.

COMPACT DIFFERENCING. An "implicit" method for numerically estimating the derivatives of data on a grid using coefficient templates spanning a more compact range of grid points than the conventional "explicit" differencing template at the same order of accuracy.

For example, conventional fourth-order differencing on a uniform grid uses a centered template spanning five values of data; compact fourth-order differencing uses two three-point centered templates, one for the given data and one for the gridded derivatives themselves, which therefore must be solved for simultaneously. The superior accuracy of compact schemes makes them computationally advantageous, provided that the grid geometry is sufficiently regular.

COMPANDOR. 1. A transmission system in which the signal-to-noise ratio is improved by signal compression before transmission, and signal expansion after reception. 2. A speech-reproducing system consisting of a compressor of the volume range at the recording end, and an expander of the volume range at the reproducing end.

COMPANION CELL. This is a very small elongate cell always found in close association with a sieve tube in higher plants. It contains a dense protoplasm with a prominent nucleus and very small vacuoles. Companion cells are assumed to function with the sieve tubes. See also **Cambium (Plant)**.

COMPARATIVE BIOLOGY. In any division of biological science, the comparative treatment focuses attention upon a limited subject, such as anatomy, but introduces into its treatment data drawn from many species. This method of study has been applied widely to the vertebrates; hence, comparative anatomy is likely to mean comparative anatomy of the vertebrates unless otherwise qualified.

The comparative method is valuable in determining the evolutionary development of organs and the relationship of species.

Comparative biochemistry may be defined as the study of the nature, origin, and control of biochemical diversity. This definition suggests that: (1) biochemical differences are to be found among organisms; (2) such differences arise during the evolving processes of organisms; and (3) the biochemical properties of organisms are under a variety of controls in nature, and presumably may be modified when the biochemical properties and their natural controls are understood.

In the approach to comparative biochemistry, popular before the 1950s and exemplified by the books of Baldwin and Florkin, biochemists studied the similarities and differences among higher organisms, mainly among animals. The compounds, such as the various phosphagens, blood-transport pigments, carotenoids, and the A vitamins, were correlated with the postulated phylogenetic position of the animals possessing these substances. The comparative aspects of nitrogenous excretion products and of salt and water balance have also been studied in great detail. Such types of studies have revealed metabolic differences among the *Metazoa*, differences related to their evolving nature and ecological niches. More recently, the distributions of the alkaloids and flavones of plants, organic acids of lichens, and the pterins of *Drosophila*, among other biochemical markers, have been analyzed in detail to help in establishing genetic and evolving interrelations.

Since about 1945, biochemistry has concentrated largely on cellular metabolism, and these studies tend to emphasize the uniformity of cellular biochemistry. Thus, almost all cells contain proteins built of the same 20 amino acids, RNA and DNA containing their characteristic constituents, common coenzymes ATP, NAD, coenzyme A, and so on. Also, many similarities could be detected in the metabolic events relating to energy and biosynthesis in many cell types, i.e., microorganisms, plants, and animals. This experience was soon interpreted by the school of Kluyver and van Niel and their students to signify a *uniformity of biochemistry*, a unity inferred to derive from a monophyletic process of organisms as they evolve from a primitive cellular type. In this view, biochemical differences among organisms are considered to reflect relatively late evolving divergences of which the metabolic differences among the *Metazoa*, e.g., patterns of nitrogen excretion, such as ammonotelism, ureotelism, and uricotelism, are clear examples. It is recognized that the biochemical differences found to exist between organisms are not only considered to be relatively late in their evolving processes, but are usually stated to represent minor alterations in the broad biochemical pattern common to many cells.

Thus comparative studies, while always remaining important as an investigative tool, have given ground to what appears to be the more important *uniformity* approach, with concentration on the fundamental aspects of biology which affect all life forms.

COMPARATOR. In computer operations, a device or circuit for comparing information from two sources.

1. An instrument for the accurate measurement of lengths or distances (usually small). The feature common to various forms is a reading microscope or telescope arranged to travel along a scale, its axis remaining parallel to a fixed line. A typical form consists of a low-power microscope mounted on a carriage movable forward or backward by a micrometer screw. The two points or lines whose distance apart is to be measured are brought into the focal plane of the microscope, the cross-hairs of which are adjusted first upon one and then upon the other. For example, the distance to be measured may be that between two star images on an astrographic plate, or the images of two spectrum lines taken by a spectrograph; in either case the plate is simply mounted on the stage of the comparator microscope. Another familiar type is the "cathetometer," consisting of a telescope sliding on a vertical scale and provided with a vernier. This instrument is used to measure heights of liquid columns, or other differences of level. See also **Cathetometer**.

2. A circuit that compares two signals and supplies an indication of agreement or disagreement. This circuit is also known as an "add-or-subtract" circuit.

COMPARATOR AMPLIFIER. A nonlinear amplifier for sensing either the polarity or the magnitude of an input signal. The amplifier output is one of two states, usually for representing the binary states 1 and 0. Where the input signal is in excess of a predetermined level (frequently zero), the amplifier output is in one state. Where the input signal is less than the predetermined level, the output remains in the other state. In the case where the predetermined level is other than zero, a comparator amplifier may be termed a *threshold detector*. See also **Threshold Detector**.

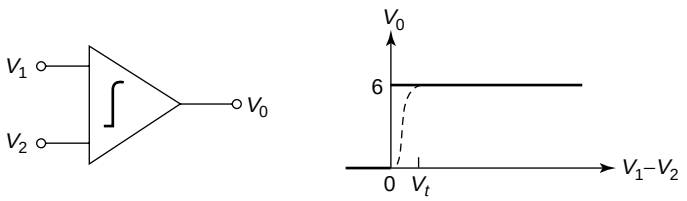

Fig. 1. Transfer characteristics of comparator amplifier.

An ideal and a practical comparator are compared in Fig. 1. The ideal characteristic is given by the heavy line. In this example, the amplifier output is +6 V when the input signal is greater than zero; and zero when the input is less than zero. However, in practice, a linear region of operation, exists between these two output levels, corresponding to a small uncertainty in the performance of the comparator. Consequently, the input level must be in excess of a threshold level V_t to make certain that the output will reach the +6 V level. Within the limitations of amplifier stability factors, the threshold voltage can be decreased by increasing the gain of the amplifier. Gains in excess of 10,000 are typical of comparator circuits.

In summary, the comparator is a high-gain single-ended or differential amplifier. Usually, the comparator is configured for fast recovery from saturation, thus permitting it to follow a rapidly varying input signal. Low zero offset is required for precision applications inasmuch as zero offset is equivalent to a shift in the threshold level. Commercial monolithic integrated amplifiers configured particularly for use as comparators are available.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

COMPASS (Navigation). An instrument used for finding direction on the surface of the earth. The oldest and most commonly used of these instruments is the magnetic compass. The directive forces are the horizontal component of terrestrial magnetism and, in a properly designed compass, the effect of the vertical component must be reduced as much as possible. The simplest form of compass is that used by surveyors, which consists of a light, thin magnet (compass needle), pivoted so that it can turn freely about an axis perpendicular to its length, and with the north-seeking end clearly marked. A compass card is mounted in the plane parallel to that in which the compass needle can turn. As shown in Fig. 1, the card incorporates "points" and other systems of marking for reading the instrument.

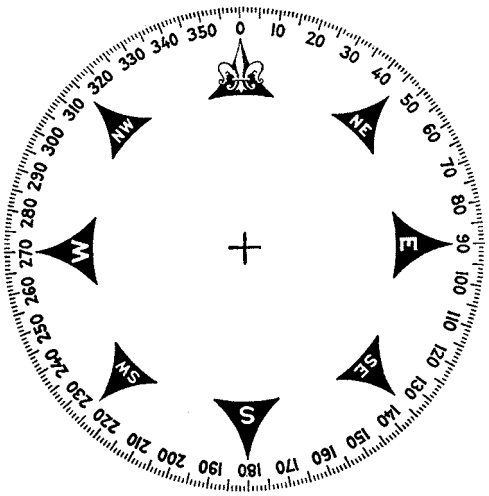

Fig. 1. Compass card.

Two principal systems are used. One system has zero both at the north and south points of the card, and reads in degrees both right and left from the zeros to the east and west points. In such a system, the northwest point would be referred to as north 45° west; and the northeast point as north 45° east. In the more widely accepted system and as shown, north is marked zero and leads to the right through the east through 360°. In this system, the northwest point is referred to as 315°; the northeast point as 045°.

For use on ships and aircraft, a much more stable system is required than that which may be satisfactory for surveyors where the environmental problems of use are minimal. If a two-pole magnet is pivoted about a vertical axis with its poles in the horizontal plane, the magnet will align itself with the horizontal component of the earth's magnetic field and indicate magnetic north, which differs from true north by the variation angle. The latter, in turn, varies from place to place on the earth. In aircraft compasses, the magnet is attached to a float in an approximately spherical-shaped chamber that is filled with liquid, thus removing most of the weight of the magnet from its pivot to reduce pivot wear and friction. The float provides a reference to dynamic vertical, and the liquid provides damping. Usually there is considerable magnetic material in an aircraft acting as a disturbing influence on the compass. Thus a compensating arrangement of small adjustable magnets usually is provided to balance out this effect.

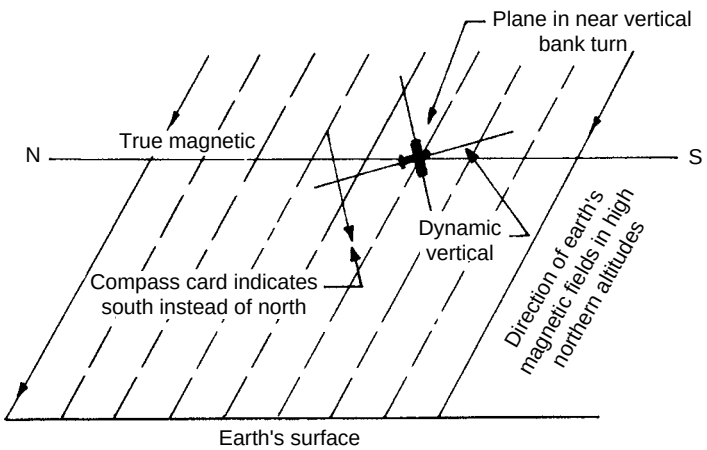

Fig. 2. Northerly-turning error.

During any acceleration, as in a turn, the float (in referencing dynamic, not true, vertical) does not align the compass magnet to read the true horizontal components of the earth's field. In fact, in a turn in one direction in high latitudes, it is possible to have the dynamic vertical at a greater angle to the true vertical than is the earth's field and thus have the compass

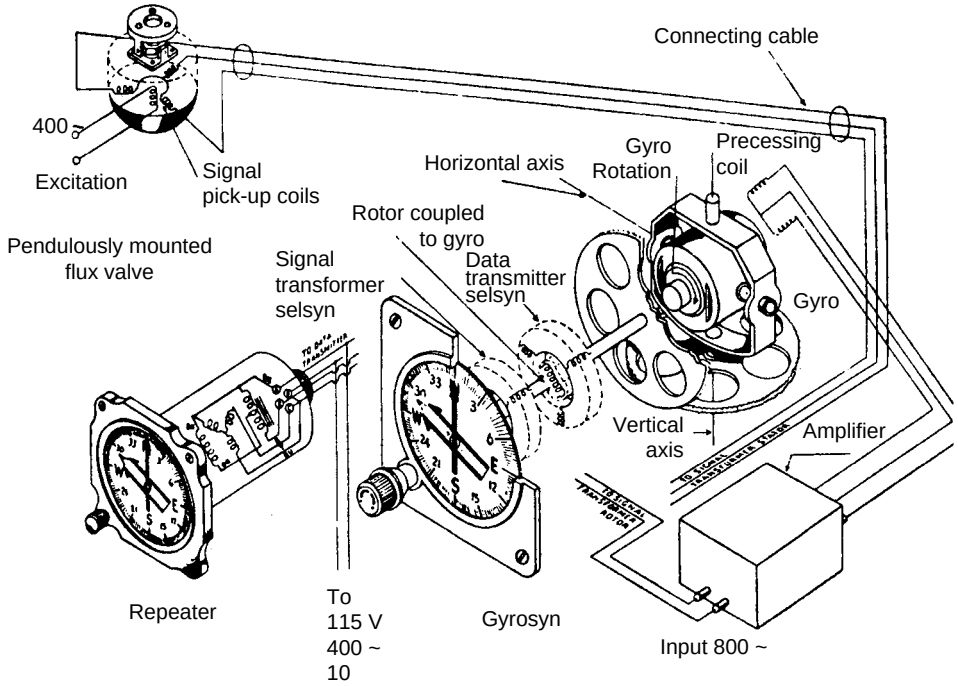

Fig. 3. Gyrosyn compass.

point south instead of north. This effect, illustrated in Fig. 2, is known as the northerly-turning error. A signal can be taken from a float or pendulous-type compass and used as a slow correction on a directional gyro, and such a long-time average will be nearly correct. This is then known as a gyrosyn compass, shown in Fig. 3.

Directional gyros are used with drift rates of 0.1 to 4 degrees an hour. Correction must be applied for rotation of the earth and aircraft velocity. Such corrections, when properly applied, give a satisfactory heading reference in very high latitudes where magnetic headings are valueless. A device of this type, known as an "all-latitude" or "polar-path" compass is shown in Fig. 4.

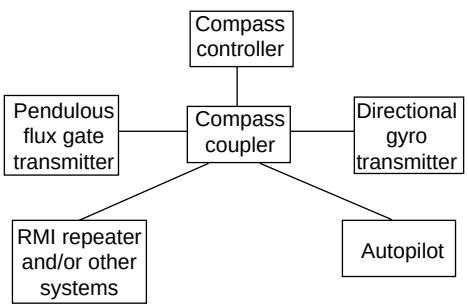

Fig. 4. Organization of polar-path compass.

On ships, a master gyro usually is installed in some well-protected part of the ship. First developed in 1911, the essential feature is a heavy gyroscope driven at high speed by electric power. The frame of the gyro is mounted in gimbals and a "ballistic tube" is attached, which causes the axis of rotation of the gyro to set itself parallel to the earth's axis of rotation, provided the instrument is stationary or moving in the east-west direction. Since the axis of rotation of the earth is in the plane of the meridian, the axis of the rotor will point true north on a stationary ship. A compass card may be attached to the gyro, but usually the gyro is used to operate repeaters in various locations about the ship.

The electrical circuit that operates the repeaters may be used for a variety of other purposes, such as for keeping a constant record of the heading of the ship and for operating the steering mechanism so that the ship will be held on a predetermined heading. However, means must be made available for constant manual intervention and for minor variations, as well as major emergency intervention, by the helmsman. For security in case of possible breakdown of the gyrocompass, a ship will also carry a standard magnetic compass for which the corrections are known at all times.

A discussion of the migration of the Earth's magnetic north pole is given in entry on **Earth**.

COMPENSATION THEOREM (Network). If a network is modified by making a change, ΔZ, in the impedance of one of its branches, the current increment thereby produced at any point in the network is equal to the current that would be produced at that point by a compensating electromotive force acting in series with the modified branch, whose value is $-i\Delta Z$, where i is the original current which flowed in the modified branch.

COMPENSATOR. A device, circuit, or other means provided in an instrument, subsystem, or component to counteract an effect which interferes with the major objective. There are many hundreds of forms of compensating means used in instruments and machines. Commonly encountered are ambient conditions, changes in which must be compensated. For example, an instrument or tool may be calibrated for so-called *standard conditions*, i.e., particular temperature, pressure, humidity, etc., conditions that may affect the accuracy of a measurement when the measurement is made outside the standard parameters. Barometers and altimeters, for example, require compensation for elevation above sea level. Filled-system thermometers require compensation for the height of the temperature-sensitive bulb in many instances. Compensation may be manual, in which case the operator of an instrument, tool, machine, and so on may refer to tables and correct what may be done arithmetically. More frequently, a compensator is thought of as a means for automatically and continuously applying a corrective counteraction. Thus, resistors are used in electrical-measuring circuits to counteract an excursion in ambient temperature. The following examples probe the applications of compensators in only two of many types of situations.

In optics, a form of compensator is an arrangement for measuring the phase difference between the two components of elliptically polarized light. See Fig. 1. This is accomplished by introducing a known, opposite phase difference of equal magnitude, which reduces the existing phase difference to zero. The most familiar form, devised by Babinet, consists of two quartz wedges, with thin optic axes at right angles to each other. When passed through this apparatus and a Nicol prism set to extinguish light plane-polarized at 45° to either axis, any given elliptically polarized light produces a system of parallel dark bands. Plane-polarized light is first used (zero phase difference), then the elliptic light of unknown phase

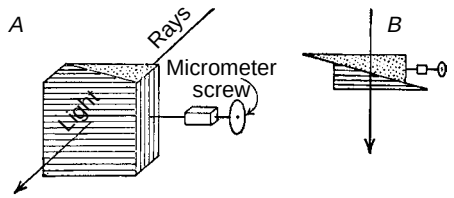

Fig. 1. (**a**) Diagrammatic sketch of Babinet Compensator: angle of wedges much exaggerated. Hatching and stippling indicate direction of crystal axes. (**b**) Wedges displaced.

difference, and the relative displacement of the wedges necessary to restore the bands to their original position gives the phase difference required.

COMPILER (Computer System). A program designed to translate a higher-level language into machine language. In addition to its translating function, which is similar to the process used in an assembler, the compiler program is able to replace certain items of input with a series of instructions, usually called subroutines. Thus, where an assembler translates item for item and produces as output the same number of instructions or constants which were put into it, a compiler, typically produces multiple output instructions for each input instruction or statement. The program that results from compiling is a translated and expanded version of the original.

Compiler language is characterized by the one-to-many relationship between the statements written by the programmer and the actual machine instructions executed. The programmer typically has little control over the number of machine instructions executed to perform a particular function and is dependent on the particular compiler implementation. Typically, the language is very nearly machine-independent and may be biased in its statements and features to a particular group of users with similar problems. Thus, these languages sometimes are referred to as problem-oriented languages (POL). Slightly different implementations of a given language are sometimes called "dialects." Some compiler languages in wide use are ALGOL, BASIC, COBOL, FORTRAN, and PL/I.

COMPLEMENT. 1. In decimal representation, the complement of a number x is $10^{\nu} - x$, where ν is some fixed integer, positive, negative, or zero. In binary representation it is $2\mu - x$, where μ is an integer. The subtraction of a number is thus essentially equivalent to the addition of its complement, and in computer construction it is generally easier to mechanize the formation of a complement than that of an arbitrary difference. In binary notation, the one's-complement of x is the number obtained when each digit x_i of x is replaced by $1 - x_i$. 2. The complement of a subset S of a set A is the set of all elements of A not included in S. 3. For the algebraic complement of a minor determinant, see also **Minor (Of a Matrix)**.

COMPLEMENTAL MALE. 1. In certain barnacles which are normally hermaphrodites a few individuals lack female organs and are called complemental males. 2. In colonies of white ants, termite reproduction is carried on principally by a highly specialized king and queen. Other sexually mature individuals resembling the immature insects are known as the second reproductive caste. The males of this caste are complemental males.

COMPLEMENTARITY PRINCIPLE. Physical phenomena may be described either in terms of particle motions characterized by a momentum p and an energy E, or in terms of waves characterized by a wavelength λ and a frequency ν. The two descriptions are connected by the equations:

$$p = h/\lambda \text{ and } E = h\nu$$

where h is the Planck constant.

COMPLEX COMPOUND. See **Ligand**.

COMPLEX NUMBER. See **Complex Variable**.

COMPLEX SIGNAL. In radar, a representation of the time-varying amplitude and phase of the received signal as the real and imaginary parts of a time-varying complex number. These parts are called the *in-phase* and *quadrature* components and are measured by coherent detection of the received signal. The in-phase signal may be obtained by demodulating the received signal with a local oscillator having the same phase and frequency as the transmitted signal, while the quadrature signal may be obtained by demodulating the received signal with the local oscillator signal advanced or retarded in phase by 90°.

COMPLEX TERRAIN. See **Meteorology**.

COMPLEX VARIABLE. A complex number has the form $(a + ib)$, where a, b are real numbers and $i = \sqrt{-1}$. It thus consists of a real part a and a pure imaginary part ib. In the study of complex numbers they are generally regarded as an ordered pair of real numbers (a, b) subject to the following laws: (1) equality, $(a, b) = (c, d)$ if, and only if, $a = c$, $b = d$; (2) addition, $(a, b) + (c, d) = (a + c, b + d)$; (3) multiplication, $(a, b) \times (c, d) = (ac - bd, ad + bc)$.

A complex number may be represented graphically on an Argand diagram. If it is described in polar coordinates it becomes $r(\cos\theta + i\sin\theta)$, where r is the absolute value, modulus, or radius vector and the angle θ is the amplitude, argument, or phase of the number.

If x and y are two real variables, then $z = (x + iy)$ is a complex variable. Thus a complex number is the special case where x, y are both constants. In either case, $(u + iv)$ and $(u - iv)$ are conjugate or conjugate complex to each other. Given a complex number of a function A, the conjugate complex is obtained by changing the sign of the imaginary part. It is often indicated by the symbol $\overline{A}$ or A^*. The product of an expression and its conjugate complex is always real.

COMPONENT. 1. In its most general usage, one of the ingredients of a mixture, or one of the distinct molecular or atomic species composing a mixture. In physical chemistry, one among the smallest number of chemical substances which need to be specified in order to reproduce a given chemical system. 2. The projection of a vector on a particular coordinate axis or along some specified direction. 3. Component of a tensor. 4. Component of a circuit, such as a capacitor, resistor, etc.

COMPONENT ANALYSIS. This is a branch of multivariate analysis which represents a k-dimensional variation as due to a number of uncorrelated components; fewer than k if possible, but if not, in such a way that a few components account for as much of the variation as possible. The components sought in practice are linear functions of the original variates. The method of analysis into principal components is to be sharply distinguished from factor analysis, notwithstanding a formal resemblance in the mathematics of the subject. See also **Factor Analysis**.

COMPOSITE FAMILY *(Compositae).* The largest family within the plant kingdom, embracing several thousand species within over 800 genera. The family represents the highest developmental attainment among the dicotyledonous plants (a plant having two cotyledons or seed leaves — see also **Dicotyledons**). Composites are mostly herbaceous plants, distributed in nearly all parts of the earth. The few members which are shrubs or trees are mainly limited to tropical regions, especially to island floras.

The composite family is divided into two groups, distinguished by the nature of its flowers. If all the flowers of a head are ligulate, the plant is a member of the *Liguliflorae*. This group contains many common plants, including chicory, dandelion, and lettuce. The plants of this group have latex vessels usually containing a white latex. See Fig. 1. The second group, the *Tubuliflorae*, comprises all composites characterized by disk flowers. These may occupy only the central portion of the head, or the latter may be entirely of disk flowers. This group lacks latex.

The leaves of most composites are alternate, often entirely radical, although in a few cases they are opposite, as in the sunflower, *Helianthus annuus*, or whorled, as in species of *Eupatorium*. Stipules are seldom found in this family. The root is most commonly a tap-root, frequently much thickened, as in the dandelion. The inflorescence is of the type known as head, or capitulum. Often the heads are aggregated in larger inflorescences of various types, as panicles or cymes or spikes. Commonly the single

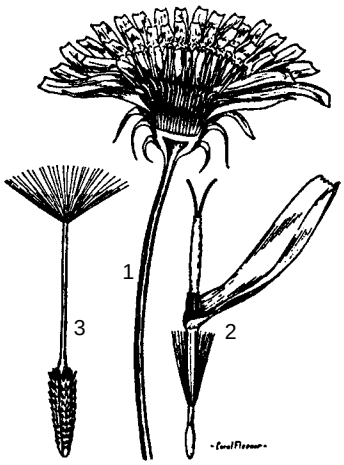

Fig. 1. Flower head and flowers of the dandelion, *Taraxacum*: (1) the inflorescence or head, composed of many flowers upon a flattened stem; (2) a single flower more enlarged; (3) a single fruit.

head is inaccurately regarded as a flower, rather than as an inflorescence. Surrounding the head is a group of bracts, making up the involucre. These bracts are usually green and serve to protect the flowers before they are mature and also to protect the maturing fruit. The flowers of a head are arranged on the enlarged end of the stem or axis, called the receptacle. This receptacle may be flat and disk-shaped, as in the common sunflower, conical as in the yellow daisy, *Rudbeckia hirta*, or otherwise. It may be smooth or covered with hairs or scales.

The individual flowers show considerable difference in structure. In many species the flowers of a head are all alike and all perfect. In other species they are of two kinds, one called ligulate and the other tubular. Ligulate flowers, also called ray-flowers, are irregular, but bilaterally symmetrical; tubular flowers, also called disk flowers, are regular. Both types occur in the head of the sunflower, where the tubular or disk flowers occupy the larger part of the receptacle, the ray-flowers being the conspicuous yellow flowers forming a ring around the periphery of the receptacle, just inside the involucral bracts. See Fig. 2. Each disk flower is perfect and regular. The calyx appears in different genera as bristles, bars, scales, or teeth, and sometimes is completely lacking. It is known as the pappus and occurs at the apex of the inferior ovary.

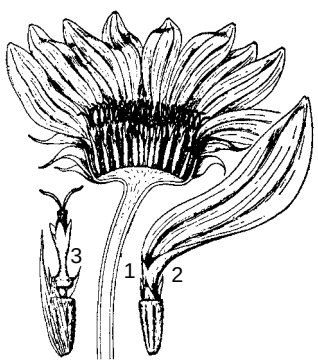

Fig. 2. Flowers and flower heads of a sunflower, *Helianthus*: (1) the flower head, cut so as to show the relation of the ray and disk flowers to the end of the stem; (2) a single ray flower; (3) a single disk flower.

Often the pappus becomes a very important structure in the dissemination of the fruit. The corolla is tubular and 5-lobed, and inserted on the apex of the ovary. The short filaments of the five stamens are inserted on the base of the corolla tube, while the anthers are attached to each other by their edges, forming a tube which surrounds the style. The pollen is discharged into the anther tube. The single pistil has an inferior ovary containing a single erect ovule, a simple style which splits into two parts, the inner surfaces of which are stigmatic. The fruit is usually of the type called an achene. Nectar is secreted in a ring-shaped nectary that surrounds the base of the style, located at the base of the tubular corolla. This nectar attracts insects, but only those with mouth parts sufficiently long to reach to the bottom of the corolla tube can obtain it. When the flower opens the pollen is shed into the anther tube. At the base of this tube the style, as yet unforked, occurs. This style elongates, pushing like a ramrod against the pollen above it, and causing an accumulation of pollen at the upper end of the anther tube.

Insects seeking the nectar necessarily come in contact with the pollen masses, which are thus likely to be transferred to another flower as the insect goes about collecting nectar. However, should insect-pollination fail, self-pollination is assured in many species, by the behavior of the styles, which emerge from the anther tube, protrude considerably, and then split and coil backward so that the inner stigmatic surface rolls down into contact with the pollen. In some cases this self-pollination is almost the only method. Many species are self-sterile, thus requiring cross-pollination by insects.

The ligulate or ray flowers differ from the disk flowers in having the corolla of five united petals forming a tubular base which gradually emerges into a flat strap-shaped lateral structure with five teeth at its tip. Growing from the tube of the corolla are the small stigma and the five coalesced stamens. In many species where the ray flowers are marginal in the head they are entirely sterile or are pistillate.

After pollination takes place, the involucral bracts close over the head, pressing tightly against it and so protecting the developing fruit. The pappus becomes a conspicuous part of the fruit in many cases and is a very important factor in insuring scattering of the fruit. In some cases the pappus forms a parasol-like group of fine radiating hairs at the tip of a long beak of the achene. These hairs make the achene buoyant, and hence capable of being carried long distances by air currents. Often the base of the hair is hygroscopic, responding to changes in moisture, so that the parasol-like structure opens and closes with decrease or increase of humidity; this may help to loosen the achene from the receptacle, and also to shove it along over the surface of the ground, or to push it into a crack in the soil.

In *Bidens*, often called beggar-ticks or beggar-lice, the pappus is in the form of stiff, usually downwardly barbed bristles which catch into the hair of passing animals or the clothing of people and so are carried about, finally breaking off and falling to the ground. In the burdock, *Arctium*, the involucral bracts form of recurved hooks which serve in the same way, the entire head often breaking off and being transported. In thistles the pappus takes the form of a tuft of long silky hairs which enable the achene to float readily through the air. In many cases members of the composite family have no special pappus development, seed dispersal being entirely accidental.

The reasons that suggest that the composite family is highest in rank are found in the massing of the individual flowers into a compact head surrounded by protecting bracts, the structure of the individual flower with its inferior ovary, its united petals forming a corolla tube, the united anthers forming the anther tube, and the reduction of the number of carpels to two with but one ovule developing. See also **Flower**.

Relatively few of the species of *Compositae* serve a practical purpose. Many are cultivated for ornamental reasons, the flowers often becoming very large and double and showy, as in the case of the *Chrysanthemum* and *Dahlia*. Less showy ornamentals are the *Aster*, *Bellis* (daisy), *Tagetes* (marigold), and *Calendula*, among others. Some composites yield oils or other substances useful to man, as *Arnica, Artemisia, Tanacetum*, *Calendula*, *Chrysanthemum*, and *Helianthus*. A few are used in the diet, such as lettuce, artichokes, endive, chicory, salsify, and less frequently, dandelion.

Lettuca, *Lactuca sativa*. An annual herb, native to Europe, Asia and northern Africa. The plant is very leafy and contains a milk-white latex. In young plants the leaves are crowded on a short stem, forming a close rosette; in older plants the stem elongates greatly and bears a panicle of heads of yellowish flowers. The achenes are flat, ribbed, and contracted into a slender beak bearing numerous soft white or brownish pappus hairs, which radiate outward like a parasol. Many varieties have been developed in cultivation. Lettuce is used almost entirely as a salad plant. See Fig. 3.

Endive, *Cichorium endivia*. An annual or biennial herb having many basal leaves which, in cultivated forms, have become very much dissected and crisped. Mature plants are tall-stemmed and have purple, rarely white, flowers, all ligulate. The plant is used either as a salad plant or as a pot-herb. It is a native of India, and has long been cultivated in European countries. It is becoming more popular in the United States.

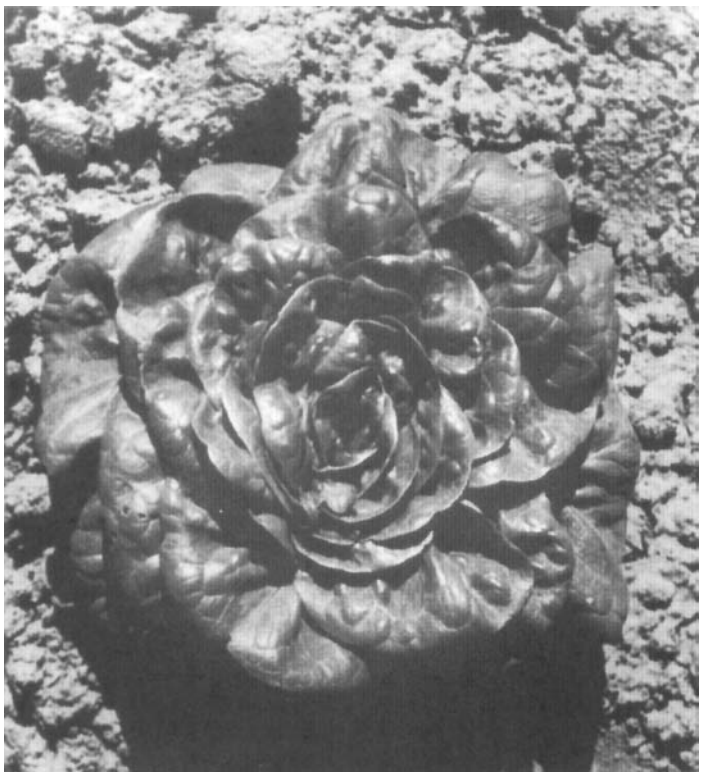

Fig. 3. Mature head of butterhead (*Bibb variety*) lettuce. (*USDA photo.*)

Chicory, *Cichorium intybus*. Also called succory, it is one of the many European plants which has become a persistent weed on introduction to North America. It is a perennial plant having a deep taproot and a stiff tough stem two or three feet (0.6–0.9 m) tall. Root leaves are numerous, forming a dense basal rosette: stem leaves are small, of various shapes, and clasping the stem. The flowers are usually blue, sometimes pink, or white. The plant is used as a salad plant or as a pot-herb, often being mistaken for dandelion. Its roots have been dried, ground and roasted and used as a substitute for coffee. There are several varieties in cultivation, one of which, Witloof chicory, finds considerable favor as a salad plant.

Salsif, *Tragopogon porrifolius*. Also called oyster plant, it is indigenous to southern Europe. It is a hardy biennial having a thick tap-root 8–12 inches (20–30 cm) long and an inch or two (2.5–5 cm) in diameter. This root is formed during the first year of growth when it bears a crowd of leaves. During the second year's growth the rather succulent branching stems grow up 2 or 3 feet (0.6–0.9 m) tall. The stem leaves are alternate, entire and clasping, and have a smooth waxy surface. The flower heads are borne on long hollow stalks, or peduncles, and have purple flowers, all ligulate. The achenes are linear and have a long slender beak with radiating pappus hairs at its tip. The roots of the plant have a flavor suggestive of that of oysters, and are used as a cooked vegetable. A yellow-flowered species also occurs, and has been widely introduced into the United States.

Artichoke (Jerusalem artichoke), *Helianthus tuberosus*. Sometimes called by its Italian name, girosole, meaning sunflower, which corrupted into English becomes Jerusalem artichoke. It is a perennial herbaceous plant having thick fleshy rootstocks, which bear somewhat irregular tubers with very evident "eyes" (actually dormant buds). The erect stems are 6 feet (1.8 m) or tall, stout and branching. The leaves are simple, ovate, and long-petioled. The heads are either solitary or in corymbs, and are composed of central disk flowers and marginal ray flowers, both yellow. The achenes are thick and hairy, with two deciduous pappus scales. The tubers are used largely as stock food, especially for hogs, but are also eaten by humans.

Helianthus annuus. The common sunflower is frequently grown, partly for ornament, partly for curiosity because of the tremendous flower heads, which often contain an enormous number of flowers, and partly for the seeds. These seeds are fed to poultry and larger caged birds. From the seeds, sunflower seed oil is expressed.

Globe artichoke, *Cynara scolymus*. Another composite grown for food. It is a herbaceous perennial native in northern Africa. The flowers form large globular heads surrounded by several rows of fleshy bracts. The basal portions of each bract and the thick fleshy receptacle are cooked and eaten. The blanched leaves of a related species, *Cynara cardunculus*, or cardoon, are often eaten like celery.

Dandelion, *Taraxacum officinale*. A stemless perennial herb, having a thick tap-root and a rosette of basal leaves which grow close to the ground. Contraction of the root each year keeps the leaves of that year's growth at the ground level. The heads, composed of yellow ligulate flowers, are borne singly on hollow peduncles. When the achenes are mature the peduncle elongates greatly, lifting the achenes well above the ground. Each achene is beaked and has a crown of pappus hairs, which aid it in floating through the air. The dandelion is frequently used as a pot-herb, and is grown extensively. Wild plants, often pestiferous weeds in lawns, are sometimes gathered in the spring for greens. The root, containing a glucoside taraxirin, has been considered by some as a tonic. The dandelion species *Taraxacum koksaghyz* was at one time considered as a source of rubber.

Ragweed (genus *Ambrosia*). This composite causes allergies in some people. It is widely distributed. It is a branching annual, ordinarily growing from 2 to 4 feet (0.6 to 1.2 meters) in height. The leaves are finely divided and thin. The flower heads are of two sorts, the staminate heads are borne in elongated racemes, while the pistillates are borne in clusters. Flowers are produced in late summer and autumn and, unlike most composites, are wind-pollinated.

COMPOSITE MATERIALS. Structural materials of metals, ceramics, or plastics with built-in strengthening agents, which may be in the form of filaments, foils, powders, or flakes of a different compatible material.

COMPOSITE NUMBER. See **Number Theory**.

COMPOSTING. See **Biosolids**.

COMPOUND (Chemical). A homogeneous, pure substance, composed of two or more essentially different chemical elements, which are present in definite proportions; compounds usually possess properties differing from those of the constituent elements.

An *addition compound* is one that is formed by the junction or union of two simpler compounds. Effectively the same as a molecular compound (see definition on the following page).

An *additive compound* is formed by an additional reaction, or by the saturation of a double bond, triple bond, or more than one of them.

An *alicyclic compound* is an organic compound containing a saturated ring of carbon atoms, such as a cycloparaffin or other hydroaromatic compound.

An *aliphatic compound* is an organic compound without ring structures, i.e., with straight chain arrangement of carbon and, possibly other, atoms. In the narrower sense, an aliphatic compound is a member of the paraffin series of hydrocarbons, or one of their derivatives.

An *aromatic compound* is an organic compound containing a ring of carbon atoms, usually unsaturated, such as a benzene, naphthalene, anthracene, and acenaphthylene ring.

An *associated compound* is a compound formed by the union of two or more molecules, usually of the same or similar chemical composition, to form a single complex molecule.

Berthollide compound. See nonstoichiometric compound in this entry.

A *binary compound* is made up of two elements in a definite molecular ratio.

A *catenation compound* has a molecular configuration resembling a linked chain, in which the atoms forming one ring pass through, but are not joined by valence forces to, the ring formed by another group of atoms. Since the two rings, while spatially interlocked, are not joined by valence forces, the application of the word compound to such aggregates may be questioned.

H.L. Frisch of AT&T Bell Laboratories has made extensive calculations of ring sizes necessary to permit the formation of various catenation compounds. He found that 20 is the minimum number of $-CH_2-$ groups in an alicyclic ring through which another ring can be catenated (threaded) without encountering excessively great repulsive forces from the alicyclic ring atoms. For threadings of two rings through a third ring, the probable minimum alicyclic ring size of the latter is $33-CH_2-$ groups; Borromean rings, formed by the interlocking of three rings (with no two of them locked separately), require a minimum of $30-CH_2-$groups.

A laboratory preparation of the simplest of these catenation compounds, two interlocking rings, has been carried out at AT&T Bell Laboratories. They started with the dimethyl ester of a 34-carbon paraffinic dicarboxylic acid, $CH_3OOC-(CH_2)_{32}-COOCH_3$, which was reacted in a suspension of metallic sodium in xylene with acetic acid to condense the terminal ester groups to form an aceloin ring compound

$O{=}C-(CH_2)_{32}-CHOH$. Treatment of the latter with deuterated hydrochloric acid reduced it to a 34-carbon alicyclic (ring) compound,

$HDC-CHD-CD_2-CHD-(CH_2)_{30}$

containing five deuterium atoms. This hydrocarbon was added to the suspension of metallic sodium in xylene, and then more of the 34-carbon dimethyl ester was added. Ring formation of the latter compound to form the aceloin occurred as before, and a small percentage of the aceloin rings were found to be threaded through the deuterated rings in the solvent, yielding a catenation compound consisting of the 34-carbon aceloin ring and the 34-carbon deuterated alicyclic hydrocarbon threaded together, but without any atoms in one ring being joined by valence bonds to those in the other.

Separation and identification of this catenation compound was effected by chromatography and infrared spectroscopy, the latter being the reason why the hydrocarbon portion of the catenation compound was deuterated.

Chelation compound. See entry on **Chelates and Chelation**.

A *clathrate compound* means, literally, an enclosed compound, a term applied to a solid molecular compound in which a molecule of one component is physically enclosed in the crystal structure of a second compound, so that the properties of the aggregate are essentially those of the enclosing compound. Examples of such "cage compounds" are those of the small molecules of SO_2, CO_2, CO and the noble gases with ice and hydroquinone, which have very open crystal structures. Another example is the clathrate of benzene with nickel cyanide.

A *complex compound* is made up structurally of two or more compounds or ions. See also **Ligand**.

A *condensation compound* is formed by a reaction in which the largest parts, constituting the essential structural elements, of two or more molecules combine to form a new molecule, with elimination of minor elements, such as those of water.

Coordination compound. See also **Coordination Compounds**.

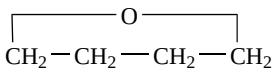
A *covalent compound* is formed by the sharing of electrons between atoms; as distinguished from electrovalent compounds, in which there occurs a transfer of electrons.

A *cyclic compound* has some or all of its atoms arranged in a ring structure.

An *electrovalent compound* is formed by ions, or by atoms which become ions by transfer of electrons between them. (See ionic compound below.)

An *endothermic compound* is a compound whose formation is accompanied by a positive change in heat content, i.e., by the absorption of heat.

An *epoxy compound* contains an oxygen bridge, as



$CH_2-CH_2-CH_2-CH_2$ (with O bridging)

which is 1, 4 epoxy butane.

An *exothermic compound* is a compound whose formation is accompanied by a negative change in heat content, i.e., with the liberation of heat.

A *heterocyclic compound* contains one or more rings composed of atoms some of which are of dissimilar elements. A few inorganic substances fall into this classification, but by far the majority of them are carbon compounds. In organic chemistry substances of cyclic structure, as acid anhydrides, lactides, lactams, lactones, cyclic ethers, and cyclic derivatives of dicarboxylic acids which are formed by the elimination of water from aliphatic compounds, are not considered among the heterocyclic substances. Derivatives of pyridine, quinoline, thiophene, thiazole, pyrone, etc., which contain heterocyclic rings that persist in the compound through chemical reactions, are considered the true members of this class. Heterocyclic rings that contain nitrogen, sulfur, and oxygen members. The noncarbon members of the ring are termed "heteroatoms," and their number is indicated by the prefixes mono, di, tri, tetra, etc. The number of members in the ring may reach as high as sixteen, as in tetrasalicylide.

A *homocyclic compound* contains a homocyclic ring, i.e., a ring composed of atoms of the same element.

The term *inclusion compound* was once used for the clathrate compounds described in this entry.

In an *inner compound* an additional valence bond has been formed between two atoms of an already existing structure, usually by loss of the elements of water or other simple substance. Inner compound formation commonly results in the formation of a ring. The inner esters, inner anhydrides, and inner coordination compounds are well-known classes of inner compounds.

An *inorganic compound* means, in general, a compound that does not contain carbon atoms. Some very simple carbon compounds, such as carbon monoxide and dioxide, binary metallic carbon compounds (carbides) and carbonates, are also included in the group of inorganic compounds.

An *intermetallic compound* consists of metallic atoms only, which are joined by metallic bonds. Such compounds may be made semiconducting if the two metals between them contribute just sufficient electrons to fill the valence bond, e.g., InAs. (See also **Alloys**).

An *interstitial compound* consists of a metal or metals and certain metalloid elements, in which the metalloid atoms occupy the interstices between the atoms of the metal lattice. Compounds of this type are, for example, TaC, TiC, ZrC, NbC, and similar compounds of carbon, nitrogen, boron, and hydrogen with metals.

An *ionic compound* is one of a class of compounds formed when atoms combine to produce molecules having stable configurations by the transfer of one or more electrons within the molecule. This type of combination is illustrated by the combination of sodium atoms and chlorine atoms to form sodium chloride. The sodium atom loses the single electron in its outer shell, and thus is left with the stable configuration of eight electrons; the chlorine atom acquires an electron to increase the number of electrons in its outer shell from seven to eight; as a result of the loss and gain of the electrons, the atoms have acquired the positive and negative charges, respectively, which constitute an electrovalent bond.

A *molecular compound* is formed by the union of two or more already saturated molecules apparently in defiance of the ordinary rules of valence. The class includes double salts, salts with water of crystallization, and metal ammonium derivatives. These salts are usually formed by Van der Waals attraction between the constituent molecules. They do not differ in any characteristic manner from compounds formed in strict accordance with the concept of valence. They are also called addition compounds.

A *nonpolar compound* is a compound in which the centers of positive and negative charge almost coincide, so that no permanent dipole moments are produced. The term nonpolar also applies to compounds in which the effect of oppositely directed dipole moments cancel. Nonpolar compounds may contain polar bonds, if their effect is canceled by opposing bonds, as may occur in a perfectly symmetrical molecule. Nonpolar compounds do not ionize or conduct electricity. Most organic compounds are to be classed as nonpolar compounds.

A *nonstoichiometric compound* has a composition not in accord with the law of definite proportions, which is therefore also called a berthollide compound. Nonstoichiometric compounds occur among the binary compounds of Group 6b, as exemplified by $TiO_{1.8}$, $Cu_{1.7}S$ and $Cu_{1.6}Se$; among the hydrides, e.g., $CeH_{2.7}$ and especially among the intermetallic compounds.

An *organic compound* is one of the great number of compounds consisting of carbon linked in chains or rings; such compounds usually also contain hydrogen and may contain elements such as oxygen, nitrogen,

sulfur, chlorine, etc. Some of the simpler carbon compounds are classified as inorganic compounds.

An *organometallic* (or *metal-organic*) *compound* is an organic compound in which one or more hydrogen atoms have been replaced by a metallic atom or atoms, usually with the establishment of a valence bond between the metal atom and a carbon atom. A metallic salt of an organic acid, in which the hydrogen atoms of a −COOH group is replaced by a metal atom, is not classified as an organometallic compound.

A *polar compound* is, in general, a compound that exhibits polarity, or local differences in electrical properties, and has a dipole moment associated with one or more of its interatomic valence bonds. Polar compounds have relatively high dielectric constants, associate readily in most cases, and include the substances that exhibit tautomerism. In the most general use of the term, polar compounds include all electrolytes, most inorganic substances, and many organic ones. Specifically, the term polar compound is frequently applied to the extreme type of polarity which arises in the presence of an electrovalent bond or, in wave-mechanical terms, to cases in which one ionic term dominates in the orbital function of the molecule. Such compounds are exemplified by the inorganic acids, bases, and salts which possess, to a greater or lesser degree the power to conduct electricity, associate, form double molecules and complex ions, etc.

In a *saturated compound* the valence of all the atoms is completely satisfied without linking any two atoms by more than one valence bond.

A *spiro-compound* contains two ring structures having one common carbon atom.

A *tracer compound* is a compound which, by its ease of detection, enables a reaction or process to be studied conveniently. Wide use has been made of isotopes, including radioactive isotopes of common elements, which are added in small quantities, in the form of the proper compound, to follow the course of an atom or a compound through a complicated series of reactions; or conversely, to determine the properties of a tracer — that is available only in quantities too small to handle alone — by adding it to a system containing chemically related elements, and then following its course throughout a given series of reactions. Considerable use of tracer compounds is made in the study of physiological reactions.

Unsaturated compound is a term specifically applied to a carbon compound containing one or more double bonds or triple bonds. One consequence of the presence of these double bonds or triple bonds, from which a broader concept of unsaturation stems, is the relative ease with which such bonds are split, and other constituents linked to them.

See also **Organic Chemistry**.

COMPOUND DISTRIBUTION. In statistics this term occurs in three senses: 1. If two or more homogeneous populations are merged, the resulting population may be said to be compound. 2. If several distributions are convoluted they are sometimes described as compounded. 3. If a distribution of a variable x depends on a parameter θ which itself has a distribution, the resultant of integrating over the distribution of θ is sometimes called the compound distribution of x.

For example, suppose a set of observations x are each drawn from a Poisson distribution $e^{-}\mu\mu^{x}/x!$ where μ varies from one observation to another according to the distribution function $F(\mu)$. The resulting distribution of x is called a compound Poisson distribution. If $F(\mu)$ is a Pearson Type III distribution, x follows a negative binomial distribution.

COMPOUND NUCLEUS. The nucleus formed in a nuclear reaction through the amalgamation of the incident nuclear particle and the target nucleus.

COMPRESSED FILES. See File Types.

COMPRESSION (Gas). The compressibility of a gas is defined as the rate of volume decrease with increasing pressure, per unit volume of the gas. The compressibility depends not only on the state of the gas, but also on the conditions under which the compression is achieved. Thus, if the temperature is kept constant during compression, the compressibility so defined is called the isothermal compressibility β_T:

$$\beta_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \frac{1}{\rho}\left(\frac{\rho}{\partial P}\right)_T \tag{1}$$

If the compression is carried out reversibly without heat exchange with the surroundings, the *adiabatic compressibility* at constant entropy, β_S, is obtained:

$$\beta_S = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_S = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial P}\right)_S \tag{2}$$

Here P is the pressure, V the volume, ρ the density, T the temperature, and S the entropy.

In adiabatic compression, the temperature rises, thus the pressure increases more sharply than in isothermal compression. Therefore β_S is always smaller than β_T.

The *compressibility factor* of a gas is the ratio *PV/RT*. This name is not well chosen since the value of the compressibility factor by itself does not indicate the compressibility of the gas.

Experimental values for the compressibility of gases can be obtained in several ways, most of which are indirect.

Since the compressibility is proportional to the pressure derivative of the volume, any experiment that establishes the *P-V-T* relation of a gas with sufficient accuracy also yields data for the isothermal compressibility. For obtaining the adiabatic compressibility from the *P-V-T* relation, some additional information is necessary [see section (c)], for instance specific heat data in the perfect gas state of the substance considered. A more direct way of determining the adiabatic compressibility is by measuring the speed of sound v, the two quantities being related by

$$v^2 = \frac{1}{\rho\beta_S} \tag{3}$$

This relation is valid only when the compressions and expansions of the sound wave are truly reversible and adiabatic. This is the case if the frequency is fairly low and the amplitude small.

Dilute gases obey the laws of Boyle and Gay-Lussac, *PV = RT*, to a good approximation. Thus, it can readily be shown that the following relations hold for the compressibility:

$$\begin{aligned} \beta_T &= 1/P = V/RT \\ \beta_S &= 1/\gamma P = V/\gamma RT \end{aligned} \tag{4}$$

where $\gamma = c_P/c_V$, the ratio of the specific heats at constant volume and at constant pressure, respectively, and R is the gas constant.

Compressed gases show large deviations from the behavior predicted by equation (4). This is demonstrated by Fig. 1, where the isothermal compressibility of argon, divided by the corresponding value for a perfect gas at the same density, is pictured as a function of density for various temperatures. It is seen, first, that at all temperatures the compressibility at high densities falls to a small fraction of the value for a perfect gas, and second, that supercritical isotherms show a maximum in the ratio $\beta/\beta_{\text{perfect}}$ as a function of density, which maximum is the more pronounced the closer the critical temperature. It occurs roughly at the critical density ρ_c. Since at the critical point $(\partial P/\partial P)_T$ equals zero, the isothermal compressibility becomes infinite at this point. The adiabatic compressibility, however, remains finite. Qualitatively, all gases show the same behavior as pictured for argon in the diagram.

The molecular theory can explain the general features of the compressibility in its temperature and density dependence. The pressure of the gas is caused by the impact of the molecules on the wall. If the volume is decreased at constant temperature, the average molecular speed and force of impact remain constant, but the number of collisions per unit area increases and thus the pressure rises. If the gas is compressed adiabatically, the heat of compression cannot flow off, thus the average molecular speed and force of impact increase as well, giving rise to an extra increase of pressure. Therefore $\beta_S < \beta_T$. The actual magnitude of the temperature rise depends on the internal state of the molecules: the more internal degrees of freedom available, the more energy can be taken up inside the molecule and the smaller the temperature rise on adiabatic compression. Thus for gases consisting of molecules with many internal degrees of freedom, adiabatic and isothermal compressibilities differ but little.

If the gas is assumed to consist of molecules of negligible size and without interaction, then the gas can be shown to follow the laws of Boyle and Gay-Lussac; therefore its isothermal and adiabatic compressibilities must be given by Equation (4). For a perfect gas, the percentage pressure rise is proportional to the percentage volume decrease if the change is small; thus the compressibility is inversely proportional to the pressure.

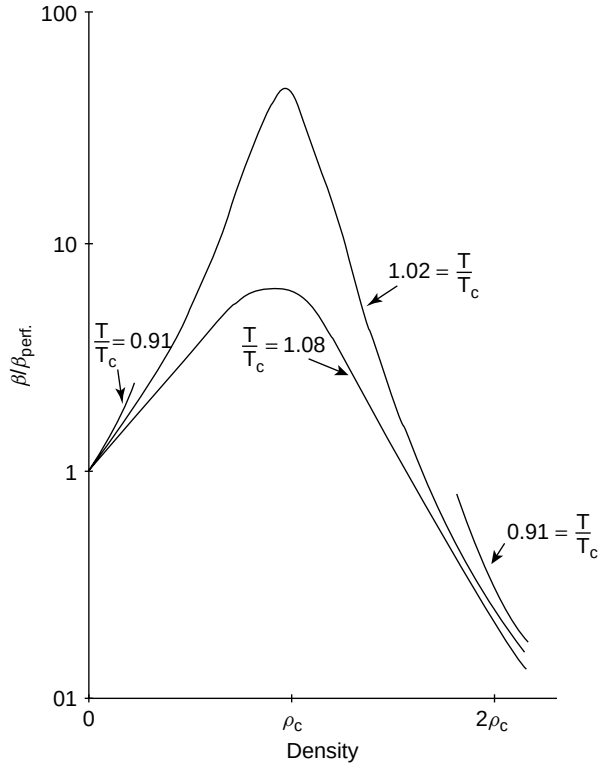


Fig. 1. The ratio $\beta/\beta_{\text{perf}}$ of the isothermal compressibility of argon to that of a perfect gas at the same density, as a function of the density, at 0.91, 1.02 and 1.08 times the critical temperature. The critical density is indicated by ρ_c.

To explain the very different behavior of real gases, the model must be modified. Suppose the molecular volume is small but not negligible. In states of high compression, where the total molecular volume becomes of the order of the volume available to the gas, the free space available to the molecules is only a fraction of what it would be in a perfect gas, and thus the real gas is much harder to compress than the perfect gas. This explains the low compressibility of dense gases and liquids (diagram).

Furthermore, one assumes that molecules, on approaching each other, experience a mutual attraction before they collide; this mutual attraction makes it easier to compress a real gas than a perfect gas. This explains the initial rise of the compressibility of a real gas over that of a perfect gas at temperatures not too far above the critical.

When compressed at subcritical temperatures, the gas condenses; that is, macroscopic clusters or droplets are formed under the influence of the attractive forces. During condensation, the pressure remains constant while the volume decreases, giving rise to an infinite compressibility in the two-phase region. At the critical point the system is on the verge of condensation and the compressibility is also infinite.

Theoretical predictions for the isothermal compressibility can obviously be obtained from any theory of the equation of state. If, in addition, data for the specific heat are supplied, the adiabatic compressibility can be derived in the same way. Thus the compressibility can be derived from the virtual expansion of the equation of state which expresses the ratio *PV/RT* in a power series in the density, the coefficients being related to the interactions of groups of two, three, etc., particles.

In the dense system the convergence of the virtual expansion is doubtful. In any case the higher coefficients are hard to calculate; here approximate theories have been developed, of which the cell model is an example.

Many semiempirical equations of state with varying degree of theoretical foundations are in use. The Van der Waals equation, a two-parameter equation that gives a qualitatively correct picture of the *P-V-T* relations of a gas and of the gas-liquid transition, is an example.

Modern developments are centered around the calculations of the radial distribution function $g(r)$, which is the ratio of the density of molecules at a distance r from a given molecule, to the average density in the gas. The compressibility can be expressed straightforwardly in terms of $g(r)$ as follows.

$$KT\beta_T = 1/P + \int_0^\infty [g(r) - 1]4\pi r^2 dr \tag{5}$$

Approximate evaluations of the radial distribution function in dense systems are being obtained as solutions to integral equations derived from first principles under well-defined approximations.

COMPRESSION (Signal). 1. In *data transmission*, a process in which the effective gain applied to a signal is varied as a function of the signal magnitude, the effective gain being greater for small than for large signals.

2. In *amplitude modulation* systems of radio communication, the amount of intelligence volume which can be modulated upon the carrier is limited to an amount which will give 100% modulation. Since the percentage of modulation depends directly upon the volume of the sound, it follows that, in order not to exceed the allowable modulation on very loud sounds, the percentage on most sounds will be rather low. Since the maximum use is made of the power and a higher signal-to-noise ratio is obtained for high degrees of modulation, it is very desirable to keep the level of modulation as high as possible. To do this the volume range of the original sound is compressed into a much smaller range. Thus, while a symphony orchestra may have a volume range of 100–110 dB, the range is compressed to about 40 dB for broadcast purposes.

3. In *television*, the reduction in gain at one level of a picture signal with respect to the gain at another level of the same signal. The gain referred to here is for a signal amplitude small in comparison with the total peak-to-peak picture signal involved.

COMPRESSION (Structural). In structural engineering, compression is used to denote the type of stress that causes the fibers of a member to shorten. A compression member of a structure is subjected to a primary compressive stress. The analysis or design is the same as that for a column. See also **Column (Structural)**.

When the member consists of two or more separate elements, known as ribs, the parts are connected to produce unity of action, prevent buckling of the individual elements, and also to prevent excessive distortion during fabrication, shipping, or erection. Tie plates and lacing are used for this purpose. The tie plates, also called stay plates or batten plates, which are rectangular in shape, are placed at the ends of the member and at intermediate points where the lacing is interrupted. The lacing bars, also known as lattice bars, are plates, angles, or channels placed at an angle to the longitudinal axis of the member. Lacing may be single or double as shown in Fig. 1. of a compression member made up of two channels, which are rolled steel sections. Single lacing should make an angle of not less than 60° with the longitudinal axis of the member. The angle for double lacing should be not less than 45°. The purpose of these minimum angles is to reduce the buckling tendency of the individual segments.

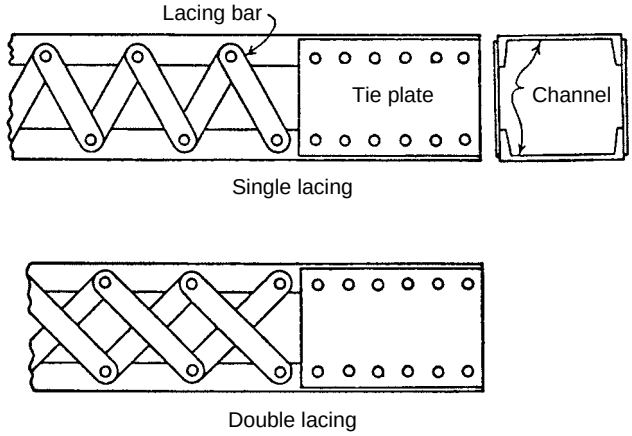

Fig. 1. Types of compression members: (**a**) single lacing, (**b**) double lacing.

COMPTON, ARTHUR HOLLY (1892–1962). Compton was an American physicist. When he was a young boy he was interested in paleontology and astronomy. His thesis began his interest in X rays. He earned his doctorate at Princeton University and then began teaching physics at

the University of Minnesota. After a year, he went to work for Westinghouse Electric and Manufacturing as an engineer but continued studies on X rays.

After WWI, Compton spent one year at the Cavendish Laboratory, then became a physics professor for Washington University in Missouri.

Compton found evidence of the existence of the photon. He is known for the Compton effect that provided evidence for the quantum model of light and for the validity of Einstein's theory of relativity. The Compton effect was a turning point in physics.

In 1923, Compton went to the University of Chicago to teach and do research. There he continued discoveries on X-ray scattering. He published spectroscopic measurements of X-rays scattered at various angles by light elements. Compton scattering is named after him. For his research, he was awarded in 1927 the Nobel Prize in Physics jointly with C.T.R. Wilson.

Compton became interested in cosmic-ray intensities in the 1930s. He went all over the world measuring cosmic-rays and showed that the rays were most intense at the poles and were the weakest at the equator.

Compton worked on the Manhattan Project helping with the development of the atomic bomb.

He also directed the construction of the first nuclear reactor at the University of Chicago.

See also **Compton Effect**; and **Scattering**.

J. M. I.

COMPTON EFFECT. This refers to the collision of a photon and a free electron in which the electron recoils and a photon of longer wavelength is emitted as indicated in Fig. 1. It is one of the most important processes by which x-rays and gamma rays interact with matter and is also one which is accurately calculable theoretically.

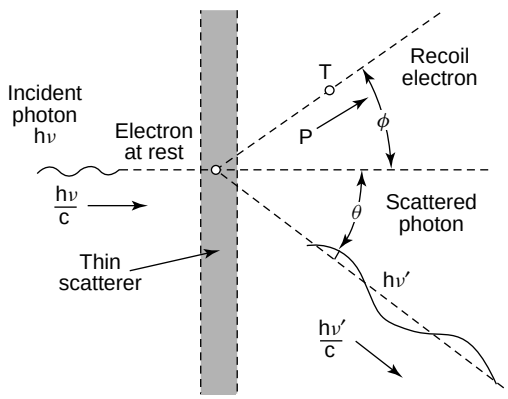

Fig. 1. Diagram showing the initial and final energies and moments for Compton scattering.

Barkla and others (1908) made many observations on the scattering of x-rays by different materials. The diffuse scattering was interpreted qualitatively by J.J. Thomson in terms of the interaction of electromagnetic waves with electrons which he had shown to be a constituent of all atoms. As more experiments were carried out with light elements, it was established by J.A. Gray (1920) that the diffusely scattered x-rays were less penetrating. This implied that the scattered radiation had a longer wavelength than the incident radiation. This could not be reconciled with Thomson's theory, which represented x-rays as continuous electromagnetic waves with wavelengths unchanged by scattering.

The effect that now bears his name was established quantitatively by Arthur Holly Compton (1923) when he published careful spectroscopic measurements of x-rays scattered at various angles by light elements. He found that x-rays scattered at larger angles had systematically larger wavelengths. In searching for an explanation of the data, he discovered that the observations were accounted for by considering the scattering as a collision between a single photon and a single electron in which energy and momentum are conserved.

The important place the effect occupies in the development of physics lies in the interpretation of the effect in terms of quantum theory. The essential duality of waves and particles was demonstrated in an especially clear way, since the collision conserved energy and momentum while both the incident and scattered x-rays revealed wave-like properties by their scattering from a crystal. In recognition for this contribution, Compton was awarded the Nobel Prize in 1927.

A complete theory for the effect was worked out in 1928 by Klein and Nishina using Dirac's relativistic theory of the electron. The calculation was one of the brilliant successes of the Dirac theory. It represents quantitatively, within the experimental uncertainties, all phenomena associated with the scattering of photons by electrons for energies up to several billion electron volts. Because of the confidence with which photon interaction with electrons can be interpreted, the Compton effect has been important in the analysis of the energy and the polarization of gamma rays from many sources.

Proton and Deuteron Compton Effect. Particle-like scattering of high-energy photons by protons and deuterons has been observed and has been referred to as the proton and deuteron Compton effect. The kinematic equations are identical to those for electrons except that the mass is that of the proton or deuteron.

Although the cross sections are smaller than that for electrons, by the square of the ratio of the masses, the scattering is easily distinguished by the characteristically higher energy of the radiation at large angles. At energies above the pion threshold, the cross section is dominated by pion nucleon resonances.

COMPTON GAMMA-RAY OBSERVATORY (CGRO). Though people have developed many new ways of looking at the stars and have made numerous discoveries, some aspects of the Universe remain mysterious and unexplored. One such aspect is the Universe as defined by gamma-ray emissions.

Gamma rays, which are at the highest end of the electromagnetic spectrum, are intriguing because scientists believe they may be a reliable record of cosmic change and evolution. The exploration of these gamma rays offers answers to perplexing questions about the explosive and dynamic physical process that make the Universe work the way it does. Exploration also answers such important questions as to the structure and dynamics of the Milky Way and other galaxies, the nature of pulsars, quasars, black holes and neutron stars, and the origin and history of the Universe itself.

On April 5, 1991, the Space Shuttle Atlantis (OV-104) placed the Arthur Holly Compton Gamma-Ray Observatory into a low-Earth circular orbit (altitude 270 miles, or 450 kilometers) at an inclination of 28.5 degrees from the equator. See Fig. 1. The purpose of the mission is to obtain gamma-ray measurements over the entire celestial sphere, with significantly improved angular resolution and sensitivity over previous gamma-ray space missions. The Compton Observatory has four highly sophisticated instruments capable of making simultaneous observations spanning more than five decades of energy. Data and information obtained from the observatory are providing great new insights into the young and growing science of gamma-ray astronomy.

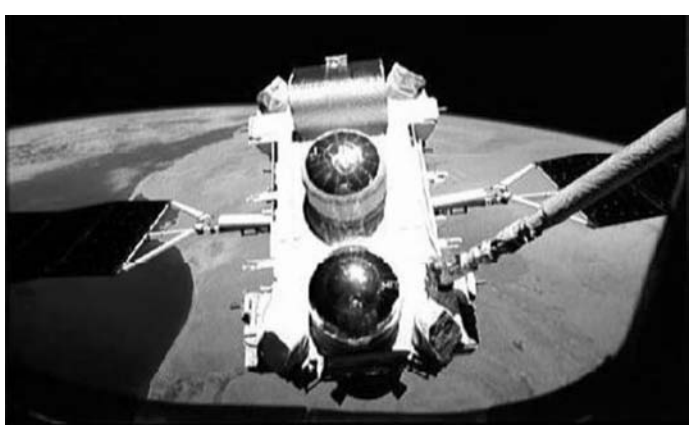

Fig. 1. Deployment of CGRO from Space Shuttle *Atlantis*. (*NASA/GSFC*.)

Previous gamma-ray missions consisted of small spacecraft equipped with specialized instruments, such as NASA's second Small Astronomy Satellite (SAS-2), the European Celestial Observation Satellite (COS-B),

NASA's High Energy Astronomy Observatories (HEAOs 1 and 3) and the Solar Maximum Mission. See Figures 2–6. Information from these missions confirmed the potential for further exploration of the gamma-ray Universe, using large sophisticated instruments covering a broad range in the high-energy spectrum.

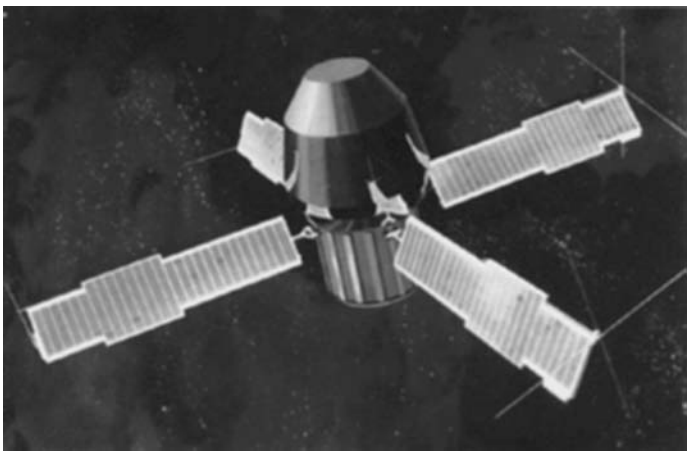

Fig. 2. Artist's conception of SAS-2 in flight. (*NASA/GSFC.*)

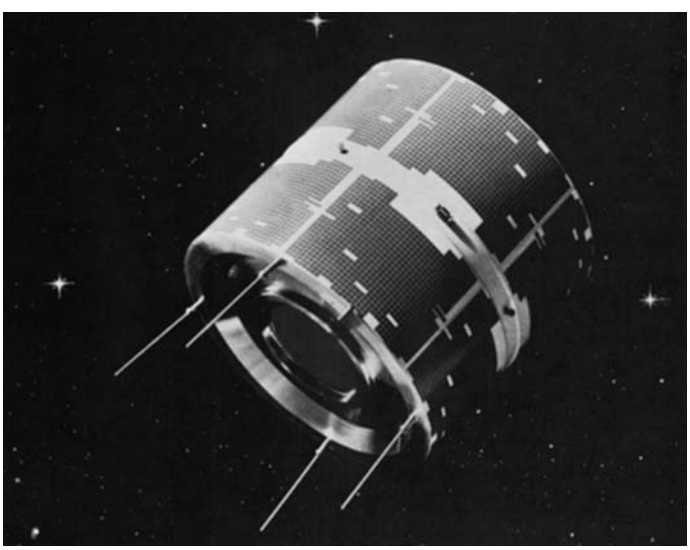

Fig. 3. The COS-B satellite. (*NASA/GSFC.*)

What Are Gamma Rays?

Gamma rays are the highest energy radiations in the electromagnetic spectrum, ranging from tens of thousands to tens of billions of electron volts (eV). An eV is a measure of the amount of energy imparted to an electron when subjected to an electrical potential of one volt. By contrast, visible light corresponds to only a few electron volts. These gamma rays provide a way to study some of the primary forces of change in the astrophysical processes. Gamma rays are thought to have originated with the "Big Bang" and subsequent expansion of the Universe, and the many energetic phenomena witnessed today. Through these gamma-ray observations one may witness the birth of elements and deaths of stars, gain clues into the mysteries of quasars, pulsars, neutron stars and peer into the space/time precipice of a black hole. In all these cases, large amounts of energy are released, and gamma rays are produced. A classical example of this process is the excitation of the nucleus of an atom (which consists of protons and neutrons), causing it to move into a higher energy state. As the nucleus drops back to its original state, one or more gamma rays are emitted. These gamma rays will have the precise amount of energy as the difference between the nucleus' low-energy state and its high-energy, or excited state. Gamma rays, the radiation that reveals the most energetic

Fig. 4. Artist's impression of HEAO-1. (*NASA/GSFC.*)

phenomena in the Universe, are particularly interesting because they are the only source of information for some events. These gamma rays from cosmic sources are able to travel across galaxies and most of the Universe without being absorbed, but cannot penetrate the Earth's atmosphere except at extremely high energies. The information they hold is not available to observatories on the ground and must be observed from space.

Compton Science Objectives

Weighing more than 17 tons, the Compton Observatory was the heaviest civilian spacecraft ever deployed from the shuttle. The spacecraft dimensions are 25.4 feet × 18.2 feet × 15.2 feet (7.7 meters × 5.5 meters × 4.6 meters). The solar array span is 69.3 feet (21 meters) between the tips of its solar arrays. See Fig. 7. These solar arrays provide the 1,800 watts of electrical power required for operation of the observatory. CGRO 's orbit is 316 miles (510 kilometers) with an inclination of 28.5 degrees. The spacecraft was built by TRW in Redondo Beach, California. The spacecraft has already exceeded its minimum life of two years, but is expected to operate for at least six years. Compton was safely de-orbited and re-entered the Earth's atmosphere on June 4, 2000 after nine years in service. During the first 15 months of operation, a detailed survey of the gamma-ray Universe has been obtained. The instruments also are viewing, in much greater depth, intriguing objects identified by the survey. This much longer observing time dedicated to a particular source or region is providing a much more detailed characterization of its properties and the processes responsible for its gamma-ray production.

Compton Operations and Instruments

NASA's Goddard Space Flight Center, Greenbelt, Md., manages the Compton mission and Science Operations and provides ground system and various supporting elements and personnel for giving commands, receiving data, tracking the spacecraft, scheduling, and maintaining its health and safety.

Data is collected 24 hours a day. Because the signals from gamma-ray emitting objects are very weak, the observatory is pointing at the science targets and collecting data for periods of up to 14 days.

Altitude adjust maneuvers are performed to focus the instruments on the next target, and data collection begins again. The observatory contains four science instruments: BATSE, OSSE, COMPTEL, and EGRET, which

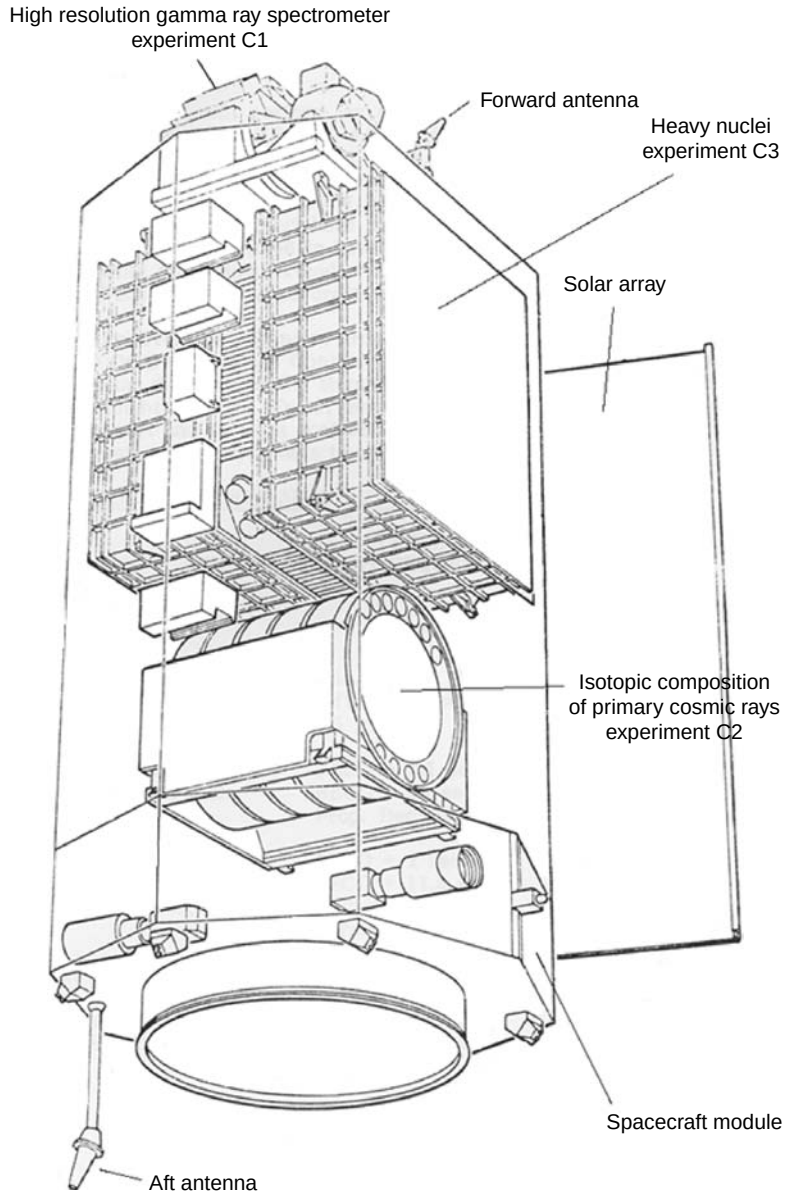

Fig. 5. Diagram of the HEAO-3 satellite. (NASA/GSFC.)

make measurements spanning the broadest range of energies ever achieved from space. See Figures 8 and 9.

Burst And Transient Source Experiment (BATSE). BATSE was developed by scientists at Marshall Space Flight Center in Huntsville, Ala., to continuously monitor a large segment of the sky for detection and measurement of short, intense bursts and other transient sources of gamma rays. This instrument also notifies, in near real-time, the other three instruments onboard of such bursts. BATSE allows the monitoring of pulsed emission from strong pulsars to time variations in these sources to a fraction of a millisecond, permitting detailed analysis of production mechanisms.

Oriented Scintillation Spectrometer Experiment (OSSE). The Naval Research Laboratory in Washington, DC, designed OSSE to detect nuclear-line radiation and emissions associated with low-energy gamma-ray sources anywhere in the sky. This information is contributing to the understanding of many types of science targets such as novae, supernovae, neutron stars, black holes, pulsars, quasars, and X-ray sources.

Imaging Compton Telescope (COMPTEL). This telescope, developed as a joint venture of Germany, the Netherlands, the European Space Agency, and the United States, has the imaging capability, broad effective aperture, and low-background that are needed to study gamma-ray characteristics of point sources, diffuse emission from the galaxy, cosmic diffuse flux, and broadened line emissions. It determines the direction of arrival, as well as the energy of, gamma-ray photons from one to 30-million electron volts.

Energetic Gamma Ray Experiment Telescope (EGRET). This instrument is the result of collaboration by scientists at GSFC, Stanford University, Grumman Aerospace and Germany. EGRET is designed to measure the higher energy gamma rays, up to 30 billion electron volts. It can measure the direction of a point source to a fraction of a degree and determine the spectrum of gamma-ray emissions. Emissions from other galaxies are being examined to study their structure and dynamics and the distribution of cosmic rays within them.

Scientific Objectives of Compton

Gamma-Ray Bursts. In 1979, a gamma-ray burst was observed near the Large Magellanic Cloud, our nearest galactic neighbor. In just 1/10 second, it unleashed more gamma-ray energy than the sun can pump out in every form over the next 1,000 years. Compton is looking at such bursts in an attempt to understand the origin of these mysterious phenomena, and is examining other kinds of transient emissions.

Supernovae. Explosions of stars are known to be sites of element formation, or nucleosynthesis. Compton is observing gamma-ray emission lines for details of this process in supernovae, and is gathering data to test current theory that cosmic rays are created in supernovae and are accelerated by shock waves.

Fig. 6. Artist's concept of Solar Maximum Mission. (NASA/GSFC.)

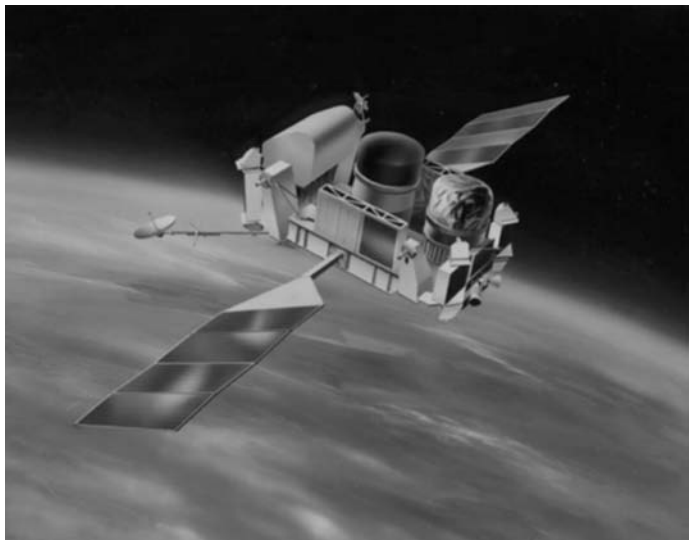

Fig. 7. Compton Gamma-Ray Observatory (CGRO). (*NASA/GSFC.*)

Galactic Structure And Dynamics. Compton is providing new insights into the evolution of galaxies over their entire dynamic range, from the first fluctuations in the Universe billions of years ago through the more recent emergence of active galactic nuclei. Compton is aiding in the study of galactic structure, dynamic balance between the binding forces of cosmic ray gas, kinetic motion of interstellar medium, and galactic magnetic fields.

Pulsars are thought to be remnants of supernova explosions. Since the first pulsar was discovered in 1968, more than 500 of these rapidly spinning neutron stars have been located. A pulsar appears to be able to produce more energy over its lifetime than the explosion, which created it, and Compton is shedding new light on the perplexities of this phenomena.

Quasars. In addition, Compton is focusing on gamma-ray luminosities thousands of times greater than those in the Milky Way. It is exploring unusually active systems such as intense radio galaxies and Seyfert galaxies or BL Lacertae objects and quasars, all of which emit far more energy than a normal galaxy and, for an unknown reason, vary in brightness. Quasars are curious objects characterized by a very high output of energy mostly coming from the centers of the galaxies. The instruments on Compton, with a sensitivity 10 times greater than earlier instruments, are scanning the heavens for new information on active galaxies.

Black Holes. The observatory can monitor the very high temperature emissions from the vicinity of stellar black holes. Compton's search for small primordial black holes are helping resolve questions relating to the large-scale distribution of matter, which is one of the keys to testing theories of an expanding Universe beginning with a colossal explosion, or "Big Bang."

Compton's Scientific Highlights

Examples of discoveries by Compton include:

- The discovery that gamma-ray bursts are "isotropic" or evenly distributed across the sky. This suggests that these powerful flashes of radiation are coming from the far reaches of space rather than from our own Milky Way galaxy, as many had believed.
- The discovery of the highest energy gamma-rays ever seen in a burst. Observed on Jan. 31, 1993, it was dubbed the "Super Bowl Burst" because it was viewed on Super Bowl Sunday.
- The discovery of a whole new class of high-energy gamma-rays sources in Active Galactic Nuclei (AGN), which are the bright and active central

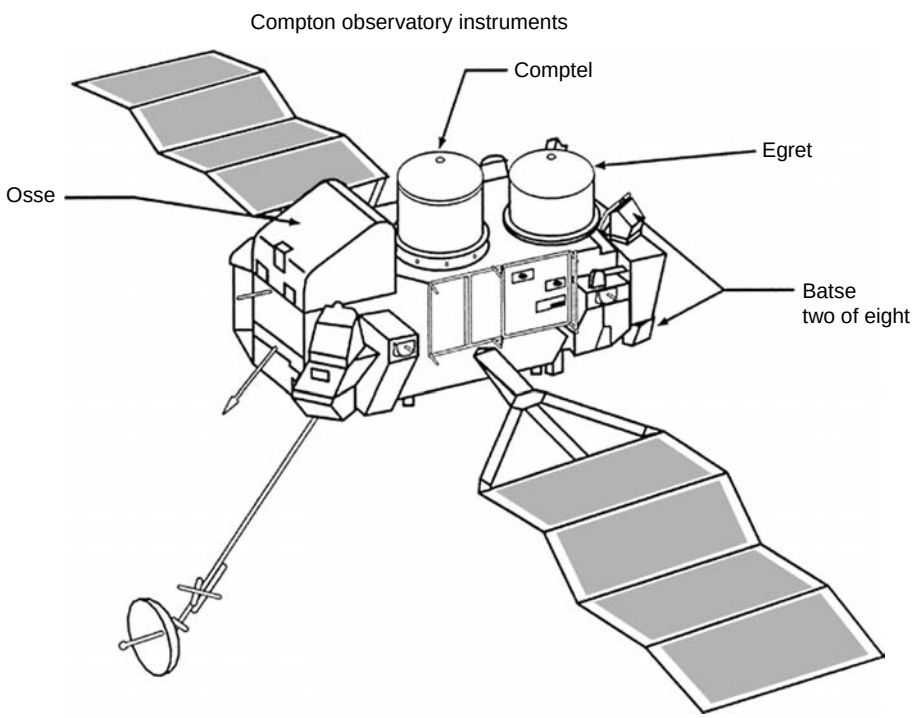

Fig. 8. CGRO instrument locations. (*NASA/GSFC.*)

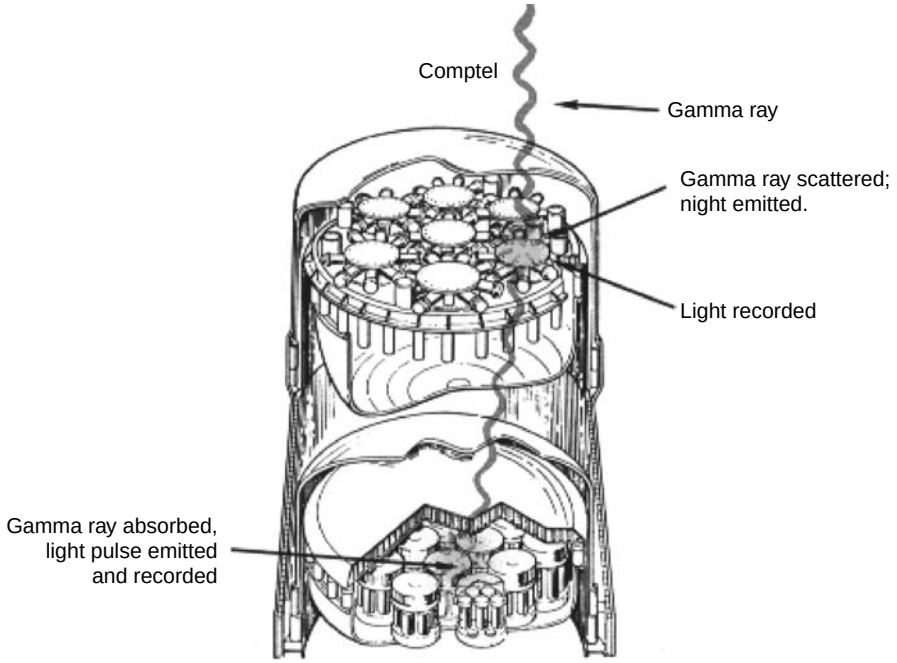

Fig. 9. COMPTEL schematic. (*NASA/GSFC.*)

cores of some galaxies. Called gamma-ray quasars, these sources are widely thought to be emissions from black holes at the centers of these galaxies as they swallow stars in their vicinity.

Instrument by Instrument:

Burst And Transient Source Experiment (BATSE)

- Found that gamma-ray bursts are isotropic, evenly distributed across the entire sky, lending credibility to the theory that the bursts are from beyond our galaxy.
- Discovered terrestrial gamma rays produced during thunderstorms, an unexpected result.
- Found 20 new transient sources not seen before by any other telescope in any wavelength; also found two new Soft Gamma-Ray Repeaters.

Oriented Scintillation Spectrometer Experiment (OSSE)

- Discovered that the gamma rays from Seyfert galaxies (a certain type of galaxy with a supermassive black hole) are thermal, that is, they are produced by pure heat (hotter than X- rays) near a black hole.
- Found that the galactic center glows in radiation from antimatter; OSSE subsequently mapped sites of antimatter in the galaxy.

Imaging Compton Telescope (COMPTEL)

- Discovered a hidden supernova remnant (the remains of a star that exploded) in the direction of the Vela/Puppis A remnants by tracing the decay of isotopes of aluminum (Al-26) and titanium (Ti-44).
- Mapped the distribution of aluminum-26 produced by supernovae; with a half-life of about 700,000 years, Al-26 provides a roadmap of nuclear synthesis (the creation of heavier metals from lighter ones) across the universe; Al-26 is also a good tracer for older supernova remnants that have since faded in optical and X-ray radiation.
- Provided enough data to demonstrate that the theory of the cause of diffuse glow of gamma rays at the energy level of 5 million electron-volts (MeV) was incorrect.

Energetic Gamma Ray Experiment Telescope (EGRET)

- Discovered gamma-ray quasars, called blazars, in which the dominant radiation is in gamma rays.
- Discovered 170 yet-unidentified sources in its catalog of 271 sources; they likely comprise exotic, new classes of objects within our own galaxy.

In conclusion Compton's lasting legacy will be its impact on gamma-ray astronomy. The telescope detected more than 400 gamma-ray sources, 10 times more than were previously known. Compton recorded over 2500 gamma-ray bursts; before Compton, only about 300 had been detected, and only one third of those had known positions. Thousands of scientific papers have been published based on Compton observations so far. On average, a Compton-specific publication appears in the scientific literature every other day.

Summary

The Compton Gamma Ray Observatory safely re-entered the Earth's atmosphere at approximately 2:10 a.m. EDT on June 4, according to calculations made by controllers at NASA's Goddard Space Flight Center, Greenbelt, Md., in coordination with the U.S. Space Command's Control Center.

As planned, pieces of the observatory that survived the re-entry landed in the Pacific Ocean approximately 2,400 miles (3,862 km) southeast of Hawaii.

The fourth and final burn needed to re-enter NASA's Compton Gamma Ray Observatory was initiated at 1:22 a.m. EDT on June 4. Compton's Attitude Control thrusters and Orbit Adjust thrusters were fired for 30 minutes. See Fig. 10.

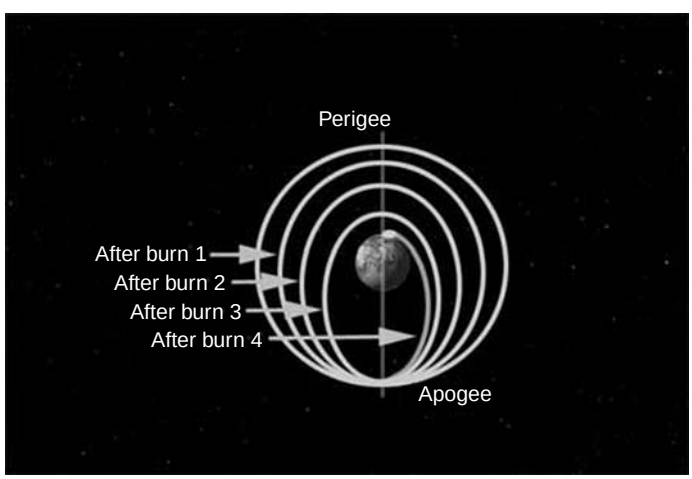

Fig. 10. This image shows the burn sequences necessary to bring CGRO to the targeted range in the South Pacific. (*NASA/GSFC.*)

After the failure of one of Compton's three gyroscopes, NASA decided to bring the satellite back via a controlled reentry. NASA determined that it

was much safer to bring the satellite back now to safe guard against further system failures in the spacecraft that might hinder a controlled re-entry.

"This was a bittersweet day for NASA," said Al Diaz, Director of the Goddard Space Flight Center. "The end of the Compton Gamma Ray Observatory mission marks the end of a remarkable spacecraft. Compton left a legacy of outstanding science and revolutionized our knowledge of the gamma ray sky. And while no one at NASA is ever happy to see the end of a science mission, prolonging this mission would have posed an unacceptable and increasing risk to human life. This was an extraordinarily complex task, involving both operations and engineering proficiency. I'm proud of this team and the job they did. They understood the significance of this task, and they performed it flawlessly."

Compton spent nine productive years in orbit. Engineers began planning for the Observatory's re-entry in April 1999 when gyroscope #3 first began experiencing problems. By the time the gyro actually failed in December 1999, engineers had devised a number of deorbit scenarios. Engineers at Goddard, assisted by their counterparts at the Johnson Space Center in Houston, spent the past five months designing a re-entry plan to safely deorbit the CGRO spacecraft.

A total of four burns were used to gradually lower the spacecraft's orbit. The first re-entry burn was conducted on May 30, and a second burn on May 31. At midnight on June 4, controllers fired CGRO's primary thrusters for a third time bringing spacecraft's low point to within 92miles (148 km) of the Earth's surface. NASA and international space agencies plan several upcoming missions to continue where Compton left off. The Gamma-ray Large Area Space Telescope (GLAST) is a proposed new high-energy gamma-ray mission to identify and study nature's highest energy particle accelerators. GLAST will be 30 times more sensitive than the Energetic Gamma Ray Experiment Telescope (EGRET) onboard the Compton Gamma Ray Observatory. Swift will be the first mission to focus on studying the newly-discovered afterglow from gamma ray bursts. Swift's rapid repointing capability will enable high-precision X-ray and optical positions to be determined and relayed to the ground for use by a network of dedicated observers at large telescopes.

The Compton Gamma Ray Observatory was the second of NASA's Great Observatories and the gamma-ray equivalent to the Hubble Space Telescope and the Chandra X-Ray Observatory.

Several missions hope to continue where Compton left off. NASA's High-Energy Transient Explorer (HETE-2). Successfully launched on 9 October 2000 at 1:38 a.m. EDT. HETE-2 will search for gamma-ray bursts and other explosive cosmic phenomena. ESA's International Gamma-Ray Astrophysics Laboratory (INTEGRAL), scheduled for launch in late 2001, will concentrate on the higher-energy X-ray and lower-energy gamma-ray band. The NASA Swift mission, scheduled for 2003, will complement HETE-2 with higher-resolution and faster response times.

Planned for 2006 is the Gamma-Ray Large Area Space Telescope (GLAST), which will serve as NASA's successor to Compton.

COMPTON RULE. An empirical relationship between thermal properties of elements, of the form

$$\frac{(\text{At. Wt.})(L_f)}{T_f} = 2$$

in which At. Wt. is the atomic weight, L_f is the heat of fusion, and T_f is the fusing point (in degrees absolute).

COMPUTATIONAL CHEMISTRY. Use of computers in organic synthesis and in chemical engineering as a more efficient means of research than conventional laboratory experimentation. The capacity of sophisticated computers for fast mathematical calculations has made then an invaluable aid in exploring and evaluating the more likely pathways for a given organic synthesis, for which there may be innumerable possible sequences. The term *heuristic* is applied to such procedures. Computers can also handle the vast complexity of quantum-mechanical calculations and aid in the elucidation of the complicated molecular structures that occur in pharmaceutical compounds and recombinant-DNA research. The Quantum Chemistry Program Exchange at Indiana University offers many programs in this field, from subroutines to major computational systems. Chemical engineers utilize computers to develop more thermodynamically efficient procedures and to consolidate overall plant operations, especially in the areas of energy consumption, reaction rates, and hazardous waste problems.

Note: Notwithstanding the immense capability of computers to point the way to solutions of chemical and engineering problems, experimentation will remain the ultimate proof of theory. It is interesting to speculate how much time and effort such empirical scientists as Goodyear and Edison could have saved had computers been available to them.

COMPUTED TOMOGRAPHY (CT). The development of computed tomography (CT) during the 1970s heralded the start of sophisticated cross-sectional imaging. Such cross-sectional images have, in turn, revolutionized the diagnostic investigation for many clinical conditions and have helped to bring radiology to the forefront as a major clinical specialty.

Development

The main pioneer of the development of CT was Sir Godfrey Hounsfield [1973]. Working for EMI in the UK, he saw that by applying computer analysis to data acquired by numerous acquisitions at different angles it was possible to create an axial image of the human torso. His initial experiments were conducted on animal models, then on the human brain (with Dr Ambrose at Atkinson Morley's Hospital, UK) and body (with Dr Kreel at Northwick Park Hospital, UK). The physics and mathematics for such a system had been proposed by Cormack some years earlier, and the whole development had been made possible by advances in computing and increased understanding of the mathematics of line integrals and Fourier analysis (many of which had been needed for X-ray crystallography, etc.). For their contributions, Hounsfield and Cormack were properly honored with the award of a Nobel Prize for Medicine. In no time, various manufacturers were producing CT machines in large numbers, with a wide range of different features.

The basic principles used in modern machines (Fig. 1) are now fairly similar amongst all the manufacturers. A fan beam of collimated X-rays emerging from an X-ray tube interacts with the tissues within the patient and reaches an array of detectors (Fig. 2). These three parts of the data acquisition will be considered in some detail. Then the complex data analysis will be discussed.

The Tube

The tube necessary for modern CT systems has evolved considerably over the past few years. Perhaps the most important aspects concern the heat capacity, dissemination of heat away from the focal spot, and overall tube cooling. When CT was first introduced, a relatively standard X-ray tube was quite satisfactory, given the slow data-acquisition pertaining at that

Fig. 1. A modern spiral computed tomography system. Note the aperture within the gantry, through which the patient moves as the examination progresses.

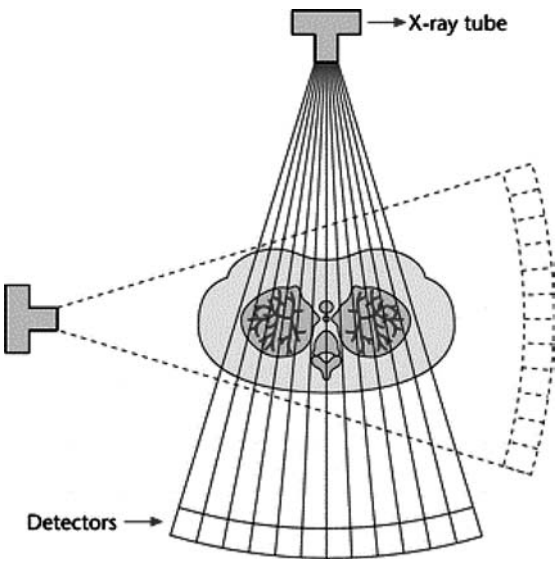

Fig. 2. Schematic diagram showing the tube traveling around the patient. The X-ray photons from the anode pass to the detectors, which convert the incident photons to an electrical signal.

time. With more modern techniques and spiral (helical) acquisitions, tube heating capacity has become a critical issue. Near-continuous exposure for 45 s is not uncommon during a long spiral acquisition (see below). Faster throughput of patients also means that there is less time available for tube cooling. There is also current keen interest in modulating tube current in proportion to body habitus, etc., in order to keep the dose as low as reasonably achievable. All these developments have made the CT tube a sophisticated and expensive item. Many CT units require a new CT tube about once a year–with about 36 h downtime during fault analysis, removal, installation and retuning of the system following tube replacement.

Interaction with Tissues

The interaction of the X-rays (approximately 120 kV) with the tissues in CT is quite similar to that in conventional radiography. By photoelectric and Compton effects, the beam is attenuated as it passes through the tissues, before passing through to the detectors. The main difference is that the tube generating the fan entry beam rotates around the torso of the patient with quite a short focus–object distance. Thus, the surface dose can be quite high. In order to obtain sufficient data with which to construct an image, a substantial dose of X-rays has to be used. For this reason the equivalent doses for many CT procedures are amongst the highest of any radiological examination; the UK National Radiological Protection Board and other bodies suggest that the effective dose for an abdominal CT can range up to about 10 mSv (equivalent to about 500 chest radiographs or around 4 years of natural background radiation).

One problem caused by the assumption of a constant kV for exposure throughout the tube rotation is that if there is a very dense object within the aperture, the "softer" (lowest kV) photons will be preferentially absorbed, leaving transmission of the "harder" (higher kV) photons. Such beam hardening leads, for example, to characteristic artifacts across the posterior fossa in cranial CT and internal to the ribs on hepatic CT. Artifacts can also arise from the humerus if the patient cannot raise his or her arms above the head. Metallic prostheses (e.g., hip replacement) pose yet another problem.

The Detectors

The detectors capture the transmitted photons. Various methods are used by different manufacturers; some have used ionization chambers, others have concentrated their efforts on scintillation crystals. Because of the need to creite an excellent image from the minimum number of photons in the minimum possible time, there is considerable commercial interest in maximum photon capture, minimum detector crosstalk and minimum "afterglow." There is also considerable current research into maximizing the area of detectors and minimizing the gap between individual detectors. Indeed, several manufacturers have introduced systems with multiple banks of detectors which allow multiple slice acquisition, thereby further reducing data acquisition times. These are known as *multidetector CT systems* which provide much better z axis resolution and improved 3D images.

Image Reconstruction

The data from the detectors are stored on a computer and converted into a line integral with Fourier analysis. The computing power now available allows image reconstruction to start after the first few projections. Thus, when the tube has finished a 1-s rotation, that image is virtually ready for analysis. In the early days of CT, various computing techniques were used which were rather slow– especially given the speed of computers in those days. Now the favored method is filtered back projection, whereby the image is reconstructed line by line in a radiating fashion. This means that a reasonable image can even be obtained from the data provided after only 180–270° rotation (with speed advantages for some cardiothoracic applications). By modulating the individual projections measured by the detectors it is possible to smooth or sharpen the interfaces on the final image. Research into these various reconstruction algorithms is keen and the results are of importance for optimal spatial resolution of bone, lung, etc.

The way in which the image is finally generated is best regarded by considering the cross-section of the torso as a giant matrix of (say) 512 × 512 picture elements (pixels). Each pixel represents a volume element (voxel) within the body. The size of the voxel relates to the slice thickness (z mm) and the size of the matrix and magnification factors within the axial cross-section ($x \times y$ mm). Commonly z ranges from 1 to 10 mm, with x and $y < 1$ mm for modern equipment.

The attenuation within each voxel (and thus of each pixel) is the average attenuation of the various tissues included. It is conveniently assessed on the Hounsfield scale in Hounsfield units (HU) (Fig. 3) in which air is −1000 HU, water is 0 HU and solid cortical bone is +1000 HU or more. The final image (generated by the computer) should be viewed on the monitor at appropriate window levels and widths (Fig. 4). The lungs, with an average attenuation well in negative range, are best viewed at a negative window level (e.g. −750 HU) and a wide window width (1024 HU). Conversely, the soft tissues should be viewed with a positive window level (+20 HU) and a narrower window width (e.g. 400 HU). Bone texture is best assessed at a high positive level (e.g., +150 HU) and a very wide window width (e.g., 1024 HU or more).

Water (0 HU) and air (−1000 HU) are used for calibration purposes. By running standard checks, the technical performance of the CT system can be calibrated on a daily basis. Such calibration forms an important component of quality assurance programs and dosimetry calculations, and also provides a check that the detectors are working satisfactorily.

Spiral (Helical Technology)

The work of Kalendar, et al.: [1990] brought about a major advance in the repertoire of CT (Fig. 5). By combining continuous exposure, made possible by slip ring technology, and continuous table transport, it proved possible to obtain data during a single breath hold (or during

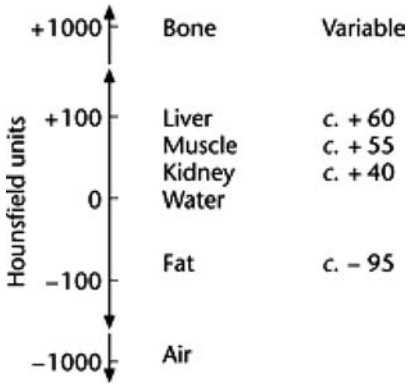

Fig. 3. Diagram showing the Hounsfield scale. The approximate values of some of the common tissues are indicated.

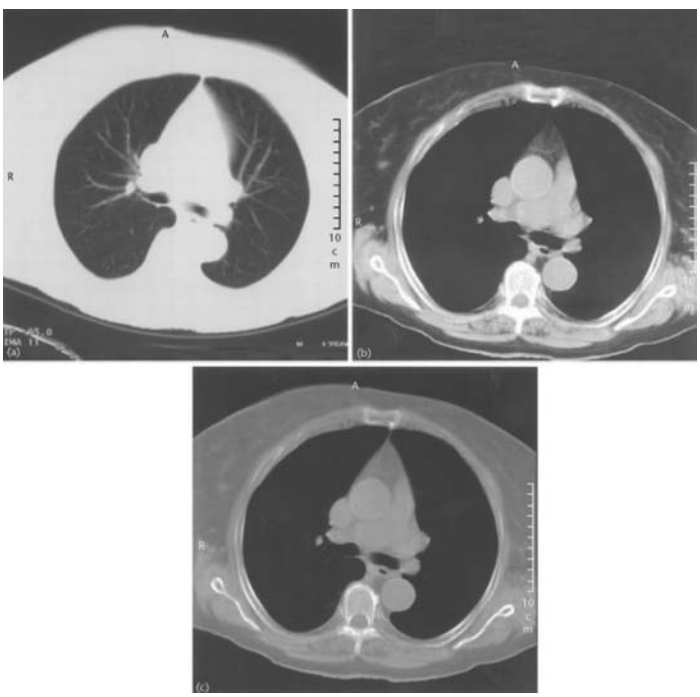

Fig. 4. Images illustrating several displays of the same electronic data obtained through a normal thorax (10-mm thick slice). (a) Viewed at lung windows: window width (WW) 1250 HU; window level (WL) −750 HU. (b) Viewed at soft tissue windows: WW 400 HU; WL +20 HU. (c) Viewed at bone windows: WW 1250 HU; WL +150 HU.

the arterial/venous phase of enhancement following a bolus intravenous injection of contrast medium). This was a significant development; hitherto the tube had to stop and travel back for successive images, with a minimum delay between images of around 5 s. Thus spiral CT meant that a whole chest could be examined during one breathhold; previously the patient had to try to take the same degree of inspiration for successive images, with frequent misregistration problems. Spiral techniques also led to the use of CT for more sophisticated vascular (e.g., pulmonary embolus) (Fig. 6) and three-dimensional applications (e.g., CT colography).

One of the radiographic principles about spiral CT that has to be understood is that of "pitch." The collimation (slice thickness) used for any individual CT application has to be chosen in advance–let us suppose 10 mm. Let us also assume that the time taken for one tube revolution is 1 s (a common data acquisition time for modern CT systems). An appropriate "pitch" (i.e. the ratio of the distance the table moves during one tube revolution to the collimation) can then be selected:

$$\text{Pitch} = \text{Table movement speed (mm s}^{-1}) \times \text{Tube revolution time(s)/slice thickness (mm)}$$

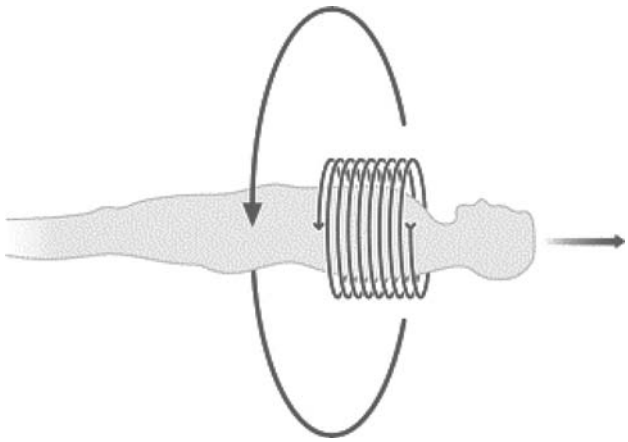

Fig. 5. Schematic diagram of spiral technology. The tube rotates continuously around the patient. The patient moves through the gantry. In this way a helical volume of data is obtained which can then be analyzed in many different ways. After Kalendar, et al.: [1990].

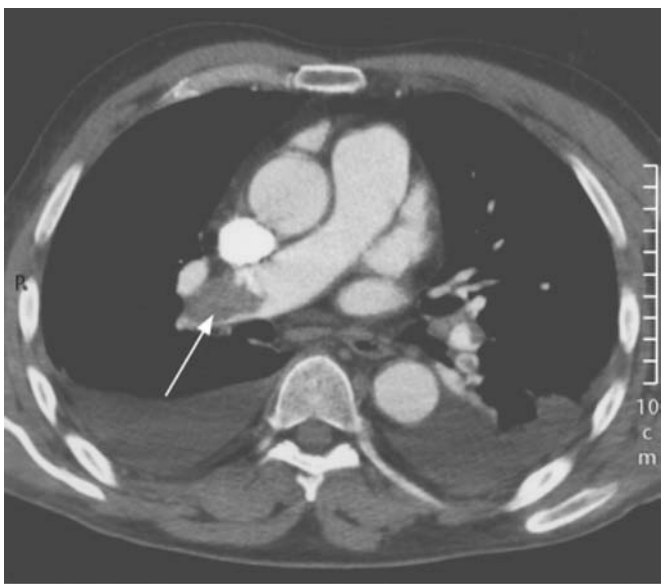

Fig. 6. Patient with a pulmonary embolus. Thrombus in the pulmonary arteries is elegantly shown as a negative filling defect (arrow) surrounded by contrast medium.

A standard approach is to use a pitch of one:

$$\text{Pitch} - 1 - 10\ \text{mm s}^{-1}(\text{table movement speed} \times 1\text{s (tube evolution)/}10\ \text{mm(slice thickness)}$$

In practice, a pitch of 1.5 is often used for radiation and economic reasons. Thus a pancreas might be examined:

$$\text{Pitch} - 1.5 - 7.5\ \text{mm s}^{-1}\text{table movement speed)} \times 1\ \text{s (tube revolution)/5 mm (slice thickness)}$$

A pitch of less than 1 is rarely used. This is because the volume of data can be interrogated at frequent anatomical intervals. As the table movement and data acquisition are continuous, a data set can theoretically be obtained at unlimited intervals (e.g., every 1 mm) and this can improve three-dimensional data sets. A standard abdominal CT examination is often performed at 10 mm intervals and a pitch of 1.5 (15 mm s^{-1} table movement and 1 s tube revolution), but reconstructed at 10-mm intervals. Further reconstruction of the data set to provide images at 5-mm intervals may overcome some interpretation problems caused by the partial volume effect. The concept of pitch becomes much more complex with the recent advent of multidetector systems.

Functional Measurements

CT was rightly hailed as a significant breakthrough because of its extraordinary combination of high spatial and high contrast resolution. The anatomical information provided by narrow collimation slices (e.g. 1 mm) reconstructed with appropriate (e.g., bony) algorithms is quite exquisite. The range of contrast available on a standard CT image is far greater (see Fig. 4) than that available on conventional radiographs. This combination provided anatomical information that hitherto had been available only with invasion of the tissues (surgery, autopsy, etc). Thus the concept grew that CT was merely a technique that reproduced anatomical information.

However, over the past few years, there has been increasing realization of the extent of functional information that CT can provide [Miles, et al.: 1991]. This largely concerns the way in which tissues take up standard iodinated contrast media. Such contrast media had long been needed in CT to demonstrate vascular structures and lesions. For example, the way in which a lesion takes up contrast medium can help the radiologist to distinguish between neoplastic and infective lesions. However, extrapolation of standard physiological principles widely used in nuclear medicine to CT data has led to techniques that allow the determination of perfusion in the various structures using a CT image, thereby producing a perfusion map (Fig. 7a). If a dose of contrast medium is given as a very rapid bolus, it reaches a sharp peak concentration within the aorta. The subsequent rate at which contrast medium arrives in various tissues can then be analyzed and perfusion (in milliliters of blood per second per milliliter of tissue) calculated:

$$\text{Perfusion} - \text{Maximum rate of enhancement of tissue } (\text{HUs}^{-1})/$$

$$\text{Peak aartic value HV}$$

Perfusion can even be measured in organs with complex vascular supply, such as the liver with its initial small arterial contribution followed by the normal larger supply from the portal vein. Thus, hepatic arterial and portal perfusion can be measured independently. Increased arterial perfusion is one indicator of metastatic involvement — even if no macroscopic metastases can be identified. Such analysis provides useful data in patients following hepatic transplantation where the surgeon has a keen interest in both arterial and portal perfusion (Fig. 7b).

Data Display

The principles of the Hounsfield scale have been discussed above in the section on image reconstruction. Suffice it to reiterate here that the electronic images generated require careful scrutiny on an independent monitor/workstation where window level and widths can be manipulated. Many additional functions are now available on commercial systems, including facilities for cinematic viewing. The attenuation of lesions can be formally measured, before and after enhancement with iodinated contrast medium (see perfusion maps above). Such analysis by an experienced radiologist can answer many clinical problems.

Occasionally it can be helpful to analyze images in another plane. One advantage of spiral CT is that numerous axial images can be reconstructed from a single volume data set. These multiple axial images can then be reformatted in the sagittal, coronal and even curved planes (multiplanar reconstructions). Inevitably spatial resolution in the *z* plane is somewhat compromised, but the image can provide conceptual assistance to a surgeon before embarking on a complex surgical operation. Multidetector systems have led to considerable improvement in the reformatted images.

Three-dimensional reconstruction by surface rendering is another tool available. By choosing certain window thresholds, it is possible to view bone, contrast medium or air–soft tissue boundaries. These allow three-dimensional views of bone, vascular structures (Fig. 8) and air-filled tubes (gut, trachea). Further computer manipulation allows the opportunity for virtual endoscopy (e.g., CT colonoscopy).

Another application is the analysis of the maximum (or minimum) intensities on selected images. By choosing certain parts of an image (e.g., by excluding skeletal contributions), the maximum CT attenuation numbers from the iodinated contrast medium within vessels can be displayed as a maximum intensity projection. Another option is to use minimum intensity projections; this has certain applications within thoracic imaging.

Clinical Applications

Despite the rapid advances within ultrasonography and magnetic resonance imaging (MRI), neither of which employ ionizing radiation, there is still expansion of the role of CT. This development of CT has been most marked for applications within the chest and abdomen, and follows the advent of spiral (helical) techniques; for many cranial, spinal and musculoskeletal problems, MRI is becoming the investigation of choice. See also **Magnetic Resonance Imaging (MRI)**.

Perhaps the most dramatic recent change of practice has been the introduction of spiral CT for pulmonary embolus [van Rossum, et al.: 1996]. A series of axial CT images is obtained during peak opacification of the pulmonary arteries following a bolus intravenous injection of iodinated contrast medium. Thrombus (which has usually come from a lower limb deep venous thrombosis) is well outlined as a negative filling defect within the opaque pulmonary arteries (see Fig. 6). This technique is rapidly replacing lung ventilation/perfusion scintigraphy (a nuclear medicine technique that often gives results of intermediate probability) and is eliminating the need for most pulmonary arteriography. During slightly later vascular enhancement, aortic dissection and other aortic disease can be accurately assessed.

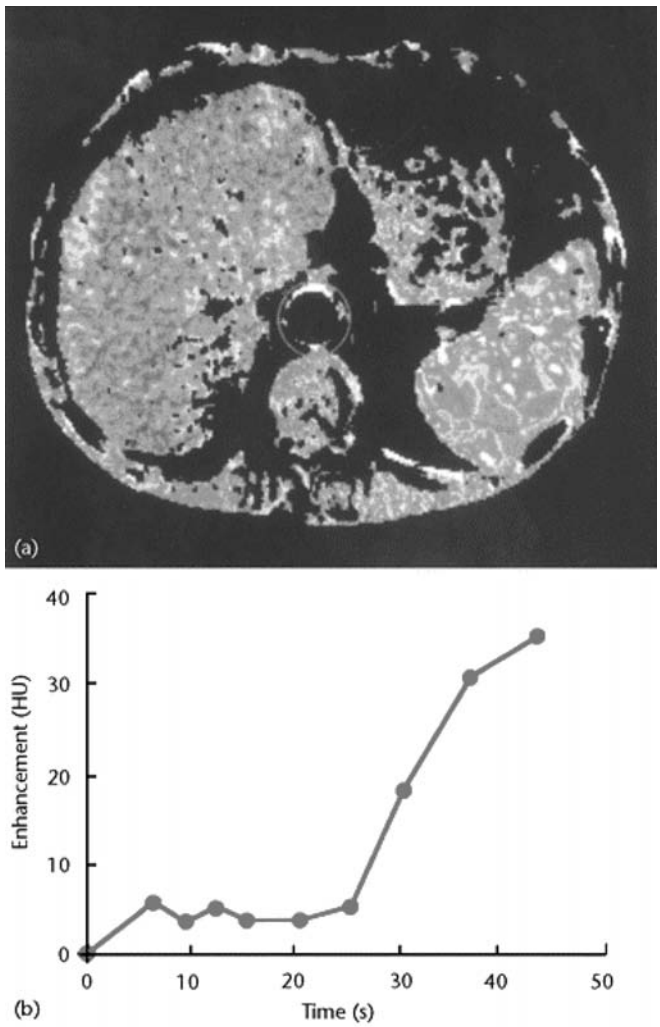

Fig. 7. Function. (a) Perfusion map of the liver derived from pixel by pixel analysis of enhancement following an intravenous bolus of contrast medium. (b) Functional graph showing early small enhancement during arterial phase, followed by the larger portal contribution.

CT has long been the ultimate radiological investigation of the chest. By showing all the structures within the cross-section, a primary bronchial neoplasm can be detected along with evidence of any spread to mediastinal lymph nodes or invasion of the chest wall. Thus, CT is widely used to detect and stage various neoplasms. It is the best method of detecting small pulmonary metastases from a wide range of tumors. Using narrow collimation and suitable reconstruction algorithms, exquisite high-resolution images of lung anatomy and disease can be obtained (Fig. 9). Indeed CT has cruelly exposed the limitations of the standard chest radiograph.

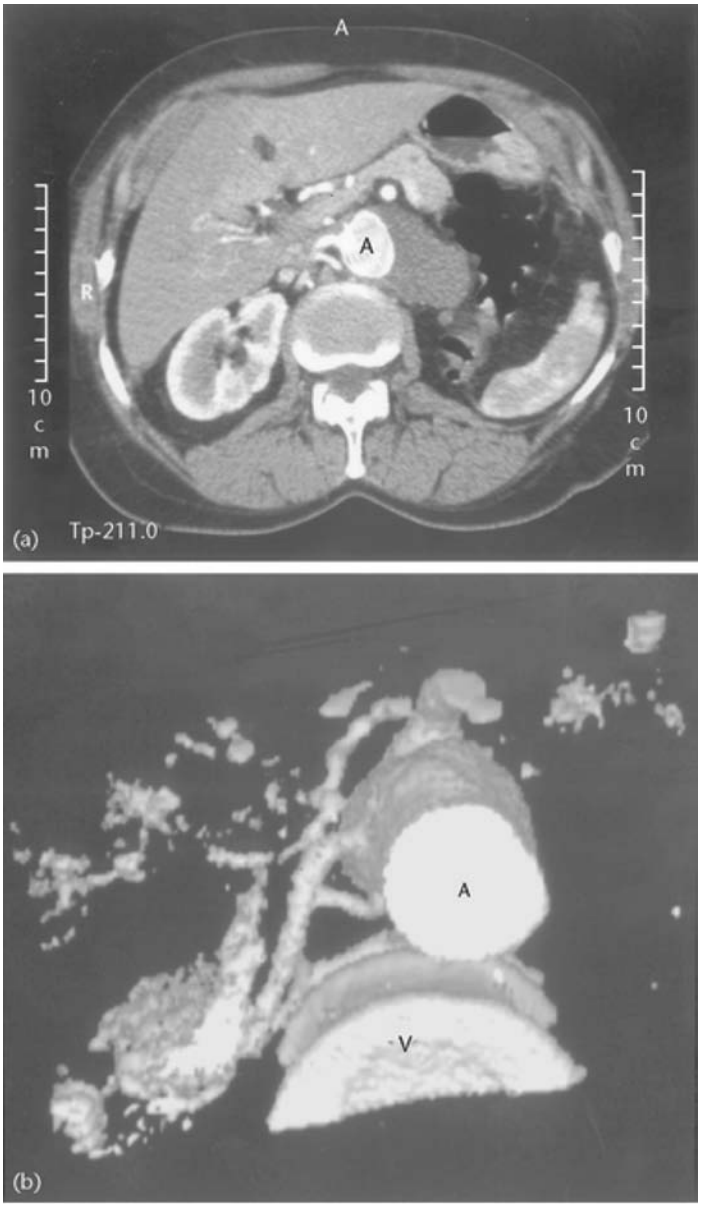

Fig. 8. Patient with an abdominal aortic aneurysm and no left kidney. (a) Standard computed tomographic image shows two renal arteries arising from the right of the aneurysmal aorta. (b) Three-dimensional surface rendered view showing the two renal arteries arising from the aortic lumen (A) anterior to the vertebra (V). The aneurysm itself is not seen.

Fig. 9. Thin high-resolution computed tomographic section (1 mm) of the thorax, reconstructed using an algorithm that maximizes edge detection. Note the exquisite depiction of the normal segmental bronchi.

Soon after its introduction, CT was rightly recognized as providing significant new information on the abdomen: normal and abnormal para-aortic nodes could be demonstrated directly (thereby making lymphography redundant); the pancreas was seen for the first time; an abdominal mass could be confidently confirmed and excluded. Indeed, CT became a credible test of exclusion for a wide range of conditions. Even those areas where CT was initially considered weak (e.g. the bowel) became accessible as spatial resolution improved. Thus, CT following prolonged administration of oral contrast medium was introduced as an alternative to barium enema in frail and elderly patients.

CT became regarded as the ultimate investigation for most intra-abdominal conditions. Throughout the 1980s it was used to stage all intra-abdominal malignancies. The main limiting factor was availability. In some parts of the world where funding was readily available, CT has been used routinely for standard surgical problems (bowel obstruction, hernias, etc.). During the 1990s, escalating medical costs, increasing awareness of the high radiation dose and the rapid development of techniques using no ionizing radiation (ultrasonography and MRI) all combined to make more circumspect use of abdominal CT. However, it remains one of the most commonly used abdominal investigations. Furthermore, spiral CT is now replacing intravenous urography in patients with possible renal colic; renal and ureteric calculi and their effects on the renal pelvis, calyces and perinephric tissue can all be demonstrated without the need for intravenous contrast medium. Although CT had long been used to diagnose and document the extent of abdominal aortic aneurysms, spiral technology has allowed elegant three-dimensional displays. Three-dimensional techniques also allow the air-filled large bowel to be evaluated (CT colography), and this technique is starting to challenge barium enema and colonoscopy for all lesions except the smallest of polyps. Limited spiral acquisition data from the right iliac fossa are now advocated by some for the diagnosis of appendicitis; in the UK, this is usually reserved for patients with equivocal clinical findings.

CT is still widely used for many cranial problems, although the increasing availability of MRI may continue to erode this practice. CT remains the preferred method for evaluating patients with cranial and maxillofacial trauma and many postoperative problems. It is still the optimal method for excluding hemorrhagic causes for cerebrovascular episodes. It provides unique anatomical data in certain ear, nose and throat problems (e.g. depiction of maxillary sinus drainage problems).

CT remains the optimal method of displaying information about complex fractures of the skeleton. This is especially important where management decisions depend on the CT findings.

COMPUTER. A device or machine capable of accepting information, applying prescribed processes to the information, and supplying the results of these processes. The computer usually consists of some combination of input/output devices, storage, arithmetic, and logical units, and a central control unit. In current terminology, a computer, once programmed, is essentially capable of performing all desired functions with a very minimum of human checking and intervention. Calculators also compute, but traditionally have required manual step-by-step guidance. With the advent of solid-state desk calculators, some of the functions which previously required manual attention are permanently wired into the device and thus calculators are meeting the definition of a computer.

In terms of fundamental technique used, computers are classified as analog or digital. Although analog computers are used in the form of devices and subsystems, such as electronic, mechanical, pneumatic, and fluidic analog computing devices and subsystems in the instrumentation and automatic control field, they may not be identified as computers per se. Certain large analog computers, identified as such, find application, but generally when the term computer is mentioned, a digital computer is inferred.

Digital computers range widely in size, capability, and cost. A digital computer may be identified in terms of size and capability, as for example a minicomputer, or microcomputer; or in terms of intended use, as for example data-acquisition computers, process-control computers, general-purpose computers, commercial computers, and special-purpose computers.

COMPUTER ANIMATION. Animation is the production of consecutive images, which, when displayed, convey a feeling of motion. Animated images are almost magical in their ability to capture our imagination. By telling a compelling story, astounding with special effects or mesmerizing with abstract motion, animation can infuse a sequence of inert images with the illusion of motion and life. Creating this illusion, either by hand or with the assistance of computer software, is not easy. Each individual image, or *frame*, in the animated sequence must blend seamlessly with the other images to create smooth and continuous motion that flows through time.

Traditionally, animation was created by drawing images of the characters for each frame in the action. At the start of the production, the animator is given *storyboards*, which are sketches depicting the sequence of major actions and illustrating the expressions of the characters. The animator also works from a finished soundtrack, which determines the timing of the piece. In older animations, the background scenery was often stationary and the characters were painted on *cels*, pieces of clear celluloid that could be stacked on top of the background. Most hand animation is created with *keyframing* where a lead animator creates the key, or most important frames, and a second animator creates the in-between frames. Regardless of the medium, the challenge for the animator is to create images that impart expressiveness and life to the character.

The most basic computer animation tools assist the process of traditional animation by automatically generating some of the frames of animation. Animation tools have also been developed to composite together multiple layers of a scene in much the same way that layers of cels are used in hand animation. Other more powerful techniques make use of algorithms that render and image from a geometric description of the scene. These techniques change the task from drawing sequences of images to using computer tools to effectively specify how images should change over time.

In addition to providing tools that give the animator new capabilities, the computer also creates new applications for animation. Computer animations can be generated in real time for use in video games and other interactive media. Combining puppeteering with computer animation allows a human operator to control an interactive character in a live performance. Realistic rendering and animation techniques enable the creation of digital actors that can be seamlessly blended with real-world footage.

A wide variety of techniques are used in the process of creating a complex computer animation such as Disney and Pixar's *Toy Story* (www.toystory.com). These techniques can be grouped into two main classes: two-dimensional (2-D) and three-dimensional (3-D). Although there is some overlap between the two classes, 2-D techniques tend to focus on image manipulation while 3-D techniques usually build virtual worlds in which characters and objects move and interact.

Two-Dimensional Animation. Two-dimensional (2-D) animation techniques contribute a great deal to computer animation by providing the tools used for sprite-based animation, blending or morphing between images, embedding graphical objects in video footage, or creating abstract patterns from mathematical equations. The impact of 2-D techniques can be as spectacular as the addition of the film character E.T., to a shot of the moon, or as subtle as the erasing of lines around matte boxes for the TIE Fighters in *Stars Wars*.

The most common form of 2-D animation is *sprite* animation. A sprite is a bitmap image or set of images that are composited over a background, producing the illusion of motion. They are usually small with respect to the size of the screen. For example, to animate a rabbit hopping across a meadow, the animator would create a sequence of images showing poses of the rabbit hopping. This sequence of images would then be composited one image per frame onto a background image of the meadow. Sprite-based animation can be done extremely quickly with current graphics hardware, and thus many elements of the scene can be moving simultaneously. The disadvantage of this technique is that the sprites come form a fixed library and subtle change in lighting and depth cannot be reproduced. Consequently, sprite animation is most often used in interactive media where rendering speed is more important than realism.

Morphing refers to animations where and image or model of one object is metamorphosed into another. In Michael Jackson's music video *Black or White*, the animators at Pacific Data Images (www.pdi.com) created morphs between people with strikingly different facial characteristics. Morphing is remarkable because it provides a startling yet convincing transformation of one image into another. Unfortunately, morphing is labor intensive because the key element of each image must be specified by hand, although automatic feature detection is an area of active research.

Embedding graphical objects into an existing image allows new elements to be added to a scene. For example, the ghosts in *Casper* and many of the dinosaurs in *Jurassic Park* were computer generated and then composited into existing footage (www.lostworld.com). Objects can also be removed from a scene. The bus in Speed flies over a gap in a partially constructed bridge. The gap was created by digitally removing a span from footage of an intact bridge. Both the processes of embedding and of removing objects are made more difficult if the camera is moving because the alteration must be consistent with the changing viewpoint.

Mathematical equations are often used to create abstract motion sequences. When the values of the mathematical functions are mapped to color values and varied with time, the motion of the underlying structures can be quite beautiful. Fractals, such as the one shown in Fig. 1, are a well-known example of functions that create attractive patterns.

Morphing and the generation of abstract images from mathematical equations can be generalized for the use in 3-D. All of these 2-D techniques can be used either on their own to create an animation or as a postprocessing step to enhance images generated using other techniques.

Three-Dimensional Animation. Three-dimensional animation involves constructing a virtual world in which characters and objects move and interact. The animator must model, animate, and render the 3-D scene. Briefly state, modeling involves describing the elements of a scene and

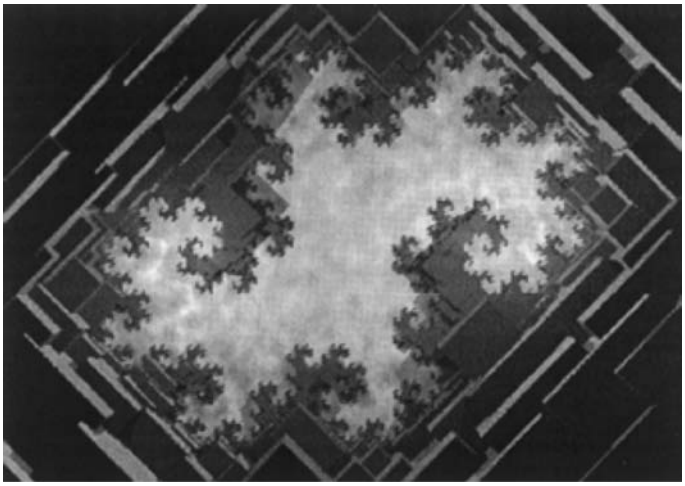

Fig. 1. Image created from fractal equations. The abstract image in this figure was created by using a type of complex mathematical equation known as a fractal. (*Image courtesy of Daryl H. Hepting*.)

placing them appropriately. Animating specifies how the objects should move in the 3-D world. Rendering converts the description of the objects and their motion into images. Modeling and rendering are, for the most part, independent of their role in the animation process but a few necessary modifications are described below.

Modeling Requirements. To animate motion, the user needs both a static description of an object and information about how the object moves. One common way to specify this additional information is to use an *articulated model* such as the one shown in Fig. 2. An articulated model is a collection of objects connected together by joints in a hierarchical, tree-like structure. The location of an object is determined by the location of the objects above it in the hierarchy. For example, the motion of the elbow joint in a human model will affect not only the position of the lower arm but also the position of the hand and fingers. The object at the top of the hierarchy, or the root of the tree, can be moved arbitrarily to control the position and orientation of the entire model.

Fig. 2. An articulated model of a human male. The structure of the joint hierarchy is shown on the left. The graphical model used for rendering I shown on the right. (*Image courtesy of the Graphics, Visualization and Usability Center, Georgia Institute of Technology*.)

A second type of model used in animation is a *particle system* or collection of points. The motion of the particles through space is determined by a set of rules. The laws of physics often provide a basis for the motion so that the particles fall under gravity and collide with other objects in the environment. Systems that are modeled well by particle systems include water spray, smoke, and even flocks of birds.

Deformable objects are a third type of model and include objects that do not have well-defined articulated joints but nevertheless have too much structure to be easily represented with a particle system. Because of the broad nature of this class, there are several fundamentally different ways to represent deformable objects, including spring-mass lattices, volumetric models, and surface representations. Water, hair, clothing, and fish are among the systems that have been successfully modeled as deformable objects.

While each of these model types can be used to describe a wide variety of objects, complex systems often require *hybrid models* that combine two or more types. The approach allows each part of the system to be modeled by the most appropriate technique. The image in Fig. 3 shows a diver entering a swimming pool. The diver is an articulated model, the water in the pool is a deformable model, and the spray is a particle system.

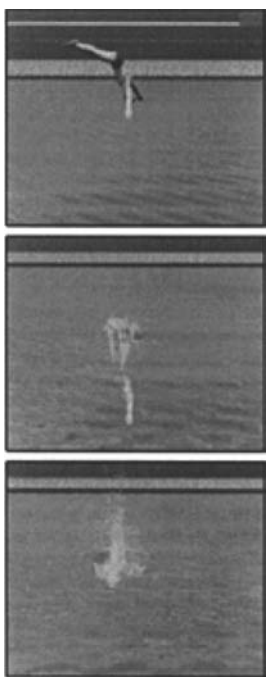

Fig. 3. A diver entering pool. These images show the combined use of an articulated model, a deformable model, and a particle system. (*Images courtesy of the Graphics, Visualization and Usability Center, Georgia Institute of Technology*.)

Rendering Requirements. *Motion blur* is a rendering technique that is required for animation but not for most still images. Animations usually display images at 24 frames or 30 frames per second, and thus a continuous motion is being sampled. This sampling process causes the rapid motion of an object to create unpleasant strobing effects, because high frequencies are masquerading as low frequencies. For example, objects such as wheels may appear to move in the wrong direction. This phenomenon, called *aliasing*, is a well-known problem in signal processing. To solve this problem, a fast-moving object can be rendered in several of the positions it had during the period of time represented by a frame. This technique creates a blurred representation of the object. While it may seem strange to think that quality can be improved by blurring, humans perceive a motion-blurred animation as more realistic.

Motion Generation. The task of specifying the motion of an animated object to the computer is surprisingly difficult. Even animating a simple object like a bouncing ball can present problems. In part, this task is difficult because humans are very skilled at observing motion and quickly detect motion that is unnatural or implausible. The animator must be able to specify subtle details of the motion to convey the personality of a character or the mood of an animation in a compelling fashion.

A number of techniques have been developed for specifying motion, but all available tools require a trade-off between automation and control.

Keyframing allows fine control but does little to automatically ensure the naturalness of the result. *Procedural methods* and *motion capture* generate motion in a fairly automatic fashion but offer little control over fine details.

Keyframing. Borrowing its name from the traditional hand animation technique, *keyframing* requires the animator to outline the motion by specifying key positions for the objects being animated. In a process known as *in-betweening*, the computer interpolates to determine the positions for the intermediate frames. For example, to keyframe hitting a baseball, the animator would post a batter at several key moments in the sequence, such as the batter's at several initial stance, the contact with the ball, and the follow-through. The remaining images would be filled in by the computer. The interpolation algorithm is an important factor in the appearance of the final motion. The simplest form of interpolation, *linear interpolation*, often results in motion that appears *jerky* because the velocities of better interpolation techniques, such as *splines*, are used to produce smoothly interpolated curves.

The specifications of keyframes can be made easier with techniques such as *inverse kinematics*. This technique aids in the placement of articulated models by allowing the animator to specify the position of one object and have the positions of the objects above it in the articulated hierarchy computed automatically. For example, if the hand and torso of an animated character must be in must be in particular locations, and inverse kinematics algorithm could determine the elbow and shoulder angles. Commercial animation packages include inverse kinematics and interpolation routines designed specifically for animating human figures. These tools take into consideration such factors as maintaining balance, joint angle limitations, and collisions between the limbs and the body. Although these techniques make animation easier, keyframed animation nevertheless requires that the animator intimately understand how the animated object should behave and have the talent to express that behavior in keyframes.

Procedural Methods. Current technology is not capable of generating motion automatically for arbitrary objects; nevertheless, algorithms for specific types of motion can be built. These techniques are called *procedural methods* because a computer follows the steps in an algorithm to generate the motion. Procedural methods have two main advantages over keyframing techniques: (1) they make it easy to generate a family of similar motions, and (2) they can be used for systems that would be too complex to animate by hand, such as particle systems or flexible surfaces.

Physically based simulation refers to a class of procedural methods that makes use of the laws of physics, or an approximation to those laws, to generate motion. Simulated motion will be realistic if the model captures the salient physical characteristics of the situation. For many applications, this realism is an advantage. Unfortunately, building a new simulation is sometimes a difficult process requiring an in-depth understanding of the relevant physical laws. Once a simulation has been designed, however, the animator may use it without understanding the internals of the simulation.

Simulations can be divided into two categories: *passive* and *active*. Passive systems have no internal energy source and move only when an external force acts on them. Passive systems are well suited to physically based simulation because the motion is determined by the physical laws and the initial conditions of the system. Pools of water, clothing, hair, and leaves have been animated using passive simulations.

Active systems have an internal source of energy and can move of their own volition. People, animals, and robots are examples of active systems. People, animals, and robots are examples of active systems. These systems are more difficult to model because, in addition to implementing the physical laws, the behavior of the simulated muscles or motors must be specified. An additional algorithm, a *control system*, must be designed to allow the model to walk, run, or perform other actions. For example, a control system for standing contains laws that specify how the hips and knees should move to keep the figure balanced when one arm is extended out to the side. Control systems can be designed by hand for figures with the complexity of a 3-D model of a human. For slightly simpler systems, they can be designed automatically using optimization techniques. After a particular control system has been built, an animator can use it by giving high-level commands such as stand, walk fast, or jump without understanding its internal details. Figure 4 shows a simulation of a running human. To compute the running motion, the animator specifies the desired velocity and a control system generates the motion. The runner's clothes are a passive cloth simulation.

Procedural methods can also be used to generate motion for groups of objects that move together. Flocks of birds, schools of fish, herds of animals, or crowds of people are all situations where algorithms for *group behaviors* can be used. In Walt Disney's animated version of *The Hunchback of Notre Dame*, most of the crowd scenes were computer animated using procedural models. This animated film is particularly impressive because computer and hand animation are seamlessly combined to create very detailed scenes.

Fig. 4. Runner in a park. All the objects in this image were animated using dynamic simulation. The runner and the child on the swing are active simulations governed by control systems. The clothing is a passive system that has been coupled to an active system. (*Image courtesy of the Graphics, Visualization and Usability Center, Georgia Institute of Technology*.)

The main advantage procedural methods have over other techniques is the potential for generating interactive behaviors that respond precisely to the actions of the user. In a video game, for example, predicting the behavior of the game player in every situation is impossible, but the characters should appear to be reacting to the actions of the player. Procedural methods allow this capability by computing a response in real time. While methods using keyframing can also respond to the player, they can only do so by picking from a fixed library of responses. Although procedural methods are currently computationally too expensive to generate motion in real time for complicated scenes, advances in computer technology may render this possible.

The automatic nature of simulation has a cost, in that the animator is not able to control the fine details of the motion. As a result, characters often lack expressiveness of individuality in their motions. Creating tools to allow the animator to control these aspects of a character is a topic of current research.

Motion Capture. A third technique for generating motion, *motion capture*, employs special sensors, called *trackers*, to record the motion of a human performer. See Fig. 5. The recorded data are then used to generate the motion for an animation. Alternatively, special puppets with joint angle sensors can be used in place of a human performer.

Motion capture is a very popular technique because of the relative ease with which many human motions can be recorded. However, a number of problems prevent it from becoming an ideal solution for all applications. First, accurately measuring the motion of the human body is tricky because trackers attached to skin or clothing shift as the performer moves, creating errors in the recorded data. Furthermore, if the object used to generate the recorded motion and the graphical object have different dimensions, the animation may have noticeable flaws. For example, if the actor were resting his arms on a real table, the arms of the graphical actor might appear to be suspended in the air or sunk into the table.

The technology used for motion capture makes it difficult to capture some motions. One class of sensors is magnetic, and metal in the

Fig. 5. A performer wearing a motion capture apparatus. The device shown is a full body magnetic tracking system. (*Image courtesy Bobby Bodenheimer*.)

environment creates noise in the data. Some sensors require that the actor be connected to the computer by an umbilical cord, thereby restricting the actor's motion. Another class of sensors is optical, and occlusions caused by props and other body parts create confusion in the data. All sensing technologies have a relatively small field of view, which limits the kinds of actions that can be captured.

In spite of these difficulties, motion capture is widely used because it automatically captures the subtleties of human motion. An animated figure generated from motion capture of Michael Jackson dancing, for example, will be recognizable as Michael Jackson. The subtle mannerisms that motion capture contains are currently beyond the reach of procedural techniques, and much of the motion found in commercial animation is generated by using captured data and "tweaking" the results by hand.

The Future. In the future, the three techniques of keyframing, procedural approaches, and motion capture will be merged to produce systems with the advantages of each approach. For example, motion capture data can be used as a source of information in the construction of a simulation. Short simulations can be used to blend between motion capture segments. Keyframing techniques can be applied to motion that was generated either procedurally or with motion capture.

The demand for animated motion is already high because of the popularity of computer-generated characters in video games and special effects in film. The list of applications that require animation will grow as improvements in graphic accelerators make feasible animated user interfaces, graphical software for education, and virtual environments for training and entertainment.

COMPUTER ERROR PROCEDURES. Computer errors fall into three principal categories: (1) central-processor errors, (2) peripheral-device errors, and (3) program errors. Program errors by far are the most common, but sometimes they may appear to be processor or peripheral errors. If an error cannot be duplicated through the use of other programs, it is almost certainly a program error.

The procedure for isolating peripheral-device errors normally consists of retrying the operation several times and logging the failures. When the failure persists, the operator is informed and the computer may wait on operator intervention, or abort the current job and logically disconnect the device. Or, the error may be documented to the operator with a return to the current program with a special indicator to permit the application programmer to determine the error procedure to be followed. This is a good approach where two different programs, each having different error-procedure requirements, are running in the same machine.

Procedures for central-processor errors are usually more difficult. Often a "warm start" is attempted. All current jobs are aborted; all of the storage is initialized where possible, and a restart from a previously defined state is attempted. If the first warm start fails, another cycle usually will be attempted. It is unlikely that a machine that cannot be warm-started can be safely used without operator intervention.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

COMPUTER GRAPHICS. People communicated by using graphics (images, symbols, etc.) before languages existed. Graphic depictions usually convey information faster than words and often with fewer chances for misinterpretation. As in the case of traffic signs, symbols have no language barrier. Graphics permit the extraction of key information from large volumes of minutia. Long before the computer, of course, it was common practice to reformat manually compiled digital tabulations into the more easily assimilable hand drawn histogram, pie chart, graph, and bar chart. Thus, it was no surprise that graphic techniques were merged with digital computer technology a number of years ago. The outstanding advantages of this combination technology are accuracy, speed, and (for run-of-mill graphics) lower cost.

Modern computer graphics plays two rather distinct roles, although the two are frequently combined: (1) the display of digital data in analog form, i.e., the computerized creation of displays (and usual accompanying hard copy) of information in chart and other formats — this may be termed the "display" side of computer graphics; (2) the creation of shapes and other images essentially from "scratch" by engineers and scientists in such applications as computer-aided design and drafting (CADD) and computer-aided engineering (CAE). This role also applies importantly to artists in the creation of attractive displays for television and of animation for motion pictures. Computer graphics permits the rotation and translation of images so that an object can be viewed from different angles. This may be termed the "design and creative" side of computer graphics.

Interactive computer graphics applies to either the display or design uses and simply permits the person at a workstation or in front of a graphics display panel to communicate in a biodirectional manner with the computer system. Usually, the more interactive a graphics system is, the better will be the flow of data into and out of the system in a very effective human/machine interface.

Computer graphics did not become established among engineers, scientists, and artists until the mid-1960s, when Ivan Sutherland invented the *Sketchpad* system. At that time, the system was given a prophetic name, "A Man-Machine Communication System." The technology was comparatively slow in developing during its early years because computer

equipment, in general, was quite costly during that era before the appearance of microprocessors, integrated chips, improved video, etc. Further, even relatively simple computer graphics systems require quite a lot of computer power. As computer graphics gained some maturity, a see-saw relationship developed between users and suppliers. However, there were but a few short periods when computer graphics did not take full advantage of available hardware. Today, computer graphics is so well established as a major market for electronic technology that the industry now considers graphics applications seriously when developing new circuits, architectures, and components. The current trend, and one that is expected to continue, reflects the exceptionally fast-growing demands of the graphics field and, in essence, outrunning the equipment available to meet these demands. Computer graphics is becoming a major factor, for example, in pushing parallel architecture of computers and the design of VLSI (very large scale integration) chips dedicated to graphics, and the incorporation of graphics commands in programmable microprocessors.

Fundamental Elements and Operations in Computer Graphics

The typical computer graphics system is comprised of (1) *input devices*, (2) *interactive devices* including software, and (3) *output devices*. The steps or stages involved consist of: (1) an original *shape* (almost any kind of diagram or picture — already on hand (in essence, data) or still in the designer's brain, i.e., in a stage of creativity; (2) introducing the shape into the computer by (a) digitizing, or (b) drawing it interactively; (3) storing the shape as a series of vectors (polygons, etc.); (4) software directed operations for manipulating the vectors; (5) displaying the shape, including translation, scaling, and rotation; and (6) capturing the final shape on some form of hard copy.

Input Devices for Computer Graphics

A standard computer keyboard is not an ideal input device for developing computer graphics. As soon as improved user interface software became available, it was no longer necessary to enter the actual graphics command strings. Instead, the operator could select what action to take or what drawing to execute by making menu selections. When choosing replaced commanding, a number of new input devices were developed. In general use today are digitizing tables with accompanying pens and pointers and several variations of mouse-like devices. These are usually used in addition to keyboards, which remain the best device for entering text.

Mouse and Trackball. The *mouse* consists of a box, about the size of a deck of cards, with one or more buttons for triggering circuits. The mouse requires a small, flat, empty surface on which to move. The graphics pointer moves on the display surface relative to the motion of the mouse on the desk surface. It is very easy to achieve pixel resolution for position and selection with a mouse. On the bottom of the mouse, two wheels set at right angles to each other drive potentiometers that are decoded to give relative movements. Thus, like the joystick, the mouse is ideal to control a cursor. It is used not to enter graphic data, but to interact with a program. The mouse also may have control buttons, which can be programmed by software.

The *trackball* operates on the same principle as the mouse, but the movement of a ball mounted on bearings within the trackball positions the cursor. It can be thought of as an upside-down mouse. The trackball within the socket turns potentiometers to produce digital coordinates.

Light Pen. This device looks like a pencil flashlight. It is used as a pointer for making menu selections from a display screen or a digitizer tablet. Some light pens will send a signal when their point is depressed, while others transmit when a button on the pen is pushed by the user. The light pen is used on vector refresh displays. Some operators find the use of a light pen rather tiring.

Joystick. Identical in function to the joystick supplied with home video games, these input devices are sometimes preferred when working with 3D drawings because of their free range of motion. They are often furnished with the simpler workstations. They operate on the same principle as the mouse and trackball. Two potentiometers, normally arranged at right angles to each other, sense the movement of the joystick and convert this into X and Y positions. Many operators find it an excellent tool for controlling a cursor on a screen. However, small, precise movements and positioning are sometimes difficult to judge.

Digitizer or Graphic Tablet. There are three main components to a digitizing tablet — the pad, tablet or surface; the positioning device that moves over the surface; and the electronic circuitry for converting points into X and Y coordinates and transmitting them to the computer. The digitizer may vary in size from a small clipboard to a full drafting table (called a digitizing table). The positioning device is usually a stylus or mouse-like device called a *puck*. The puck functions like the mouse, but it also has a crosshair sighting area in it which promotes the placement of the puck over a given point with a high degree of accuracy. These positioning devices may be used (1) to place a graphic element on the screen, (2) to make a menu selection from the screen, or (3) make a menu or symbol selection from the digitizing tablet itself. In many applications, a portion of the digitizer surface is dedicated as a permanent menu of commands relevant to the workstation's use and often is an extensive symbol set.

Touchscreen. This is probably the simplest graphic input device because it requires no associated button for triggering events. This can be done by sensing a change in the presence of a finger or some other object. A touchscreen occupies no desk or console space and appears, to the user, to be an integral part of the screen. It is especially useful to naive users for selecting one of several widely spaced items displayed on a screen. Because of calibration problems, cathode ray tube curvatures, and the coarse resolution of touchscreens and of human fingers, implementations using touchscreens must be carefully planned, and applications are limited. It is very important that systems be designed to trigger the event upon removal of the finger from the screen rather than approach of the finger. This allows the user to correct the initial (often inaccurate) position of the cursor by moving the finger until the graphics pointer is properly positioned over the desired object, at which point the finger can be removed, triggering the selection of the object. Touchscreens usually are not used for applications requiring accurate positioning or interactions over an extended period of time.

Interactive Devices — Displays

The needs for interaction between the operator and the computer graphics system vary widely between applications. As mentioned earlier, in process control applications, the interaction is mainly used by the operator for calling up information on what is going on in a manufacturing area. Calling for temperature trends or machine speed trends are examples of where a graphic display is usually far better than attempting to compare digitally tabulated information. This need differs considerably from computer-aided design and engineering applications. The entry of color and, somewhat later, of three-dimensional needs into the field of computer graphics have increased both complexity and cost of graphics systems.

Although computer graphics has evolved over the last few decades from simple pen plotters all the way to sophisticated color raster terminals, the underlying concepts have remained virtually unchanged. The basic commands for the pen plotter permitted a pen tied to some type of mechanical device to be moved over a surface to a new position with either the pen up, or down against the paper. The contrasting colors of the pen and paper then produced an image. The word "move" meant go to a new position with the pen up; "draw" meant a change in position with the pen down.

Early cathode ray terminals (CRTs) followed the same basic format, but with pen up or down replaced by beam "off" or "on." The excitation of the screen phosphors by the electron beam resulted in a glow along the path of the beam to generate the image. As the beam progressed to draw other lines, the glow would fade and have to be refreshed continuously to remain visible. As the number of lines to be displayed increased, the time between each repaint of a line would increase — to the point that the display would begin to flicker. The end-points of each vector also had to be stored and accessed quickly to support the refresh cycle, further limiting the number of lines that could be displayed. These types of terminals were called *vector*, *calligraphic*, or simply *refresh* terminals.

Direct View Storage Tube (DVST). This device eliminated the flicker problem by continually flooding the screen with a field of electrons. A charged screen between the viewing screen and the electron gun blocked the path of electrons and the viewing screen remained dark. A second sharply focused beam was then used to electrically "burn" a hole in the blocking screen to allow the flood electrons to strike the phosphors and generate the image. Once drawn, a line would remain steady on the screen until the blocking screen was reset. While flicker was eliminated, the dynamic animation capabilities of the refresh terminals were no longer possible. Once the line image was displayed, its end locations were no

longer needed, enabling the stable, although possibly cluttered, display of virtually any number of vectors. The storage tube technology also made possible relatively quick and low-cost hard copy of the screen image at the push of a button. Because of the stability of its image, ease of hard copy, and relatively low cost, the DVST became a graphics standard for over a decade.

Refresh terminals and the DVST were typically monochromatic. Prior to 1979, the requirement for color in computer graphics generally dictated the use of a film recorder. Such systems were beyond the budgets of most technical organizations. Real affordability in color graphics commenced in the early 1980s when manufacturers turned to raster technology for their terminals.

Color Raster Technology. Use of rasters for analog signals was commonplace long before gaining favor with the graphics community. In fact, raster scopes have been used on a daily basis since the 1950s in millions of homes equipped with television sets. Unlike the refresh or DVST beam which moves between the end-points of lines, a raster beam always follows the same path, painting the screen in a series of closely spaced horizontal lines. The intensity of the beam is then modulated as it travels to produce the picture. To the device, a line is no longer a line, but a series of disconnected On/Off pulses in a continuously scanned raster. For color systems, three beams are used to individually excite red, green, and blue phosphors on the screen. See also **Television (TV)**.

However, in computer graphics, unlike television, the intensity at each addressable location (called a picture element or simply *pixel*) on a raster graphics screen must be calculated. For a monochromatic screen with a resolution of 512×512 (similar to the resolution of a standard TV tube), over a quarter of million points must be determined. Not only must each of these points be calculated, but they must be stored in a form that can be accessed over and over at the scan rate of the device. For a color device, the amount of red, green, and blue information at each pixel also has to be calculated and stored. Although raster systems provided the picture stability of the DVST and the dynamic ability of the refreshed terminals, the cost for the enormous memory requirements of a raster system stifled their use for a number of years. Not until new storage technology reduced the cost of memory did raster terminals become economically feasible.

Early color raster systems had eight possible colors (red, green, blue, magenta, cyan, yellow, black, and white). These colors could be indicated and stored for each pixel as the "on/off" (bit) condition of the three color electron guns. The three bits 000 would indicate black (all guns off while passing that pixel), 100 might indicate red, 010 green, 001 blue, and 111 white. Having two guns specified as "on" would then give the other three colors, that is, magenta as red and blue guns "on" (101); cyan as green and blue (011); and yellow as red and green guns "on" (110). These terminals usually were furnished with an extra bit of information per pixel, which was used to indicate a blink on or off. The "blink" would cause the pixel to alternate between the specified color and the general background color. Thus, a 512×512 system would require four bit values for each of the 262,144 pixels to have the ability to display any of the eight colors and a blink function at each pixel.

While this seemed a logical approach to the specification of eight colors, users quickly demanded more and more colors, which require more latitude than that available with beam "on/off" type storage.

Bit Plane Approach. Providing an orderly method for specifying any number of colors and, at the same time, providing the user with the ability to custom select the display colors from a much larger palette, the *bit plane approach* became popular. The bit plane approach can be visualized as a three-dimensional storage matrix or block of zeros and ones. The front of the block has the same number of locations across and up as the screen has pixels. The depth direction is then used to specify a *look-up table location* rather than a color. The combinations available with one bit plane of information (0 or 1) would provide access to a look-up table with two possible colors; two bit planes, a four-color look-up table; four bit planes, a 16-color look-up table; eight bit planes, a 256-color look-up table, and so on. In fact the maximum number of simultaneous colors for a raster graphics terminal would be two raised to the number of bit planes. The original four-bit systems could, therefore, drop the blink function and use the four bits to specify access to 16 locations in a color look-up table.

Color Look-Up Table. The LUT itself contains the color specification. With the number of bits in the look-up table exceeding the number of bit planes, the flexibility of LUTs can readily be seen. In the fourbit plane system example just given — if each color entry in the LUT has six bits of information (two bits for each of the red, green, and blue components), then each pixel can still have any of 16 colors, but the user can choose the 16 from any of 64 combinations of red, green, and blue. Thus, instead of having the color guns either off or on, each can take on four or more intensity values. The user builds the table to suit individual needs. Some systems even permit the LUT to be loaded with variations of a single color. The example LUT could also have been configured by the manufacturer to have eight storage bits per entry, allowing a 256-color palette; or even 24 bits per entry for a palette of over 16 million colors. The advantage is that all 24 bits would not have to be stored for each pixel. Only four bits would be stored for each pixel to address the LUT where the description of the limited number of 24-bit colors could be found. This results in savings of 20 bits per pixel, or five megabits of storage per image. Of course, the total number of colors displayable at one time remains limited.

Number of Colors. How many colors are enough? That number remains controversial. For manufacturers of 16-color systems, the answer is obviously 16 or less. In reality, the number of colors needed is a balance of cost and application. Simple graphs and charts can become garish and inappropriate if too many colors are used without a good deal of artistic flair. Even worse, a multitude of colors may confuse or dilute the central theme of the graphic. Therefore, eight colors may be entirely sufficient. For scalar data mapped over two-dimensional geometries, 16 colors permit additional discrimination of the data. Many systems and software support 16 colors for displaying scalar data over three-dimensional surface geometries as well, but the subtle visual cues that give depth and form to the geometry are lost. As a result, time will be wasted in interpreting the geometry as well as the data. For this type of application and for more advanced types of three-dimensional graphics, 24 bit planes per pixel (16 million colors) give smooth shading for all three color guns and may be more appropriate.

Other Display Devices. Techniques in addition to those just described, include LCDs (liquid-crystal displays), LEDs (light-emitting diodes), plasma displays, etc.

Graphics Generators and Software

The display of graphics on a screen is accomplished by a graphics generator. Again, the requirements vary considerably with the end-use of the graphics. Although computer graphics for process control do not approach the detail of computer-aided engineering and design applications, they can be quite complex, requiring medium resolution screens, such as 512×512 or 640×640 pixels. This presents a problem in transmitting data to the graphics generator. A complex display, addressing each of the available picture elements on the screen, may require thousands of bytes of command data to draw it, yet update times of 1 to 2 seconds are also expected. At least two strategies have evolved to deal with this problem. One reduces screen complexity by requiring character cells of approximately 6×10 pixels to be the smallest addressable area on a screen. The other strategy reduces the amount of information that must be transmitted by storing most of the picture-drawing commands in the graphics generator while maintaining pixel addressability.

Compared with CAD systems, control computer graphics are much easier to use, with advanced user interfaces that allow full menu-driven graphics development and linking. Linking means that each symbol on the screen that will be updated must be tied to the appropriate data coming from the factory operation.

In color graphics, a large amount of software already exists to support typical engineering applications that involve lines and surfaces. The surface routines typically use hidden routines to give realistic three-dimensional images. For raster devices, these algorithms usually sort the image back-to-front, using polygon fills or point-by-point calculations. Volumetric algorithms that represent full, both internal as well as external, data are seeing increased technical application.

Standards. Computer graphics standards have been long in the making. Without standards, software developed to run a graphics terminal of one manufacturer may not work on a terminal designed by a different manufacturer. For example, a command to draw in the color red may be "ESC V4" for one terminal; "ESC P1θ/CR" for another terminal, and "1 CO: SP Cl Cl CR" for still another terminal. Graphics standards have been under study since the early 1970s. The Graphical Kernel System (GKS) was originally a standard for two-dimensional (2D) graphics

developed in West Germany, but competed for a number of years with a three-dimensional (3D) standard (CORE) proposed by the Association for Computing Machinery. Work to extend GKS to three dimensions has been underway. The GKS library consists of approximately 200 subroutines that the application programmer utilizes to produce and manipulate graphics. Use of these subroutines as a standard interface gives all graphic terminals the ability to understand and execute the same subroutine calls. Because GKS was not developed for a modeling system, some users of CAD systems prefer the Programmers Hierarchical Interactive Graphics System (PHIGS).

Final Output Forms

Three-Dimensional Graphics. The ability to display objects and scenes in three dimensions on a two-dimensional medium has been a goal sought by technologists for decades, as witnessed by the numerous attempts made by the motion picture industry where the objective was mainly that of providing believability and sometimes shocking realism. To some extent, the computer-generated 3D scenes now appearing on entertainment television share these earlier objectives. However, within the relatively recent past, 3D computer graphics is assuming much more serious and productive roles and is being adopted by many disciplines, ranging from mechanical and architectural computer-aided design and engineering, cartography, and training through simulation, to medical and other scientific research. Automotive and aerospace engineers were among the first proponents and users of 3D graphics in their workstations. See Fig. 1. Three-dimensional graphics are now an intimate part of many CAE (computer-aided engineering) systems. See also the entry on **Automation**.

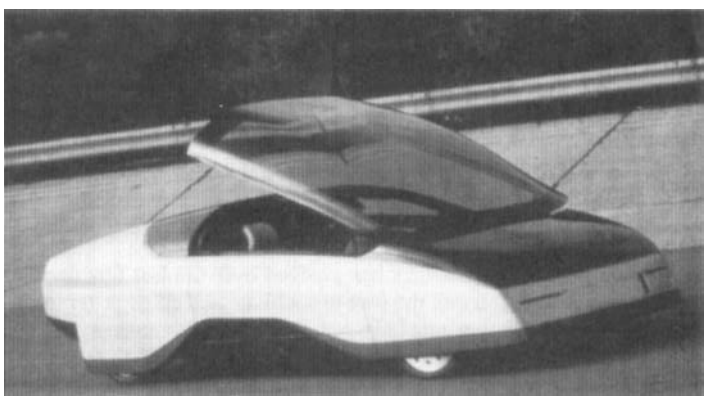

Fig. 1. Facsimile of 3D color-graphics presentation of an auto manufacturer's concept of a 21st-century design.

A substantial portion of the computing power required to produce 3D graphics is devoted to shading, which creates the appearance of depth in an object displayed on a flat screen. Shading is achieved by filling the polygons making up the screen image with various colors (shades) that represent light reflecting off the surfaces. The most basic and simple shading technique is called *faceting*. This requires few computer resources inasmuch as it just involves filling the polygons with one shade each of a single hue. *Faceted shading*, unfortunately, has a primitive appearance — curved surfaces no longer appear perfectly smooth, but have a fish-scale texture. *Linear shading* requires more processing, but it produces much more realistic images by varying the light intensity across each polygon. The shading is linearly graded from computed values at the polygon's corners. Some objects take on a surrealistic artificial smoothness, appearing as though indirectly lighted. In *Gouraud shading*, more realism results from grading a polygon's light intensity along its edges, as well as at its corners. Although there is one disadvantage to this method, namely, the Mach band effect which produces distracting discontinuity between abutting polygon edges, the Gouraud method is replacing linear shading in work- stations as their computer power increases. *Phong shading* eliminates much of the Mach band problem by grading not just along a polygon's edges, but across the surface itself. The present disadvantage is that the Phong technique requires hardware that can process data at 100 million pixels per second. *Ray tracing* offers the most realistic shading in 3D graphics. However, its computing-power requirements are still too large for most desktop workstations. Currently, however, the extremely complex calculations required to color each pixel can be handled by the latest, most powerful graphics engines, collections of networked high-end workstations, and some massively parallel computers. The question is affordability.

The thrust for more affordable systems is affecting new frame-memory architecture as described in the article on **Digital Computer**.

Until recently, the bandwidths of contemporary image memories and controllers limit most desktop graphics systems to 1 million pixels per second — at least 100 times too slow for highly realistic, interactive 3D graphics, as typified by Fig. 2.

Fig. 2. Facsimile of ray-traced image of a grassy field contains 400 billion polygons. The original color-graphics image was made by John Snyder (*California Institute of Technology*).

More recent systems handle 820 million floating-point operations per second. The system can transform 200,000 vectors per second and display 16 million Gouraud-shaded pixels each second. The parallel architecture (Fig. 3) consists of up to 64 distributed digital signal processor chips that take the place of typical single processors found in earlier graphics engines. Each of these processors addresses its own portion of the frame buffer, which speeds up access. Distributed addressing also allows for a large 48-megabyte frame buffer (the larger the buffer, the more realistic the image). The system shown in Fig. 4 solves the bottleneck problem with its distributed processing method. Graphics information from the host is fed to a processor pipeline (transformation pipeline), which manipulates the data and passes it to an array of processing elements (pixel nodes). Each processor in the array is dedicated to managing a portion of a very large frame buffer and each connects to its buffer portion by way of its own bus. Once the nodes have worked over the data, they send it to the video controller by way of a high-speed backplane or bus (pixel funnel).

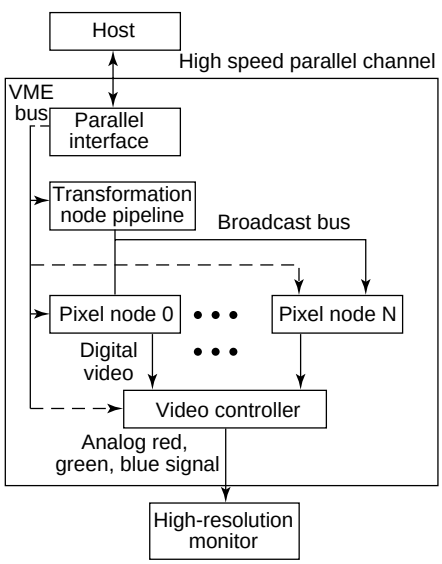

Fig. 3. Parallel architecture used in pixel machine. Independent pixel nodes speed up image drawing and rendering. (*AT&T*.)

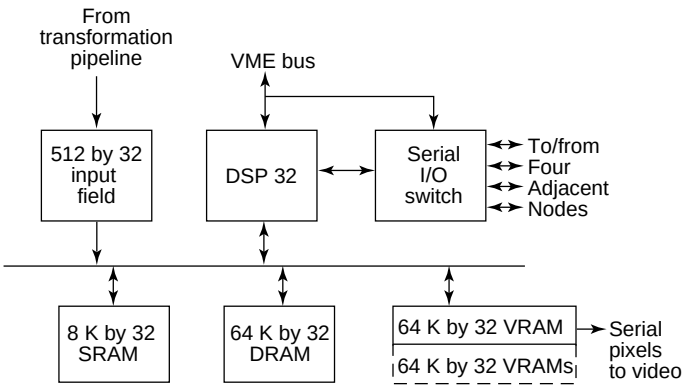

Fig. 4. Pixel nodes in pixel machine. Each pixel node is designed around a signal-processing chip which can be reprogrammed to run various algorithms (*AT&T*).

Emphasis on Reality

Well over a quarter-century of research has refined the photorealism of computer graphics. Early algorithms were developed for *direct lighting* only. Then, global illumination phenomena with *indirect lighting*, surface inter-reflections, and shadowing were modeled with ray tracing, radiosity,[1] and Monte Carlo simulations.

Graphic simulation has become basic to modern aerospace, mechanical, structural, and architectural engineering. These have included demonstrations in real time of flight situations, train operation, auto driver education, as well as teaching the operators of numerous machines that require full inter-reactions between an operator and machine system characteristics and typi-call situations that may occur routinely or in emergency operation. Health and medical professionals use the display of human and research animal organs that have been reconstructed from information obtain through radiation and tomographic scans. Efforts to provide more effective imagery, including depth perception and motion, are continuing apace. Success to date has been related to the computer power available.

In an excellent paper, D.P. Greenberg (Cornell University) outlines a five-step sequence for creating a computer graphics image, the process sometimes referred to as the graphics "pipeline." The details, beyond the scope of this article, are well outlined. (See Greenberg reference listed.) In essence, the steps are:

1. *Preparing a three-dimensional model*. This includes the geometry, positions, and orientation of all objects, including materials characteristics (textures, finishes, etc.). Also included are details of illumination, such as the geometry of light sources, the distribution of light energy, and the spectral characteristics of emissions.
2. *Perspective transformation*. Each vortex of the geometry describing the environment is mathematically transformed to generate a true perspective picture on an image plane. Certain elements are culled. The picture is bounded within a preset cone or frustrum of vision.
3. *Visible surface determination*. Surfaces are sorted in depth so that only those elements closest to the observer are displayed.
4. *Intensity of color determination*. The intensity or color of each element is computed according to a light reflection model.
5. *Image display*. Conversion of the image plane intensity information into displayable form. (For a TV image, the picture is rendered by selecting the appropriate red, green, and blue intensities for each dot or pixel in the visible scene.)

Particularly, as of the early 1990s, so-called "virtual reality" was being applied to more frivolous uses, including video games. The lay media have provided excessive hype to such applications. Goggle-type displays have proved particularly intriguing to electronic display users.

COMPUTER OPERATING SYSTEM. Generally defined as a group of interrelated programs to be used on a computer system in order to increase the utility of the hardware and software. There is a wide range in size and complexity and in application of an operating system. The need for operating systems arose from the desire to obtain the maximum amount of service from a computer. A first step was the simple monitor systems providing a smooth job-to-job transition. Modern operating systems contain coordinated programs to control input/output scheduling, task scheduling, error detection and recovery, data management, debugging, multiprogramming, and on-line diagnostics.

Operating system programs fall into two main categories: (1) control programs, and (2) processing programs:

- Control Programs
  - Data management, including all input/output
  - Job management
  - Task management
- Processing Programs
  - Language translators
  - Service programs
    - Linking programs
    - Sort/merge
    - Utilities
    - System library routines
  - User-written programs

Control programs provide the structure and environment in which work may be accomplished more efficiently. These are the components of the supervisor portion of the system. Processing programs are programs that have some specific objective that is unrelated to controlling the system work. These programs use the services of the supervisory programs rather than operating as a part of them.

Data management is involved with the movement of data to and from all input/output devices and all storage facilities. This area of the system embraces the functions referred to as the input/output control system (IOCS), which frequently is segmented into two parts, the physical IOCS and the logical IOCS.

Physical IOCS is concerned with device and channel operations, error procedures, queue processing, and, generally, all operations concerned with transmitting physical data segments from storage to external devices. *Logical IOCS* is concerned with data organization, buffer handling, data-referencing mechanisms, logical-device reference, and device independence.

Job management involves the movement of commands through the system input device, their initial interpretation, and the scheduling of jobs so indicated. Other concerns are job queues, priority scheduling of the jobs, and job accounting functions.

Task management is concerned with the order in which work is performed in the system. These include management of the control facilities, i.e., central processing unit, storage, input/output channels, and devices, in accordance with some task priority scheme.

Language translators allow users to concentrate on solving logical problems with a minimum of thought given to detailed hardware requirements. In this category are higher-level languages, report generators, and special translation programs.

Service programs are needed to facilitate system operation, or to provide auxiliary functions. Sort programs, program-linking functions, tape-print and file duplication, and system libraries are within this group.

User-written programs are programs prepared specifically to assist the user in the accomplishment of his objectives.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

COMPUTER VISION SYNDROME (CVS). According to the American Optometric Association (AOA), Computer Vision Syndrome (CVS) is "the complex of eye and vision problems related to near work which are experienced during, or related to, computer use." For the computer user, that translates to red, itchy, watery, irritated eyes, along with eye fatigue, difficulty focusing, and a variety of other problems.

In the United States, it is estimated that about two-thirds of those who use a computer, nearly 60 million people, suffer from related eye or vision problems. The National Institute of Occupational Safety and Health reports that 88% of people that work at computers for more than three hours per day, suffer from eyestrain.

At greatest risk for CVS are those who spend two or more continuous hours at the computer every day. Each year, this includes a larger proportion of the workforce, and it includes most students, who now routinely use the computer for both work and play.

Currently no clinical evidence suggests that computer use, results in permanent vision problems. However, that fact is little comfort to those who experience eye discomfort because their occupations or schoolwork keep them at computers several hours every day. Eye doctors are becoming concerned that the twenty first century could see an epidemic of computer-related eye problems unless businesses, schools, and computer manufacturers devote substantial resources to solving the problem.

Reading a computer screen is hard on the eyes because of the way the characters are formed on the monitor. The video display is made up of pixels, or tiny dots, rather than solid images as on a printed page. Because the eyes cannot "lock" focus on these dots, they must continually focus and refocus to keep the image sharp. This refocusing results in stress to the eye muscles. In addition, eyes blink less frequently when using a computer, causing the eye surface to dry out and become irritated. The irritation makes focusing even more difficult, which can lead to headaches and neck pain.

Many of the problems related to CVS are ergonomic, relating to the body's relationship to its work environment. For instance, when a monitor is positioned too high, eyes must be open wide to look up and view it. Therefore, the eyelids are retracted farther than normal and more tears evaporate. On the other hand, if the monitor is low and one is looking down to view it, the eyes will remain moist, reducing the chance of dry eye. According to some studies, eyes produce more tears than normal when looking down.

Computer Vision Syndrome can be even worse for people who have refractive disorders, binocular vision, accommodative (focusing) disorders, or dry eye.

Children who use computers may be even more susceptible to CVS than adults. Children often keep performing enjoyable tasks, such as computer games, with great concentration for hours with few breaks. This type of prolonged activity, without significant breaks, can cause eye focusing problems and eye irritation.

Employees suffering from CVS experience headaches, eyestrain, itchy eyes, blurred vision, fatigue, and tense muscles. Extreme CVS can even cause nausea, poor nutrition and loss of appetite, migraines, and cluster headaches. In addition to a strain on the muscles that control eye movement and focusing, prolonged computer use can also cause a tightening of facial muscles around the cheeks, temples, and nose. This facial tightening leads to reduced blood circulation, compounding the effects of eye fatigue.

Parents should be aware of how long their child spends on the computer at one time. Children often do not mention such symptoms as blurred vision caused by nearsightedness, farsightedness, or astigmatism because they think everyone sees the way they do. Uncorrected farsightedness can cause eyestrain at the computer because the eyes must work hard at focusing on a near object for an extended period of time. Every child over the age of 4 should have a comprehensive eye exam to be sure that vision problems are diagnosed and corrected. This is particularly important because children now spend so much time in front of a computer.

Prevention

The most important factors in preventing and treating CVS have to do with the ergonomic environment, which is the body's position relative to the computer and the external environment. This includes lighting conditions, chair comfort, location of reference materials (perhaps using document holders), and the position of the monitor, keyboard, and mouse.

To prevent CVS, try to rest your eyes when using the computer. Rest your eyes for 15 minutes after two hours of continuous computer use. Also, for every 20 minutes of computer time, look into the distance for 20 seconds — the "20/20" rule.

Special eye drops are available to help relax tired eyes and supplement the lack of natural tear flow during computer use, but the best treatment is to prevent the problems from occurring. To minimize chances of getting dry eye when using a computer, make an effort to blink frequently. Blinking keeps the front surface of your eye lubricated. Also, closing your eyes and rolling them behind your closed eyelids can help keep your eyes moist. If there are air vents in the room, try to prevent the draft from passing between your eyes and the computer monitor.

Eyeglass wearers should consider using eyeglass lenses specially designed for computer users to help reduce CVS. Tinted lenses can sometimes help with glare and flicker. Gray or brown graded tints (which gradually get darker from top to bottom) seem to be best because they do not change color perception. See also **Dry Eye**.

Vision Rx, Inc., Elmsford, NY

COMPUTING EFFICIENCY. Of a computer, the percentage of the successful computation time during a defined period to the total time in that period. Also called *operating ratio*.

COMPUTING IN SPACE. See **Space Technology 8(ST8) Mission**.

COMPUTING SCALE. See **Sclae**.

CONANT, JAMES BRYANT. (1893–1978). An American chemist and educator, born in Boston, who received his doctorate in chemistry from Harvard in 1916 and was president of Harvard for 20 years (1933–1953). His major scientific activities included pioneering research on chlorophyll and important contributions to the Manhattan Project. Perhaps his greatest achievements lay in the educational field, in which he exerted a strong liberalizing influence at both the collegiate and secondary school levels. He also was ambassador to postwar Germany and educational adviser to Berlin. He wrote many books on science and education, including basic chemical tests, and received a number of scientific and educational awards.

CONCENTRATION (Chemical). The quantity of matter or of a particular type of matter that exists in a unit volume, as the strength of a solution in mass of solute per unit mass of solution; or in the number of moles, hydrogen ions, etc., contained per unit volume or per unit mass.

The most commonly used method of expressing concentration is by stating the percentage, that is, parts by weight of the given substance in 100 parts by weight of the stated material. There are several exceptions to this method of expressing concentration, and the units used should be carefully recorded or observed, depending on whether the reader is operator or reader respectively. Ethyl alcohol, in water mixtures, is commonly reported as a stated percent by volume, where 50.0% by volume is equivalent to 42.47% by weight. Beverage and industrial alcohol also is rated in terms of proof, 200 proof indicating pure ethyl alcohol, that is, absolute alcohol containing no water. See also **Ethyl Alcohol**. Gases in a mixture are commonly reported by volume percent, thus nitrogen in air 78.0% by volume (equivalent to 75.5% by weight).

The concentrations of substances in solution are expressed variously: percent by weight of the actual material stated; percent by weight of a material calculated chemically from the actual material; grams of the actual material (or a material calculated chemically from this) per 100 milliliters of solution; gram moles (the formula weight taken in grams) of the actual material per liter of solution (this is molar or formal concentration and the abbreviations, M or F, respectively, are used to express it); and gram equivalents–(the equivalent weight taken in grams of the actual material per liter of solution (this is normal concentration and the abbreviation, N, is used to express it).

Since the concentration is proportional in many individual cases to an easily determined physical constant, such as specific gravity (e.g., of solutions), the index of refraction, specific rotatory power (e.g., sugar solutions, terpenes), such constants are frequently used to ascertain and express concentration data.

See also **Demal Solution**; **Gram-Equivalent**; **Gram-Molecular Weight**; **Molal Concentration**; **Molar Concentration**; **Mole Fraction**; **Mole (Stoichiometry)**; **Mole Volume**; and **Normal Concentration**.

CONCENTRATION (Process). In the processing of various materials, it frequently is required to increase the proportion of one material in a mixture or solution by removing all or part of one or several other components. A simple example is the retrieval of impure sodium chloride from seawater by solar evaporation of the water. Concentration is a prime reason for several of the chemical engineering unit operations described elsewhere in this volume, such as: *solid-solid* separations, as by screening, jigging, tabling, flotation, sublimation, and freeze-drying; or *liquid-solid* separations, as by filtering, centrifuging, drying, evaporating, crystallizing, leaching, expressing, and prilling; or *gas-solid* separations, as by gravity settling, electrical precipitation, cyclone and impingement settling; or *gas-gas* separations, as by absorption, adsorption, gaseous diffusion, chromatography, and electromagnetic methods; or *liquid-liquid* separations, as by distillation, dialysis, and extraction; or *liquid-gas* separations, as by drying, boiling, and condensing.

The process of concentration normally connotes an increase in the proportion of one material rather than a full separation of all other materials from the target material. Raw ores, for example, frequently will contain only a small percentage of the desired mineral. Thus, an ore may be concentrated from a fraction of 1% (wt) to 50% (wt) or more. The gaseous diffusion separation of $^{235}UF_6$ (required for nuclear fission reactors) from the natural occurring $^{238}UF_6$ (comprising 99.3%, wt) of the starting materials is an extreme example of concentration. Over 4,000 diffusion stages are required in a large atomic fuels plant to effect this concentration. Prior concentration of ores is known as *beneficiation*. This is described under **Iron**. See also **Classifying (Process)**.

CONCENTRATION (Statistics). As used in statistics, consider: if a variable $x \geq 0$ has frequency function $f(x)$, and distribution function

$$F(x) = \int_0^x f(t)\,dt$$

the incomplete first moment is defined as

$$\phi(x) = \frac{1}{\mu_1'} \int_0^x t f(t)\,dt$$

where μ_1' is the first complete moment $\phi(\infty)$. The graph of ϕ as ordinate against F as abscissa is called the *curve of concentration*. The coefficient G defined by

$$G = \frac{\text{M.D.}}{2\mu_1'}$$

where M.D. is the mean difference, is called the *coefficient of concentration*.

The concentration curve is convex to the F axis and the more it deviates from the straight line joining (0, 0) to (1, 1), the greater is the amount of concentration of total frequency in the lower part of the range of x.

CONCH *(Mollusca, Gastropoda).* Any of numerous species of large marine mollusks (*Mollusca*). The spiral shells have a long aperture, in many species beautifully colored. The shells are used for ornaments and as horns, and the animals are sometimes eaten. See also **Mollusks**.

CONCHOID OF NICOMEDES. A rational algebraic curve of fourth order. Its equation in rectangular coordinates is $x^2y^2 = (a + y)^2(b^2 - y^2)$ and in polar coordinates, $r = a\csc\theta \pm b$ The curve can be produced geometrically as follows. Select a point on the negative Y-axis at a distance a from the origin. This is called the pole of the conchoid. Draw a secant line from this point with equal lengths b above and below the OX-axis. As this secant rotates about the pole, the points at its ends, P and P', generate the upper and lower branches of the conchoid. It is symmetric about the Y-axis and the X-axis is its asymptote. The appearance of the curve differs as a and b vary. The point $(0, b - a)$ on the lower branch is a node, cusp, or conjugate point as $a \lessgtr b$ (see also **Singular Point of a Curve**).

The name of the curve comes from its shell-like shape (*L. concha*, shell). The one described here was discovered by Nicomedes, a Greek mathematician who lived about 240 B.C., and who used it to solve the Delian problems of angle trisection and cube duplication.

Actually, conchoid is often used to describe a general class of algebraic curves, which can be constructed in a similar way. They can be generalized by using a secant through a conic section. The limaçon, for example, can be produced in this way.

CONCHOLOGY. The study of molluscan shells. The word is sometimes applied to the study of mollusks generally but this field is more accurately called malacology.

CONCORDANCE. In the theory of ranking, a coefficient measuring the agreement among a set of ranks. If m rankings of n objects are arranged one above the other and the rankings summed for each object; and if S is the sum of squares of these n sums measured from their mean value $\frac{1}{2}m(n + 1)$ the *coefficient of concordance* is given by

$$W = \frac{12S}{m^2(n^3 + n)}$$

CONCRETE. Concrete is a mixture of fine and coarse aggregates firmly bound into a monolithic mass by a cementing agent. The cement ordinarily employed for concrete is the standard Portland cement. The aggregates are usually sand and crushed stone or gravel. Crushed slag or cinders are used in special kinds of concrete. The formation of concrete can be thought of as a process in which the voids between the particles of coarse aggregate are filled by the fine aggregate, and the whole is cemented together by the binding action of the cement. The nature of Portland cement in this respect is described under **Cement**.

Due to its strength, permanency, and relatively low cost, concrete is one of the most important building materials employed in modern construction. It is widely used for foundations of all types, buildings, bridges, dams, retaining walls, highways, and other purposes too numerous to mention. However, the success of concrete in meeting any particular set of conditions, depends upon the proper correlation of many factors bearing on the selection and mixing of the materials, the placing of the concrete, and the original design. Concrete is strong in compression, but relatively weak in tension. Therefore structures in which the concrete is likely to be in tension must be reinforced with steel rods, which carry the tension. For strong permanent concrete, the aggregates should be clean, coarse, and well graded. River or coarse sand is better than pit sand, and should always be used where possible. Table 1 gives typical concrete mixes, with the characteristics of each.

This table is suitable for preliminary estimates only, or for small amounts of concrete. It should be remembered that research and development in the science of concrete proportioning have advanced to the point where little short of a laboratory analysis can establish the best and most economical mix for a given condition. The strength of the cementing agent is a

TABLE 1. DATA ON CONCRETE MIXES TO YIELD 1 CUBIC YARD OF CONCRETE

function of the water-cement ratio, and therefore strength will vary widely depending upon the amount of water used. To obtain maximum strength, the water-cement ratio should be kept as low as possible. Type and gradation of aggregate, moisture content of the sand, and water-cement ratio are typical factors taken into account in a complete analysis for the specification of large amounts of concrete work.

Concrete should be transported rapidly from the mixer to the forms, so that no initial set will have occurred before the concrete is placed in its final position. It is necessary to place concrete in the forms with care to prevent segregation of the lighter and heavier parts. This precludes dropping the concrete into place from any height. After the "green" concrete has been poured, it should be cured, or hardened, slowly over a period of about a week, during which time it should be protected from vibration, freezing, and a too-rapid rate of drying out. Strengths of concrete are usually classified on the basis of 28-day strength. Most of its strength will be acquired in this time but there is a slow increase in strength for a much longer period thereafter.

For small projects, particularly around the home, a variety of premixed dry cements and concretes are available. These simply require the addition of the requisite amount of water and adequate mixing.

Prestressed concrete elements for use in construction has increased severalfold since World War I. See also **Prestressed Concrete**. The concrete block industry also has expanded greatly during the same period, replacing brickwork and stonework for many applications because of economy and speed. In addition to the usual cement, sand, and gravel, concrete blocks are also available with several other ingredients to lower the weight and density of the blocks, increase thermal insulative qualities, and to add color. See also **Brickwork**; and **Ceramics**.

CONCRETION. A term used in petrology and geology for spheroidal or discoidal aggregates formed by the secretion of silica, calcium carbonate, gypsum, or other chemical compounds around an original nucleus. See also **Oölite**; and **Accretion (Geology)**.

CONDENSATE. A vapor may be reduced to liquid by removal of such portion of the latent heat of evaporation as it may contain. The act is called condensation, and the liquid is condensate. It is the property of vapors that the condensate is dense as compared to the vapor, which, in condensing, formed it; that is, there is considerable shrinkage of volume upon a reversion to the liquid state. The thermal condition of the condensate immediately upon formation is that of saturated liquid at the temperature of vapor. See also **Distillation**.

CONDENSATION. In general, condensation is the change in matter of a substance to a denser phase, such as gas (or vapor) to a liquid. Condensation commonly occurs when a vapor is cooled to a liquid, but can also occur if a vapor is compressed (i.e., pressure on it increased) into a liquid, or undergoes a combination of cooling and compression. Liquid which has been condensed from a vapor is called *condensate*. Condensation of vapor into liquid is the opposite of evaporation or boiling and is an exothermic process, meaning it releases heat. See also **Condensate**.

Condensation can also refer to: In meteorological usage, this term is applied only to the transformation from vapor to liquid; any process in which a solid forms directly from its vapor is termed deposition, and the reverse process sublimation. In meteorology, condensation is considered almost exclusively with reference to water vapor that changes to dew, fog, or cloud. Condensation in the atmosphere occurs by either of two processes: cooling of air to its dewpoint, or addition of enough water vapor to bring the mixture to the point of saturation (that is, the relative humidity is raised to 100 percent). When either of these processes occurs, condensation ensues only if condensation nuclei or other surfaces are present. In the complete absence of such, condensation does not occur at nominal saturation. The spontaneous formation of liquid or solid droplets from water vapor (homogeneous nucleation) is opposed by the surface free-energy increase that attends the creation of new surfaces of the liquid or solid phase. Only for extreme supersaturation does this free-energy balance swing in favor of spontaneous nucleation.

In chemistry, a condensation is a chemical reaction in which two molecules react to form a single larger molecule, with the loss of a small molecule such as water.

In computer science, the condensation algorithm for realtime visual tracking.

CONDENSATION NUCLEUS. 1. A particle, either liquid or solid, upon which condensation of vapor begins.

2. Specifically, in meteorology, a particle upon which condensation of water begins in the atmosphere.

CONDENSATION RATE. The number per square centimeter per second at which molecules condense on a surface.

CONDENSATION SHOCK WAVE. A sheet of discontinuity associated with a sudden condensation and fog formation in a field of flow. It occurs, e.g., on a wing, where a rapid drop in pressure causes the temperature to drop considerably below the dew point. Also called *condensation shock*.

CONDENSATION TRAIL. A visible trail of condensed water vapor or ice particles left behind an aircraft, an airfoil, etc., in motion through the air. Also called a *contrail* or *vapor trail*. Condensation trails may persist and encourage the formation of a layer of cirrus clouds. Condensation trails may form by either of two distinct processes. First, addition of water vapor to the swept path of the aircraft inevitably accompanies exhaust of combustion products from the engines. If the humidifying effect of this addition overbalances the concomitant addition of the heat of combustion, exhaust trails may form depending on mixing with air from the environment. The thermodynamics of this process is such that the effect becomes important only for rather low temperatures of the order of those encountered near the tropopause, so this type of condensation trail is only usually observed for high-altitude flight. On occasion, exhaust provides needed condensation nuclei, but this effect has not been fully investigated. Second, in air that is clear, but almost fully saturated, the aerodynamic

pressure reduction that accompanies flow of air around propeller tips and around wingtips can so cool the air as to induce condensation and form aerodynamic trails. The latter propeller-tip trails and wingtip trails are seldom as dense as are exhaust trails. Under some conditions the pressure reduction lowers the temperature below that for homogeneous condensation of ice and the trail consists of ice particles even at ambient temperatures as warm as $-15\,^{\circ}\mathrm{C}$ ($5\,^{\circ}\mathrm{F}$). Wingtip trails only occur with aircraft of such heavy wing-loading as to yield very strong tip vortex circulations. Interceptor planes pulling out of dives, and hence imposing temporarily heavy wing-loading, may produce transient tip vortex trails. Faint vortex trails may appear aft of the corners of flaps during aircraft landings.

CONDITIONAL INSTABILITY.

1. The state of a layer of unsaturated air when its lapse rate of temperature is less than the dry-adiabatic lapse rate but greater than the moist-adiabatic lapse rate. Under such conditions a parcel of air at the environmental temperature is unstable to upward vertical displacements if it is saturated, unstable to downward displacements if it is saturated and contains cloud water, but stable to all small vertical displacements if it is unsaturated. For descending air containing only rain water, the stability depends on both the lapse rate and the drop-size distribution. This definition does not require that such a parcel be obtained by adiabatic displacement from any level. It also does not require that the energy released from latent heating (CAPE) be greater than the convective inhibition (CIN) required to bring the parcel to its level of free convection.

2. Similar to definition 1 except that it must be possible for a parcel displaced adiabatically from some level and with conservation of total water mixing ratio to attain the environmental temperature in a saturated state.

The choice of usage of the term "conditional instability" has been uncertain and sometimes controversial for at least 50 years. Haurwitz defined it approximately as definition 1, and this has been most frequently accepted. However, Byers used a definition similar to definition 2. Beers separated the definition into three subdefinitions, "stable type," corresponding to definition 1 when a moist parcel cannot be obtained, and "pseudolatent"and "real latent," corresponding to definition 2 but with the last requiring essentially that CAPE (convective available potential energy) be greater than CIN (connective inhibition). Dutton subscribes to the Haurwitz definition, while Emanuel develops a definition similar to definition 2, but with elaboration similar to that of Beers.

AMS

CONDOR *(Aves, Falconiformes)*. A large vulture of the Andes of Peru and Chile. This bird reaches a length of more than 4 feet (1.2 meters) and a wing expanse of 10 feet (3 meters) and is among the largest birds now existing. A smaller condor has been reported from Ecuador and the California vulture, *Gymnogyps californianus*, is also called a condor. The last species occurs in lower California, living in the mountains. It is sometimes larger than the condor of South America. All of the condors eat carrion.

While some species of condor are of particular concern to naturalists because they have, until recent years, been a disappearing form, the condors are not considered friends by the Indians of the Andes. The birds attack deer and vicuna and these animals are of great economic importance to the natives. The birds also may light on the backs of larger cattle and, aided by the sharp, huge, curved claws and strong bill and jaws, will tear flesh from the cattle. The animals may die from these injuries and the birds return to consume the carcass. These birds are tenacious, ravenous, and tough.

The adult California condor is reported to have a wing span of 9 to 10 feet (2.7–3 m) and weigh from 18 to 22 pounds (8.2–10 kg), making it one of the largest birds native to North America. The bird's nesting, roosting, and feeding grounds cover 11 million acres (4.5 million hectares). The bird is reported to travel up to 150 miles (241 km) in search of food. The California condor was one of the first species to be put on the U.S. endangered species list (1967). At that time, the total condor population was estimated at 40 birds, down from an estimated 500 birds in the mid-1800s. In 1984, the number of birds had dropped to fifteen. Since then, six adult birds have died leaving (at last official count, 1986) only six birds in the wild. There were 21 birds in captivity (for breeding) in the Los Angeles and San Diego zoos. The condor's survival potential is hampered by a low reproduction rate (usually one egg every two years) and the fact that a bird must be six to seven years old to reproduce.

The bill is long and slender; the tongue has serrated edges. The body is rather slender; the neck is bare with a white ruff. The naked head is elongated and rugose, with nostrils that can scent a carcass miles away. The condor is gluttonous and may eat until it cannot fly. Under such conditions, in order to escape danger, the bird may kick at and scratch its throat area until a portion of the food is regurgitated, thus lightening the body weight. The bird has been known to eat from 10 to 16 pounds (4.5 to 7.3 kilograms) of flesh without disturbing in any way its desire for food on a subsequent day. When the bird has overeaten, the Indians take revenge on its state of immobility at which time they can be more easily caught and killed.

The condor roosts and lives at high altitudes, far above the habitat of most mammals. However, from these high altitudes, the bird senses the presence of life below and is exceedingly keen in its senses for determining prospective dietary items. Vultures, hawks, and condors, in particular, are known to possess the keenest senses of sight and smell of any vertebrate. These birds are endowed with two focus points in each eye. For objects nearby, monocular vision is used; for distant objects, binocular vision is used. The eyes are situated laterally and are capable of numerous types of movements.

The egg is large and white, about $3\frac{1}{2}$ inches (9 centimeters) in length and hatches in about 7 weeks. The young bird is able to fly at 1 year, but remains with the parents for at least another year.

Coloration of the condor varies with species; it is Usually gray-black or brown, with the feathers in a somewhat tile-like pattern. Some birds are brilliantly black all over. The male's wings are about half-white in most cases. The feather tips are white with spots, making the male the more ornamental of the two sexes. The plumage is hard and can provide protection from bullets or arrows that do not come in directly from short distances. The tail has 12 feathers and is short, black, tapering to a thin edge. Nests are constructed of sticks and located on the ground.

CONDUCTION (Heat). See **Heat Transfer**.

CONDUCTIVITY. 1. The ability to transmit, as electricity, heat, sound, etc.

2. A unit measure of electrical conduction; the facility with which a substance conducts electricity, as represented by the current density per unit electrical-potential gradient in the direction of flow. Electrical conductivity is the reciprocal of electrical resistivity and is expressed in units such as mhos (reciprocal ohms) per centimeter. It is an intrinsic property of a given type of material under given physical conditions (dependent mostly upon temperature). Conductance, on the other hand, varies with the dimensions of the conducting system, and is the reciprocal of the electrical resistance.

CONDYLE. A rounded prominence on a bone, associated with a joint.

CONE. A solid formed by a closed conical surface, the lateral surface of the cone, and a plane, called the base of the cone, cutting the surface in a closed curve. The names cone and conical surface are frequently used interchangeably but it is proper to distinguish between them for the former is a solid and the latter a surface.
